the randomized multicenter NICE-SUGAR trial of intensive glucose control (target 81–108 mg/dL) versus conventional (target  $\leq 180$  mg/dL) in over 6000 medical and surgical ICU patients showed a significantly higher 90-day mortality in the group treated with intensive glucose control, which was accompanied by a significantly higher rate of severe hypoglycemia. Considering these data and other studies, the most recent consensus guidelines suggest that intensive glucose control should be avoided, and glucose levels should be targeted to  $\leq 180$  mg/dL in critically ill patients.

### Summary

Although morbidity and mortality remain high in critically ill patients with sepsis and septic shock, important studies have taught us that early and aggressive resuscitative care for septic patients improves outcomes (Fig. 41.1). Once concern for sepsis is raised, broad-spectrum antibiotics should be administered, and the patient should be aggressively resuscitated with boluses of intravenous crystalloid (with use of vasopressors as needed) until organ perfusion is restored, all while a search for the source of infection is undertaken. In patients who remain at a high risk for death after the early resuscitative phase, adjunctive supportive therapies can be considered, including low-dose steroids for patients who remain hemodynamically unstable despite vasopressors and insulin therapy (avoiding tight glucose control and concomitant hypoglycemia but instead targeted at a glucose of  $\leq 180$  mg/dL) to avoid significant hyperglycemia. This is an exciting time in the development of treatment strategies for sepsis because ongoing and future trials will continue to optimize our care of these critically ill patients.

## Chapter Review

### Questions

1. A 67-year-old man with a history of hypertension and prostate cancer presents to the ED with fever and confusion. Physical examination is notable for a systolic blood pressure of 50 mm Hg, heart rate 150 beats per minute, respiratory rate 40 breaths per minute, and an O<sub>2</sub> saturation of 94% on room air. His mucous membranes are dry, and he is noted to have poor skin turgor. Microscopic examination of the urinary sediment reveals >200 white blood cells/high-power field and innumerable bacteria. What is the next most appropriate step in the management of his hemodynamic status?
  - A. Vasopressin
  - B. Norepinephrine
  - C. Phenylephrine
  - D. Place large-bore peripheral intravenous (IV) or central venous catheter and bolus with crystalloid
  - E. Dopamine
2. A 47-year-old man with a history of alcohol-induced cirrhosis is brought to the ED with fever, confusion, and worsening ascites. Blood pressure on presentation is 60/30 mm Hg. Sepsis arising from spontaneous bacterial peritonitis is suspected, and central venous and arterial catheters are placed. He receives 8 L of normal saline, and his blood pressure improves to 70/40 mm Hg and he still appears intravascularly dry on your examination with a central venous pressure of 2 mm Hg. What is the most appropriate next step?
  - A. Initiate treatment with IV vasopressin.
  - B. Bolus with normal saline.
  - C. Start dobutamine.
  - D. Start stress dose steroids (i.e., hydrocortisone 50 mg intravenously every 6 hours).
3. In the case presented in question 2, the patient's mean arterial blood pressure remains at 55 mm Hg despite continued and adequate fluid resuscitation. You administer broad-spectrum antibiotics, draw a number of laboratory studies including a lactate level, and prepare to admit him to the medical ICU. The next appropriate step in his management is:
  - A. Airway intubation to initiate mechanical ventilation
  - B. Start IV dopamine.
  - C. Bolus with normal saline.
  - D. Transfuse 1 unit of packed red blood cells.
  - E. Begin a norepinephrine infusion.
4. An 82-year-old woman with a history of diabetes and recurrent lower extremity ulcers caused by infections with multidrug-resistant organisms is admitted from the skilled nursing facility with hypoxia and altered mental status. Per report of the nursing home staff, she developed a cough productive of purulent sputum 3 days before admission. Physical examination reveals a temperature of 102.5°F, heart rate 120 beats per minute, blood pressure 70/40 mm Hg, and oxygen saturation of 88% on 4 L via nasal cannula. Chest imaging shows bilateral airspace opacities consistent with pneumonia. After initial stabilization of the patient, what is the most appropriate initial antibiotic regimen?
  - A. Azithromycin
  - B. Vancomycin
  - C. Piperacillin/tazobactam
  - D. Cefepime, vancomycin, and azithromycin
5. A 52-year-old woman is admitted to your ICU with septic shock caused by multilobar pneumonia. Broad-spectrum antibiotics are administered, she is aggressively volume resuscitated, and mechanical ventilation is initiated for respiratory failure. She is supported with multiple vasopressors and develops refractory hypotension, and you add treatment with low-dose hydrocortisone to her regimen. Her fingerstick glucose is 275 mg/dL. Which of the following is the most appropriate next step regarding management of her hyperglycemia?
  - A. No specific treatment; continue monitoring, and treat only if glucose rises above 300 mg/dL.
  - B. Temporarily discontinue enteral nutrition.
  - C. Begin IV insulin via continuous infusion, and target a glucose level  $\leq$ 110 mg/dL.
  - D. Begin IV insulin via continuous infusion, and target a glucose level  $\leq$ 180 mg/dL.

### Answers

1. D
2. B
3. E

## Essentials of Hemodynamic Monitoring

KATHLEEN J. HALEY

**H**emodynamic monitoring is commonly used to optimize fluid, inotropic, vasodilator, and pressor therapy in critically ill patients. Traditionally, hemodynamic monitoring has relied on invasive techniques to obtain hemodynamic assessments such as central venous pressures and/or pulmonary artery (PA) pressures. Recent technological advances have greatly improved the performance of noninvasive approaches, such as bedside ultrasound and analyses of arterial pressure changes. Although invasive hemodynamic approaches have remained the gold standard techniques, the advances in the noninvasive methods to assess hemodynamics allow them to be considered as alternative approaches. This section will review the most frequently used hemodynamic monitoring approaches, their indications, and limitations.

The two most common clinical syndromes for which hemodynamic monitoring is used in critically ill patients are shock and pulmonary hypertension. The most common indication for hemodynamic monitoring in critically ill patients is to optimize management of shock. There are four basic categories of shock, defined by their typical hemodynamic derangements: cardiogenic, obstructive, hypovolemic/hemorrhagic, and distributive (summarized in [Table 42.1](#)). Although the types of shock have typical hemodynamic profiles, the abnormalities within a given patient may vary substantially from the classic profile. Patients can also have multiple types of shock concurrently, and their relative contributions to the patient's symptoms can vary. For example, a patient with significant coronary artery disease and urosepsis may have an early course dominated by features of septic shock but then subsequently develop cardiogenic shock. Hemodynamic monitoring can be useful in these patients to individualize therapy.

Another common indication for hemodynamic monitoring is to diagnose and manage patients with pulmonary hypertension. The assessment of pulmonary arterial pressures by echocardiography is challenging, and measuring PA pressures remains the gold standard for diagnosis. The pulmonary vascular resistance is frequently not reflected by systemic blood pressure measurements. Therefore PA pressures

and vascular resistance are used to evaluate responses to vasodilator therapy in these patients.

### Invasive Hemodynamic Monitoring

#### Arterial Lines

Continuous blood pressure monitoring is one of the most common hemodynamic monitoring practices used in the intensive care unit (ICU), with approximately 8 million arterial lines placed annually in the United States. The radial artery is the most frequently accessed vessel, with over 90% of arterial lines using this vessel. However, arterial lines can be safely placed in the ulnar, femoral, axillary, dorsalis pedis, and posterior tibialis arteries. Less commonly used sites include the brachial and temporal arteries. In addition to the beat-to-beat information about the blood pressure, the variation in the arterial line tracing with the respiratory cycle can provide diagnostic information about factors that may contribute to hemodynamic instability, such as high intrathoracic pressures, pericardial disease, or intravascular volume depletion.

Radial and ulnar arterial lines have low rates of complications. A review of more than 60,000 arterial line placements in 57,787 surgery patients at the Mayo Clinic in Rochester, Minnesota, from 2006 to 2012 showed that only 21 patients developed ischemic or neurologic complications requiring consultation by a vascular surgeon or neurologist. Of these, the complication in 10 patients resolved with conservative management. The low rate of vascular complications is attributed to the rich collateral blood supply to the hand. The modified Allen test is frequently used to assess the adequacy of the hand collateral circulation, although its ability to evaluate collateral flow is limited by a high false-negative rate. Although the frequency is low, serious ischemic complications including pseudoaneurysm and digital ischemia can be devastating and may require excision or even amputation and can be life-threatening. Factors associated with increased likelihood of developing complications include duration of catheter use, catheter size larger than 20 gauge,

**TABLE 42.1** Typical Hemodynamic Abnormalities in Shock

Shock Classification	Clinical Examples	CVP	Cardiac Output	SVR
Hypovolemic/ Hemorrhagic	Acute blood loss Severe dehydration	Low	Low	High
Obstructive	Massive pulmonary embolism Severe pulmonary hypertension Cardiac tamponade	High	Low	Normal or high
Cardiogenic	Acute myocardial infarction Severe ventricular failure	High	Low	High
Distributive	Sepsis Anaphylaxis Postoperative vasoplegia Neurogenic	Normal or low	High	Low

*CVP, Central venous pressure; SVR, systemic vascular resistance.*

and female gender. More common complications of arterial lines include transient vasospasm or ischemia, which occurs in up to 35% of patients, and insertion site hematoma in up to 14.4% of patients.

Infection related to an arterial line is uncommon. Although a wide range of insertion site colonization, between <1% and 22.5%, has been reported in the literature, infections caused by the arterial line are reported in <1% of patients. Interestingly, inconsistent adherence to optimal aseptic technique during catheter insertion is frequently noted with arterial lines placed in an emergent setting, which may contribute to high rates of insertion site colonization.

The major limitations to using arterial line monitoring include changes in the waveform that alter the systolic and diastolic blood pressures, such as overdampening. However, the mean arterial pressure (MAP) is not changed by the presence of over- or underdampening, and so the arterial line can still be used to guide therapy if this occurs. An additional problem occurring with arterial lines is discordant blood pressure readings between a noninvasive reading and the arterial line reading. Comparisons of invasive and noninvasive blood pressure readings in patients show that the noninvasive pressure can underestimate the systolic pressure in hypertensive patients but give falsely high systolic

readings in hypotensive patients. In both cases, however, the MAP is similar to that obtained with invasive arterial monitoring. If the arterial line is properly calibrated and the system is leveled at the height of the cardiac atria, then the arterial line reading is considered the gold standard for blood pressure assessment.

### Central Venous Pressure

Central venous pressure (CVP) is the pressure in the superior vena cava near the caval atrial junction and so reflects the right atrial pressure. The CVP tracing (Fig. 42.1) has five components: three peaks (a, c, and v) and two descents (x and y). The “a” wave occurs when the filled atria contract at the end of ventricular diastole. This provides the atrial kick, which optimizes the filling of the ventricle before ventricular systole. The “x” descent follows the “a” wave and corresponds to atrial diastole. The two x-descents are x and x'. The two parts of the “x” descent are separated by the “c” wave. The initial part of the “x” descent is caused by the pressure decrease attributed to the start of atrial diastole. As the ventricle fills during ventricular diastole, the tricuspid valve closes. Ventricular systole then begins with isovolumetric contraction, which is a period of muscular contraction without any blood being ejected from the ventricle. During this,

the tricuspid valve is pushed into the right atrium (RA), which increases the pressure in the atrium, causing the “c” wave. As ventricular systole continues, the blood is ejected, the tricuspid valve remains closed, and the pressure in the atria decreases further as the atrial base is pulled down. This produces the second part of the “x” descent. During atrial diastole, the atrium fills due to venous return. At the end of atrial diastole, the atrial pressure again increases, which causes the “v” wave. The “y” descent occurs as the tricuspid valve opens at the start of ventricular diastole, and the blood empties from the atria to the ventricles. Thus the “y” descent corresponds to ventricular diastole. The electrocardiogram (EKG) tracing can be used to identify the components of the CVP tracing. The “a” wave follows the P wave on the EKG. The “v” wave occurs slightly after the T wave on the EKG.

Relating the CVP tracing with the events of the cardiac cycle gives a framework to analyze the characteristic tracings seen with dysrhythmias and valvular dysfunction. For instance, because the “a” wave is caused by the coordinated contraction of atrial systole, it is not seen in atrial fibrillation. Tricuspid regurgitation increases the volume of blood in the RA during atrial diastole. Thus tricuspid regurgitation causes a large “v” wave, which sometimes appears as a merged “c-v” wave. Tricuspid stenosis delays the emptying of the RA and is therefore associated with consistent large “a” waves, termed *giant “a” waves*. Atrial systole that is not coordinated with ventricular filling will produce intermittent large “a” waves, which reflect atrial contraction against a closed tricuspid valve. These are called *cannon “a” waves* and occur in atrial flutter and dysrhythmias associated with atrial-ventricular dissociation such as complete heart block and ventricular tachycardia.

The major complications associated with the use of the CVP for hemodynamic monitoring include complications related to both the central line insertion and complications associated with the catheter itself. Any central line has complications such as hematoma, infection, arterial puncture, and pneumothorax. Ultrasound guidance is an effective technique to minimize complications associated with the insertion procedure. The rate of line infections can be minimized by the use of meticulous aseptic technique and full sterile draping during line insertion and subsequent dressing changes. The use of a procedure checklist is a reliable way to ensure adherence to best practices during line insertion and has been shown to have durable effects in reducing line-associated complications, including infections. Complications relating to the line itself include dysrhythmias and thrombosis. Maintaining correct line placement within the distal superior vena cava (SVC), which can be determined by chest x-ray, can minimize the risk of dysrhythmias. The central line is a nidus for thrombosis, and critical illness is characterized by hypercoagulability. However, critically ill patients are also frequently at increased risk of bleeding. Therefore the routine use of anticoagulation is not recommended for critical patients unless there is a specific indication for this therapy. Instead, standard deep venous thrombosis pharmacologic prophylaxis and removing the

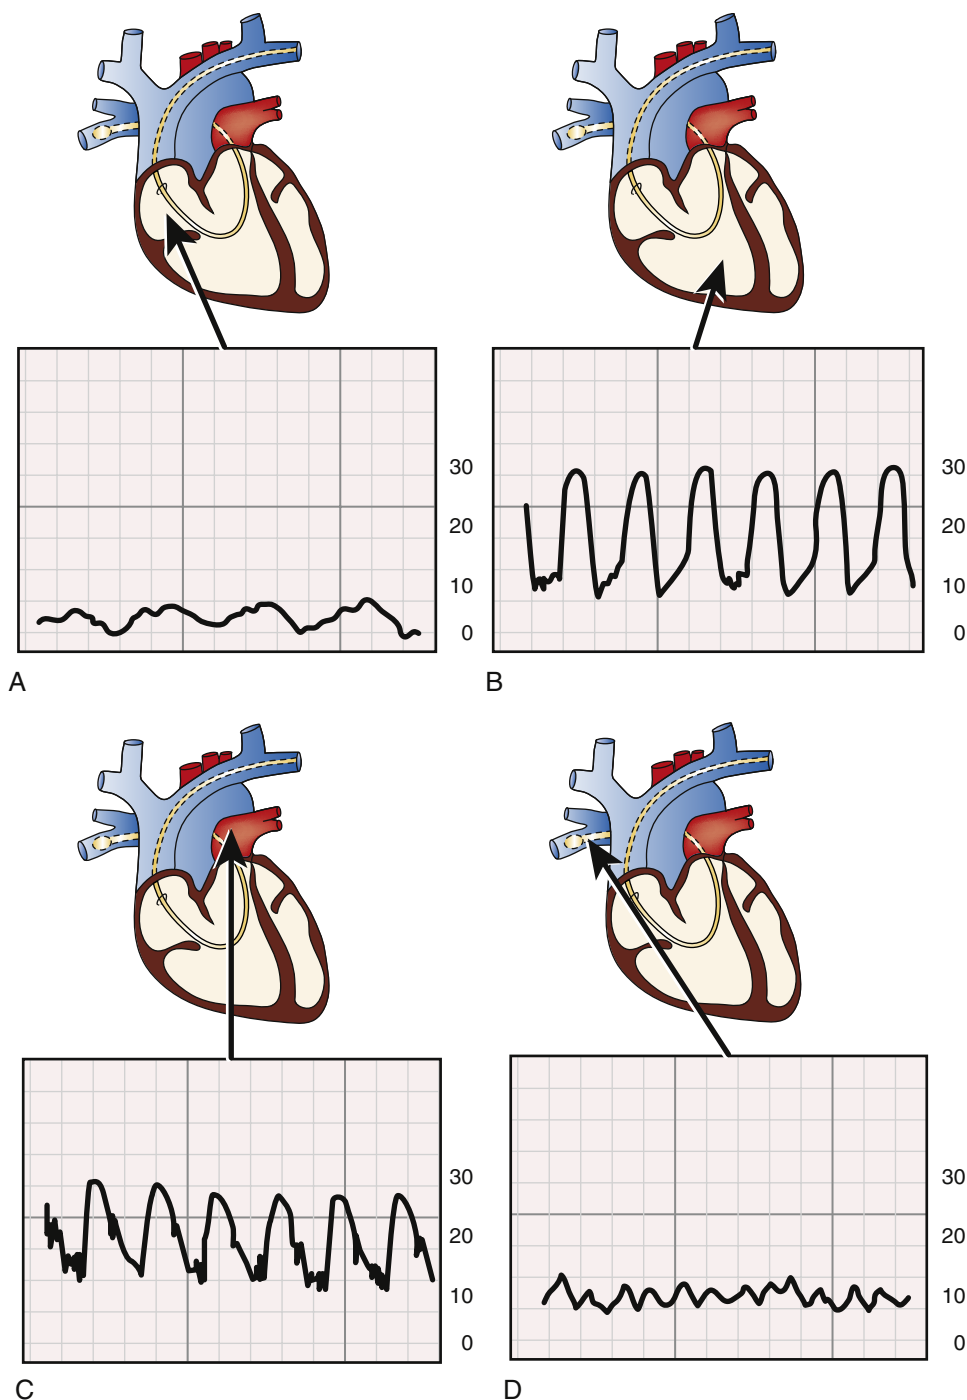

central line as soon as feasible are recommended to minimize the risk of thrombosis in these patients.

Classically, the CVP has been thought to reflect the intravascular volume status of the patient. The volume status is then used to estimate the probability that the patient’s blood pressure will increase following volume expansion. However, there are several factors impacting the CVP that may lead to a poor correlation between the CVP and volume status. These factors include the intrathoracic pressure, right ventricular compliance, pericardial pressure, and tricuspid valve function. Thus there is frequently a poor correlation between the CVP and the response to an intravascular volume challenge, even in the setting of a low CVP. The predictive value of a single CVP measurement is especially poor. Analyzing dynamic changes in the CVP during the respiratory cycle can give a more reliable estimation of the likelihood of fluid responsiveness. Given the significant limitations in using the CVP, the current recommendations are to use it as part of a clinical gestalt, rather than a stand-alone indicator of intravascular volume.

### Pulmonary Artery Catheter

Measurement of the pressures in the PA is the gold standard for hemodynamic assessment. The pulmonary artery catheter (PAC) can directly measure pressures in the PA. Additionally, the PAC can be used to obtain samples of mixed venous blood. These data can be used to calculate the cardiac output (CO), cardiac index, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR). PACs are essential tools in the evaluation and management of pulmonary vascular disease. They are also used to guide therapy in heart failure and to evaluate pericardial disease such as constriction or tamponade. They are also frequently used to guide inotropic and pressor support in the perioperative period for cardiac and selected thoracic surgical procedures. In contrast, routine PAC use has not been shown to benefit critically ill patients, although they can be indicated for patients with combined cardiogenic and septic shock.

PACs can be positioned at the bedside by monitoring the typical pressure waves as the catheter moves through the vasculature. Selected patients with difficult cardiac or valvular anatomy may benefit from the use of fluoroscopy to guide catheter placement. The typical pressure tracings obtained with the PAC are shown in Fig. 42.2. A simultaneous EKG tracing is performed when the PAC is floated to facilitate correct identification of the waveform components. The catheter is floated into position with the balloon inflated. The pressure tracing obtained in the RA is very similar to the CVP tracing in the SVC. The RA pressures are low, and typical values range from 2 to 7 mm Hg. As the catheter tip travels into the right ventricle (RV), the tracing changes to high systolic values followed by low diastolic values, with typical values being 15–25/3–12 mm Hg. Once the catheter reaches the main PA, the tracing changes to show the PA systolic value, which is similar to the RV systolic pressure; the dicrotic notch, which is caused by the pulmonic

• **Fig. 42.2** Representative pressure tracings obtained with the pulmonary artery catheter with electrocardiogram. A typical pressure tracing from the right atrium is given in (A), from the right ventricle in (B), the pulmonary artery in (C), and the pulmonary artery occlusion pressure in (D). (From Hollenberg SM. Hemodynamic monitoring. *Chest* 2013;143:1483.)

valve closure; followed by the PA diastolic pressure, which is higher than the RV diastolic pressure. Typical values for the PA are 15–25/8–15 mm Hg. Of note, although the PA systolic can approach systemic blood pressure values in the setting of severe chronic pulmonary hypertension, the values seen in acute pulmonary hypertension are much lower. Thus in acute massive pulmonary embolism, the PA systolic may only be approximately 45 to 50 mm Hg, even in the setting of acute RV failure.

As the balloon travels farther into the PA, the pulmonary artery occlusion pressure (PAOP), also called the *wedge pressure*, is obtained. Typical normal values range from 6 to 15 mm Hg. Correct placement of the PAC will show the PAOP tracing when the balloon is inflated and the PA tracing when the balloon is deflated. Because of the risk of PA rupture with prolonged inflation of the balloon, the PAC balloon is kept deflated except when the PAOP is being assessed, or the catheter position is being advanced.

• **Fig. 42.3** Pulmonary artery occlusion pressure waveform with electrocardiogram showing relation of the “a” and “v” waves to the “P” and “T” waves, respectively. (From Ragosta M. Normal waveforms, artifacts, and pitfalls. In: Ragosta M, ed. *Textbook of Clinical Hemodynamics*. Philadelphia: Saunders; 2008:16–27.)

In addition, the balloon is always deflated when the catheter is withdrawn, even for small adjustments in catheter position. The PAOP has five components. The “a” wave reflects atrial systole. The small “c” wave is caused by the closure of the mitral valve and is frequently not visible. The “v” wave is caused by atrial filling during ventricular systole. The “x” and “y” descents reflect atrial and ventricular diastole, respectively. The “a” and “v” waves frequently have similar appearances, but they can be correctly identified using the EKG tracing. The “a” wave occurs after the QRS complex, and the “v” wave occurs after the T wave (Fig. 42.3).

The PAOP is used to estimate the left ventricular end diastolic (LVED) volume, which is the cardiac preload. However, the PAOP accurately reflects the LVED pressure only under certain conditions. First, there must be an uninterrupted blood column between the PAC balloon and the left atrium. To have an uninterrupted blood column, the PAOP is measured in west lung zone 3, where the pulmonary arterial pressure exceeds both the alveolar and the pulmonary venous pressures (Fig. 42.4). Second, the PAOP should be measured at end expiration using the mean value of the PAOP “a” wave. This times the measurement to correspond with the end of LV diastole. Third, using the LVED pressure to accurately estimate the LVED volume requires a stable, normal LV compliance. The relationship between the LVED volume to the LVED pressure is given by the Frank-Starling curve. Fourth, there must not be any significant left atrial space occupying lesion, such as an atrial myxoma. Lastly, there must be near normal mitral valve function, and there must not be significant aortic valve regurgitation. Mitral valve pathology, both regurgitation and stenosis, causes the PAOP to reflect the left atrial pressure instead of the LVED volume. The regurgitant volume associated with aortic insufficiency causes premature mitral valve closure, and so the PAOP underestimates the LVED volume. If these conditions are met, then the PAOP accurately reflects the LVED pressure and can be used as an indirect measure of the LVED volume. To have an uninterrupted blood column, the PAOP

• **Fig. 42.4** West lung zones showing the pressure relationships among the pressures in the pulmonary artery (PA), alveolus (PA<sub>v</sub>), and pulmonary vein (PV). In zone 1, the alveolar pressure exceeds both the arterial and venous pressures: PA<sub>v</sub> > PA > PV. In zone 2, the arterial pressure exceeds the alveolar pressure. Both the arterial and the alveolar pressures exceed the venous pressure: PA > PA<sub>v</sub> > PV. In zone 3, the arterial and venous pressures exceed the alveolar pressure: PA > PV > PA<sub>v</sub>.

is measured in west lung zone 3, where the pulmonary arterial pressure exceeds both the alveolar and the pulmonary venous pressures. Even when the PAOP is obtained in west zone 3, however, it may not accurately reflect the LVED volume. Mitral valve pathology, both regurgitation and stenosis, causes the PAOP to reflect the left atrial pressure instead of the LVED volume. Thus there are several caveats in the interpretation of the PAOP pressure.

The most common calculated values from the PAC are the CO and the SVR and PVR. The CO is usually calculated using the thermodilution technique, in which the PAC intermittently heats an area of the catheter near the proximal (RA) port, and the thermodilution curve is obtained by a thermistor in the PAC tip, thereby providing a near continuous calculated CO. The thermodilution technique is not reliable in the setting of tricuspid regurgitation. This is because the regurgitant jet into the RA mimics the effects of a poor cardiac output. Similarly, an overestimation of the CO occurs in the setting of a significant left-to-right intracardiac shunt. If the thermodilution CO is not thought to be reliable, then the CO can be calculated using the Fick equation:  $CO = VO_2 / 10(CaO_2 - CvO_2)$ . In this equation,  $VO_2$  is the oxygen consumption and is assumed to be 250 mL per minute.  $CaO_2$  is the oxygen content of arterial blood,

and  $CvO_2$  is the oxygen content of mixed venous blood, which is obtained by analyzing a sample from the PA. The oxygen content of blood is given by the following equation:  $1.36 \times \text{hemoglobin} \times O_2 \text{ saturation}$ . The very small value of the oxygen dissolved in blood is generally omitted from the oxygen content calculation.

The vascular resistance is calculated from the pressure change divided by the flow, which is the cardiac output. Pressures are measured in mm Hg and the vascular resistance is measured in dynes-second/cm<sup>-5</sup>, and 1 mm Hg = 80 dynes-second/cm<sup>-5</sup>. Therefore the pressure change is multiplied by 80 to convert the units from mm Hg to dynes-second/cm<sup>-5</sup>. The SVR is calculated by the pressure change across systemic vasculature (the MAP – the CVP) divided by the CO. In analogous manner, the calculation for the PVR is the pressure change across the pulmonary vascular bed (PAP – PAOP)/CO.

In addition to providing an indirect measure of cardiac preload, the PAC can be used to diagnose and monitor cardiac, pulmonary vascular, and pericardial diseases. For example, an elevated PAOP with a decreased CO and elevated SVR supports the diagnosis of cardiogenic shock. Intracardiac shunting can be identified by comparing the oxygen saturation in the RA, RV, and PA. A significant left-to-right shunt results in a step up, which is an increase of more than 10% in oxygen saturation. Pericardial disease causes typical changes in the PAC pressures. Cardiac tamponade results in poor diastolic filling of the ventricles, and so the “y” descent is minimized. In addition, tamponade causes equalization of the diastolic pressures from the CVP, RV, PA, and PAOP. The PAC pressure tracings in constrictive pericarditis similarly show equalization of the diastolic pressures. However, the noncompliant pericardium of constrictive pericarditis allows rapid early diastolic ventricular filling which ends abruptly. This causes a rapid “x” and “y” descent, which gives the “M” or “W” sign in the PAOP tracing. In addition to pressure tracings, some PACs have an oximeter at the catheter tip, which provides continuous mixed venous oxygen saturation readings. The mixed venous oxygen saturation can be a useful adjunct to hemodynamic information in diagnosing and monitoring shock.

There are multiple complications associated with PAC use. These include complications similar to the complications associated with any central venous line, such as infection, pneumothorax, arterial puncture, and air embolism. Complications that are more specific to the PAC include arrhythmias; particularly ventricular dysrhythmias, cardiac valve damage, and PA rupture. In addition, complications such as coiling and knotting can occur; these are caused by the movement of the long PAC catheter in the dynamic environment of the heart and PA. Moreover, because the PAOP is an indirect estimate of the LVED volume and is affected by multiple factors such as left ventricular (LV) compliance, intrathoracic pressure, and valvular dysfunction, there are frequently significant challenges in interpreting the data obtained from the PAC. Multiple clinical trials

have not shown a mortality benefit from the routine use of the PAC for patients with sepsis or acute respiratory distress syndrome. Thus despite the abundance of detailed hemodynamic measurements obtained with a PAC, these catheters are not recommended for routine hemodynamic monitoring in critically ill patients.

## Noninvasive Hemodynamic Monitoring

Recent technological advances have resulted in multiple approaches for noninvasive hemodynamic assessment. There are several proprietary monitoring systems currently available and three general approaches used for these systems, all of which have significant limitations. The first approach analyzes changes in electrical resistance or conductance across the thoracic cavity to estimate CO and/or stroke volume. The performance of these systems becomes less reliable in the setting of unstable critical illness because they are sensitive to tissue edema, which is a common problem in these patients. In addition, these systems can have decreased reliability in patients with hyperdynamic states, which is a frequent problem for unstable critically ill patients. The second approach analyzes the arterial waveform to assess dynamic changes in CO and stroke volume during the respiratory cycle. Greater variation is associated with a greater response to intravenous fluids. However, these approaches are not reliable when the patient is spontaneously breathing. They also require that the patient is in sinus rhythm. The third approach uses changes in the end-tidal carbon dioxide to track changes in CO. This requires that the patient is mechanically ventilated, and even then, these systems become less reliable in the setting of severe lung dysfunction. Thus the noninvasive systems are generally more reliable and have greater utility for perioperative hemodynamic monitoring than for unstable critically ill patients in the ICU. One noninvasive approach that can be used in critically ill patients even in the presence of atrial fibrillation or spontaneous respirations is a passive leg raise (PLR). Elevating both legs above the level of the heart mimics the effects of a fluid bolus and is a reliable indicator of fluid responsiveness. The limitations are that this technique can be uncomfortable for the patient, requires sustained elevation of both legs for up to 2 minutes, and should not be performed if the patient has femoral lines. In addition, PLR is not reliable in patients with abdominal hypertension.

Bedside echocardiography has become a widely used noninvasive technique for hemodynamic assessment. Extensive training is required for a detailed assessment of cardiac function. However, the skills needed to reliably evaluate a patient's overall cardiac function and likely fluid responsiveness require much less training. Although transesophageal echocardiography can be used in critically ill patients, transthoracic echocardiography is more commonly used for these assessments. The views most frequently used for such a qualitative assessment are the subcostal inferior vena cava (IVC), subcostal 4-chamber, apical 4-chamber,

• **Fig. 42.5** The most common echocardiographic views and representative images obtained for bedside echocardiography. Ao, Aorta; IVC, inferior vena cava; LA, left atrium; RA, right atrium; LV, left ventricle; RV, right ventricle. (From Guerin L, Vieillard-Baron A. The use of ultrasound in caring for patients with sepsis. *Clin Chest Med.* 2016;37:299-307.)

• **Fig. 42.6** Representative bedside ultrasound image showing change in the inferior vena cava (IVC) diameter during the respiratory cycle. The diameter of the IVC is measured perpendicular to the long axis, as indicated by the arrow. The maximal and minimum diameters are indicated by the double-headed arrows. (From Kent A, Bahner DP, Boulger CT, et al. Sonographic evaluation of intravascular volume status in the surgical intensive care unit: a prospective comparison of subclavian vein and inferior vena cava collapsibility index. *J Surg Res.* 2013;184:561-566.)

parasternal short axis, and parasternal long axis (Fig. 42.5). These views allow a rapid qualitative assessment of LV and RV function and visualization of the IVC. Although the size of the IVC can be used to estimate RA pressures, the static measurement has not been a reliable predictor of fluid responsiveness. The dynamic change in the IVC diameter

with respiration can provide a more reliable assessment of the patient's likely response to a fluid challenge and can be useful for both spontaneously breathing and mechanically ventilated patients. A change of at least 18% to 50% in the diameter of the IVC with respiration supports likely fluid responsiveness (Fig. 42.6). Greater changes in the IVC diameter have greater positive predictive value. The limitations to this technique include difficulty in obtaining clear windows because of chest wall thickness, morbid obesity, or surgical dressings. In addition, high abdominal pressures or mechanical ventilation can minimize dynamic changes in the IVC diameter, even in fluid-responsive patients. The reliability can also vary with the criteria used to determine fluid responsiveness. Despite these limitations, echocardiography has gained acceptance as a useful noninvasive approach to evaluate hypotensive critically ill patients.

## Summary

Hemodynamic monitoring is used to diagnose and treat shock. Optimizing fluid management for critically ill patients is important, because both hypovolemia and fluid overload are deleterious. Both invasive and noninvasive approaches can provide useful data to guide the treatment of critically ill patients. All the available hemodynamic monitoring modalities have limitations; therefore no single approach can be relied upon for all patients. Instead, the hemodynamic information must be analyzed as part of the overall clinical picture to develop the best treatment strategy for each patient.

## Chapter Review

### Questions

- Your patient is a 63-year-old man with metastatic lung cancer and coronary artery disease who was admitted for febrile neutropenia following chemotherapy. He was transferred to your unit after developing hypotension, chest pain, and respiratory distress early this morning. A pulmonary arterial catheter has been placed and shows CVP 18 mm Hg, PA 33/19 mm Hg, PAOP 18 mm Hg, CO 2.5 L/min, and SVR 1370 dynes/s/cm<sup>-5</sup>. What is the most likely cause of his hypotension?
  - Sepsis
  - Cardiogenic shock
  - Pulmonary embolism
  - Cardiac tamponade
  - Mixed septic and cardiogenic shock
- Which of the following best predicts a positive response to a fluid challenge in a hypotensive patient?
  - Low CVP
  - Increased systolic blood pressure (BP) following passive leg elevation
  - Low CO with high SVR
  - Low PAOP
  - Unchanged IVC diameter during respiration
- Your patient is a 50-year-old man with severe lung disease who was admitted to the ICU because of respiratory failure and hypotension in the setting of pneumonia. His initial examination showed jugular venous distension and a systolic murmur along the left sternal border. A pulmonary arterial catheter has been placed because of a concern that the patient has mixed cardiogenic and septic shock. This morning, his BP is 82/45 mm Hg and his CO is 4.5 L/min. Which of the following would be the best next step?
  - Start pressors because the patient is hypotensive despite an adequate CO.
  - Obtain a cardiac echocardiogram to evaluate for signs of RV strain because jugular venous distension in a hypotensive patient suggests pulmonary embolism.
  - Start an inotrope to elevate the CO because the normal CO is inadequate in sepsis.
  - Check the arterial line for dampening because the patient should not be hypotensive if the CO is within the normal range.
  - Obtain a cardiac echocardiogram, and consider a fluid challenge because tricuspid regurgitation can cause an overestimation of the CO.
- Which of the following is associated with cannon “a” waves?
  - Mitral regurgitation
  - Cardiac tamponade
  - Atrial fibrillation
  - Complete heart block
  - Tricuspid regurgitation
- You are treating a patient with cardiogenic shock. Which hemodynamic profile would be most consistent with this diagnosis?
  - CVP 14 mm Hg, PA 36/16 mm Hg, PAOP 18 mm Hg, CO 4.7 L/min, SVR 970 dynes/s/cm<sup>-5</sup>
  - CVP 16 mm Hg, PA 35/18 mm Hg, PAOP 22 mm Hg, CO 2.5 L/min, SVR 1350 dynes/s/cm<sup>-5</sup>
  - CVP 5 mm Hg, PA 25/13 mm Hg, PAOP 10 mm Hg, CO 2.5 L/min, SVR 1460 dynes/s/cm<sup>-5</sup>
  - CVP 18 mm Hg, PA 45/20 mm Hg, PAOP 16 mm Hg, CO 4.2 L/min, SVR 1070 dynes/s/cm<sup>-5</sup>
  - CVP 12 mm Hg, PA 30/16 mm Hg, PAOP 14 mm Hg, CO 5.6 L/min, SVR 700 dynes/s/cm<sup>-5</sup>

## Arterial Blood Gases

JEREMY B. RICHARDS AND DAVID H. ROBERTS

An arterial blood gas (ABG) provides clinically useful information about an individual's acid-base status, the partial pressure of arterial carbon dioxide, the partial pressure of arterial oxygen, and the arterial oxygen saturation. Hypoxia, dyspnea, or suspected acid-base disturbance is a clear indication to check an ABG. Altered mental status, critical illness, and acute respiratory distress syndrome (ARDS) are specific clinical syndromes or presentations that may warrant obtaining an ABG.

An ABG is helpful in evaluating pulmonary pathophysiology because an ABG can quantify the presence and severity of hypoxia and/or hypercapnia. An ABG can rapidly provide information about oxygenation, ventilation, and acid-base status; therefore ABGs are particularly useful and common in the critical care setting.

### Technical Considerations: How to Obtain an Arterial Blood Gas

An ABG may be obtained from any artery. Relative contraindications to performing an ABG include uncontrolled coagulopathy, superficial cutaneous infection over the artery, the absence of a detectable pulse, or the presence of an atrioventricular fistula.

Because arterial puncture carries the potential complication of arterial laceration and/or hematoma with compromise of blood flow to distal tissues, easily accessible arteries perfusing tissue with adequate collateral circulation should be used in most circumstances. Large arteries may be accessed in the absence of collateral circulation because it is unlikely that a hematoma would cause occlusion or a laceration would compromise distal flow.

The radial artery is easily accessible because it is superficial and has adequate collateral circulation (the ulnar artery in the medial arm). The femoral, dorsalis pedis, brachial, and axillary arteries are potential alternative sites for obtaining an ABG when the radial arteries cannot be accessed.

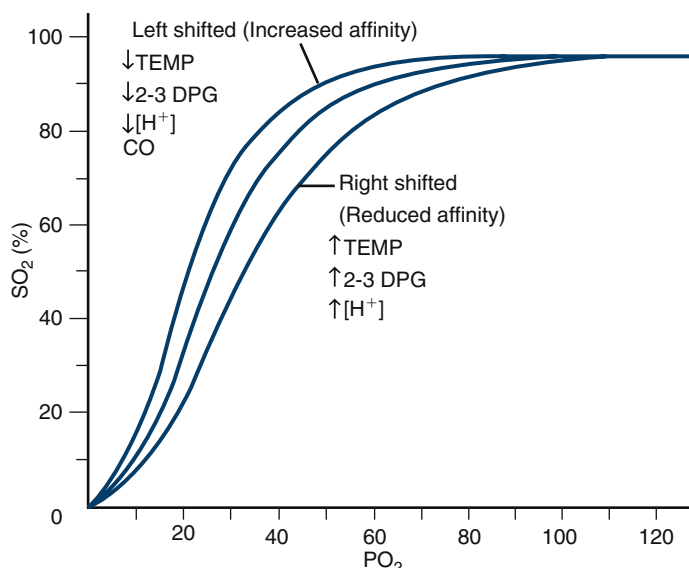

Before obtaining an ABG from the radial artery, a modified Allen test should be performed. The hand is held above the level of the heart and a fist is made while the radial and

ulnar arteries are simultaneously compressed. The hand is then lowered below the level of the heart, and the fist is opened. Compression of the ulnar artery is released while maintaining compression of the radial artery; the hand should reperfuse within 6 seconds if the ulnar artery is adequately perfusing the hand. If the modified Allen test is negative (i.e., color does not return to the hand within 6 seconds, indicating inadequate perfusion), the contralateral radial and ulnar arteries should be assessed. If both hands demonstrate inadequate ulnar circulation, alternative sites for obtaining an ABG should be considered to avoid causing decreased tissue perfusion and possible damage to the hands.

If the individual is awake and alert, a small amount of subcutaneous lidocaine may be administered before obtaining the ABG. Lidocaine should not be injected directly over the artery, rather slightly lateral or medial to avoid creating a weal over the vessel. Superficial anesthetic is typically sufficient; administering deeper dermal lidocaine is usually not necessary to ensure comfort.

To perform an ABG, prepackaged kits containing the requisite supplies are typically available. The kits contain a syringe preloaded with heparin powder (to minimize clotting), a needle (typically 22 gauge for the radial artery), and a filter cap to place on the syringe for transport.

The clinician may palpate the pulse while attempting to access the artery; however, if too much pressure is applied to the proximal artery, the artery may be occluded and blood flow obstructed. Palpating the artery distal to the access site will prevent this complication. Alternatively, light palpation proximal to the puncture site is acceptable. The needle should be oriented with the bevel up. When the needle enters the artery, a flash of blood will appear in the syringe. If the aperture of the needle is within the artery, blood will spontaneously fill the syringe without needing to apply suction to the syringe. After an acceptable quantity of blood has been collected, the needle is withdrawn and protected, and pressure is applied over the access site. The protected needle is removed and safely discarded, and the filter cap is placed on the syringe. Bubbles should be removed by expelling them through the filter cap.

• **Fig. 43.1** Oxygen dissociation curve. *CO*, Carbon monoxide; *2-3 DPG*, 2,3-diphosphoglycerate; *H<sup>+</sup>*, hydrogen; *PO<sub>2</sub>*, partial pressure of oxygen; *SO<sub>2</sub>*, sulfur dioxide; *TEMP*, temperature. (From Walker HK, Hall WD, Hurst HW. *Clinical Methods*. 3rd ed. Boston: Butterworths Elsevier; 1990:256.)

The capped syringe should be rapidly transported to the laboratory for processing. Some recommend placing the syringe on ice before transport to minimize cell degradation, clotting, and changes in the partial pressure of the gases of interest.

When multiple serial ABGs are needed, an arterial catheter may be placed to facilitate frequent measurements and minimize repeated needle sticks.

## Hypoxemia

Oxygen is present in arterial blood in two forms: bound to hemoglobin and dissolved in the plasma. The oxygen saturation (*SaO<sub>2</sub>*) represents oxygen bound to hemoglobin in arterial blood, whereas the partial pressure of oxygen (*PaO<sub>2</sub>*) represents oxygen dissolved in arterial plasma.

*PaO<sub>2</sub>* includes only molecules dissolved in the plasma because oxygen bound to hemoglobin does not directly influence the measured partial pressure in the plasma. *PaO<sub>2</sub>* is measured by an electrode that senses oxygen molecules not bound to hemoglobin.

*SaO<sub>2</sub>* denotes the percentage of available hemoglobin binding sites to which oxygen is bound. For example, an *SaO<sub>2</sub>* of 90% means that out of 100 available hemoglobin binding sites, 90 are bound by oxygen. *SaO<sub>2</sub>* should be directly measured by coximetry rather than extrapolated from the measured *PaO<sub>2</sub>*.

There is a well-defined relationship between *PaO<sub>2</sub>* and *SaO<sub>2</sub>*. When a molecule of oxygen passes from the alveolus to the pulmonary capillary, it is initially dissolved in the plasma. The oxygen molecule then rapidly binds to an available hemoglobin binding site. When bound to hemoglobin, the molecule of oxygen does not contribute to the pressure gradient of oxygen between the alveolus and pulmonary capillary, thereby allowing for more oxygen to diffuse from the alveolus into the bloodstream. In general, the more dissolved oxygen

molecules there are (i.e., the higher the *PaO<sub>2</sub>*), the more oxygen will bind to hemoglobin (i.e., the higher the *SaO<sub>2</sub>*).

Therefore the *PaO<sub>2</sub>* may be considered a “driver” of *SaO<sub>2</sub>*. The relationship of *SaO<sub>2</sub>* and *PaO<sub>2</sub>* is graphically described by the oxygen dissociation curve (Fig. 43.1).

Although they are clinically valuable parameters, neither *PaO<sub>2</sub>* nor *SaO<sub>2</sub>* provides quantitative information about the total amount of oxygen in arterial blood. The total quantity of oxygen in arterial blood is referred to as the arterial oxygen content (*CAO<sub>2</sub>*) and is described by the equation:

$$CAO_2 = (1.39)(Hb)(SaO_2) + (PaO_2)(0.003)$$

where *Hb* is hemoglobin (in g/dL), 1.39 is the volume of oxygen (mL) that can be bound by a gram of hemoglobin, and 0.003 is the solubility coefficient of oxygen in plasma. *CAO<sub>2</sub>* is expressed in milliliters of oxygen per deciliter.

The arterial oxygen content therefore is essentially the sum of the *SaO<sub>2</sub>* and *PaO<sub>2</sub>* (corrected for hemoglobin content and solubility, respectively). *CAO<sub>2</sub>* is the most physiologically relevant estimation of the quantity of oxygen delivered to peripheral tissues.

## A-a Gradient and the Alveolar Gas Equation

The transfer of oxygen from the alveolus to the blood in the pulmonary capillaries is described by the alveolar (A) to arterial (a) gradient. The A-a gradient provides a rough estimation of how oxygen transfers across the alveolar-capillary membrane. The partial pressures of oxygen in the alveolar and arterial compartments are used to determine the A-a gradient.

The *PaO<sub>2</sub>* is directly measured by obtaining an ABG. The partial pressure of oxygen in the alveoli (*PAO<sub>2</sub>*) must be calculated by the alveolar gas equation:

$$PAO_2 = PiO_2 - (PaCO_2/R)$$

where  $P_{iO_2} = (P_{\text{bar}} - P_{H_2O}) \times F_{iO_2}$ ,  $P_{\text{bar}}$  is barometric pressure (760 mm Hg at sea level),  $P_{H_2O}$  is the partial pressure of water vapor (47 mm Hg), and  $F_{iO_2}$  is the fraction of inhaled oxygen.  $P_{aCO_2}$  is the partial pressure of carbon dioxide in arterial blood, and  $R$  is the respiratory quotient (estimated to be 0.8 under normal conditions).

If the patient is breathing room air ( $F_{iO_2} = 0.21$ ) at sea level, the equation can be simplified:

$$PAO_2 = (F_{iO_2} \times 713) - (5/4) P_{aCO_2}$$

or

$$PAO_2 = 150 \text{ mm Hg} - (1.25 \times P_{aCO_2})$$

A-a gradient =  $PAO_2$  (calculated) –  $PaO_2$  (measured) Normal range = 0 to 10 mm Hg or  $2.5 + 0.21 \times (\text{age in years})$  mm Hg.

There are a number of assumptions in the alveolar gas equation that must be considered when using the A-a gradient clinically. The respiratory quotient is the amount of carbon dioxide produced divided by the amount of oxygen consumed, described as:

$$R = \dot{V}_{CO_2} / \dot{V}_{O_2}$$

where  $\dot{V}_{CO_2}$  is carbon dioxide production and  $\dot{V}_{O_2}$  is oxygen consumption.

The amount of carbon dioxide produced may vary markedly depending on a patient's metabolic state. For example, patients with sepsis and systemic inflammation may initially have very high  $CO_2$  production. Sepsis is also characterized by decreased oxygen uptake, further skewing the respiratory quotient from its assumed value of 0.8.

$F_{iO_2}$  influences the A-a gradient, as higher  $F_{iO_2}$  results in a higher A-a gradient. Increasing age is also associated with a higher A-a gradient. These factors need to be considered to determine whether or not the calculated A-a gradient actually represents abnormal oxygen transfer and uptake.

Hypoxemia can be caused by a variety of pathophysiologic processes including ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) mismatch, shunt, alveolar hypoventilation, reduced  $PaO_2$  in the inhaled air, or diffusion abnormality (typically does not cause hypoxemia at rest at sea level). A truly elevated A-a gradient is consistent with  $\dot{V}/\dot{Q}$  mismatch, shunt, or diffusion abnormality. In cases of hypoxemia caused by alveolar hypoventilation or reduced  $PaO_2$ , the A-a gradient is normal.

The  $PaO_2/F_{iO_2}$  ratio is another metric of hypoxemia that is frequently used in the critical care setting. The normal  $PaO_2/F_{iO_2}$  is 300 to 500 mm Hg. A  $PaO_2/F_{iO_2}$  ratio of <300 mm Hg indicates a clinically significant gas exchange derangement.

### Effects of Supplemental Oxygen

Supplemental oxygen increases the  $PAO_2$  in patients who are ventilating normally by increasing the  $F_{iO_2}$ . Increased  $PAO_2$  leads to an increased driving pressure of oxygen across the alveolar membrane. In a patient with  $\dot{V}/\dot{Q}$  mismatch, increased  $PAO_2$  leads to an increased  $PaO_2$ . In the setting

of shunt, in which blood passes through the lungs without making contact with the alveolus for gas exchange to occur, supplemental oxygen does not improve hypoxemia.

In the absence of a complete shunt, the amount of increase of  $PaO_2$  for a given amount of supplemental oxygen can be estimated. It should be emphasized that measurements of  $PaO_2$  vary over time without any significant change in clinical status, so the fidelity of equations predicting changes in  $PaO_2$  for a given increase in  $F_{iO_2}$  is limited. In addition, methods of administering oxygen make estimating the precise percentage of oxygen inhaled difficult. Specifically, an awake patient receiving oxygen by nasal cannulae may breathe with varying inspiratory flow rates, thereby entraining varying volumes of ambient air (with a  $F_{iO_2}$  of 0.21), decreasing the accuracy of predicting the relative contribution of nasally delivered oxygen. Fig. 43.2 demonstrates the approximate relationship between increased  $F_{iO_2}$  and  $PaO_2$  in hypothetical patients with varying degrees of  $\dot{V}/\dot{Q}$  mismatch.

Plane travel is an interesting circumstance in which supplemental oxygen may be necessary for patients who normally do not require it. The alveolar gas equation reminds us that barometric pressure is the primary driving force of gas into the alveoli. By law, airplane cabin pressure is set at the equivalent of no higher than 8000 feet (~560 mm Hg); usually cabin pressure is the equivalent of 6000 to 8000 feet. For people without lung disease or shunt, this decrease in barometric pressure is well tolerated. However, for patients with pulmonary disease, depressurization to 8000 ft may be dangerous. Before flying, the predicted  $PaO_2$  at 8000 feet should be calculated for such patients using the following equation:

$$\begin{aligned} \text{Predicted } PaO_2 \text{ at 8000 ft} &= 0.294 \left( \frac{PaO_2 \text{ on RA}}{\text{at sea level}} \right) \\ &+ 0.086 (\text{percentage predicted } FEV_1) + 23.211 \end{aligned}$$

If the patient's predicted  $PaO_2$  is unacceptably low (i.e., <60 mm Hg), providing supplemental oxygen to increase the patient's  $F_{iO_2}$  can counterbalance the effects of decreased barometric pressure while flying. Alternative methods for assessing whether a patient would tolerate plane travel include having the patient breathe hypoxic gas (15.1% oxygen, called the *hypoxia altitude simulation test*) or measuring  $PaO_2$  in a hypobaric chamber. These methods may be more accurate but may also require additional equipment.

### Carboxyhemoglobinemia and Methemoglobinemia

Hemoglobin molecules can lose affinity for oxygen by binding to carbon monoxide (CO) or by transforming into methemoglobin. CO avidly and irreversibly binds to hemoglobin, decreasing the binding sites available for oxygen to bind to hemoglobin. Hemoglobin bound to CO is referred to as *carboxyhemoglobin*.

• **Fig. 43.2** Changes in  $P_{aO_2}$  with increasing  $F_{iO_2}$  with varying degrees of  $V/Q$  mismatch. (From Tobin MJ. *Principles and Practice of Mechanical Ventilation*. New York: McGraw-Hill; 2006:760.)

Methemoglobin is formed when ferrous iron ( $Fe^{2+}$ ) is oxidized to the ferric state ( $Fe^{3+}$ ); this oxidative change decreases oxygen-carrying capacity by changing the hemoglobin tetramer's ability to bind and release oxygen to tissues. Methemoglobinemia can be congenital or acquired. Congenital forms of methemoglobinemia may be caused by enzyme deficiencies (such as diaphorase I deficiency). More commonly, methemoglobin is acquired as a result of oxidizing medications causing ferrous iron to convert to the ferric state. Dapsone, nitrates, local anesthetics (such as benzocaine), trimethoprim, and sulfonamides are potential causes of methemoglobinemia.

In these conditions, an ABG may reveal a normal  $P_{aO_2}$ . The measured  $SaO_2$ , however, is abnormal as the amount of oxygen bound to hemoglobin is decreased. It is important to recognize that peripherally measured oxygen saturation levels with pulse oximetry will be normal; an ABG is necessary to determine the true degree of hypoxia in these conditions. Pulse oximetry is normal (or near normal) in these conditions because light emitted by the pulse oximeter is increased by carboxyhemoglobin and methemoglobin, which the oximeter reports as oxygen (rather than CO saturation or methemoglobin levels).

Both carboxyhemoglobinemia and methemoglobinemia are treated with supplemental oxygen (including intubation and mechanical ventilation if necessary). Methemoglobinemia may be treated with methylene blue (1–2 mg/kg over

5 min) because it reduces the iron ion in hemoglobin to its ferrous ( $Fe^{2+}$ ) state, allowing the hemoglobin to bind and carry oxygen. Carboxyhemoglobinemia may require treatment in a hyperbaric oxygen chamber. Increasing the  $P_{aO_2}$  (by increasing the barometric pressure) may make the pressure gradient for oxygen across the alveolar membrane high enough for oxygen to displace avidly bound CO from hemoglobin.

## Acid-Base Disorders

### Hypercapnia and Acute Respiratory Acidosis

Increased carbon dioxide levels (referred to as hypercapnia) occur because of hypoventilation. Carbon dioxide readily diffuses from the bloodstream across the alveolar-capillary membrane; it is removed from alveoli by the process of ventilation. The limiting step in the elimination of carbon dioxide is not diffusion from the pulmonary circulation to the alveoli; rather it is the efficiency and efficacy of ventilation. This relationship is described via the following equation:

$$\dot{V}_A = (\dot{V}_{CO_2} \times k) / P_{aCO_2}$$

where  $\dot{V}_A$  is alveolar ventilation,  $V_{CO_2}$  is the metabolic production of  $CO_2$ ,  $k$  is a proportionality constant, and  $P_{aCO_2}$  is the partial pressure of carbon dioxide in arterial blood (in mm Hg).

When  $\dot{V}_A$  decreases,  $P_{aCO_2}$  must increase proportionally, assuming that  $\dot{V}_{CO_2}$  does not change. Understanding that hypoventilation is the cause of elevated blood levels of carbon dioxide is important in diagnosing and treating hypercapnia.

Alveolar ventilation cannot be readily measured in the clinical setting. However, minute ventilation ( $\dot{V}_E$ ) is easily determined:

$$\dot{V}_E = \text{Respiratory rate} \times \text{tidal volume}$$

$\dot{V}_A$  is the portion of the  $\dot{V}_E$  that does not include dead space ventilation:

$$\dot{V}_A = \dot{V}_E (1 - v_d/v_t)$$

where  $v_d/v_t$  is dead space fraction.

The  $v_d/v_t$  may be measured by the ventilator in mechanically ventilated patients. Specifically, exhaled carbon dioxide is collected and measured over a certain period of time;  $v_d/v_t$  can be calculated via the following relationship:

$$v_d/v_t = (P_{aCO_2} - P_{E_{CO_2}}) / P_{aCO_2}$$

where  $P_{E_{CO_2}}$  is the expired  $CO_2$ .

Clinically therefore the relationship between  $\dot{V}_A$  and  $P_{aCO_2}$  can be represented by the following equation:

$$\dot{V}_E (1 - v_d/v_t) = (\dot{V}_{CO_2} \times k) / P_{aCO_2}$$

$\dot{V}_E$ ,  $v_d/v_t$ , and  $P_{aCO_2}$  are all easily measured parameters, and  $\dot{V}_{CO_2} \times k$  is thought to be relatively constant. When  $\dot{V}_E$  decreases,  $P_{aCO_2}$  must increase. When  $v_d/v_t$  increases,  $P_{aCO_2}$  must increase. Both of these situations (increased  $v_d/v_t$  and decreased  $\dot{V}_E$ ) result in alveolar hypoventilation (decreased  $\dot{V}_A$ ).

Acute respiratory acidosis occurs when  $\dot{V}_A$  decreases suddenly. Because the continued, efficient elimination of carbon dioxide is important for preservation of a neutral acid-base status, a sudden decrease in  $\dot{V}_A$  and a sudden increase in  $\text{PaCO}_2$  causes a rapid decrease in pH.

Causes of decreased  $\dot{V}_A$  are classically divided into central and peripheral processes. Central hypoventilation may occur for a variety of reasons. Intoxication, particularly with opiates or other central nervous system (CNS) depressants, may result in a blunted central respiratory drive and decreased  $\dot{V}_A$ .

Peripheral causes of decreased  $\dot{V}_A$  include neuromuscular disorders or neuromuscular blocking medications that cause weakened or inefficient muscles of respiration. When tidal volume and/or respiratory rate decreases,  $\dot{V}_A$  decreases, and  $\text{PaCO}_2$  rises. Severe airways obstruction, such as a chronic obstructive pulmonary disease (COPD) exacerbation, may also result in acute hypoventilation and hypercapnia.

It is rare that small increases in  $v_d/v_t$  alone result in hypercapnia. Carbon dioxide so readily diffuses across the alveolar membrane that minimal increases in  $\dot{V}_E$  can compensate for small increases in  $v_d/v_t$  and maintain a normal or near-normal  $\text{CO}_2$ .

Treatment of hypercapnia is centered on treatment of the underlying process. In certain circumstances, mechanical ventilation may be necessary to achieve adequate  $\dot{V}_E$  and  $\dot{V}_A$  to correct hypercapnia.

## Compensatory Mechanisms

### Chronic Respiratory Acidosis

Chronic respiratory acidosis is an interesting condition in which a patient experiences persistent alveolar hypoventilation. Persistent alveolar hypoventilation and persistently elevated  $\text{PaCO}_2$  result in changes in kidney function in an effort to restore acid-base neutrality. Specifically, normally functioning kidneys respond to persistent acidemia by increasing retention of bicarbonate ( $\text{HCO}_3^-$ ) while increasing excretion of hydrogen ion. Over several days, the kidneys' response results in elevated serum  $\text{HCO}_3^-$  levels and the return of serum pH toward normal.

Reasons for chronic alveolar hypoventilation, and thereby chronic respiratory acidosis, include central and peripheral processes (Box 43.1). Central processes include pathologies such as obesity hypoventilation syndrome (OHS, or the so-called *Pickwickian syndrome*). In patients with OHS, chronic hypoventilation leads to a "reset" of the carotid bodies and the central medullary respiratory centers. The physiologically acceptable  $\text{PaCO}_2$  is liberalized, and centrally mediated respiratory drive is decreased because of increased tolerance for elevated  $\text{PaCO}_2$  by the central respiratory centers. Similarly and rarely, a stroke in the medullary respiratory center can result in central hypoventilation.

As with acute respiratory acidosis, neuromuscular diseases or advanced obstructive diseases such as COPD can result in chronic respiratory acidosis. Progressive

### • BOX 43.1 Causes of Respiratory Acidosis

- Chronic obstructive pulmonary disease: emphysema, severe asthma, chronic bronchitis
- Neuromuscular diseases: amyotrophic lateral sclerosis, diaphragm dysfunction and paralysis, Guillain-Barré syndrome, myasthenia gravis, muscular dystrophy
- Chest wall disorders: severe kyphoscoliosis; status postthoracoplasty; flail chest; less commonly, ankylosing spondylitis, pectus excavatum, or pectus carinatum
- Obstructive sleep apnea
- Obesity-hypoventilation syndrome
- Central nervous system (CNS) depression: drugs (e.g., narcotics, barbiturates, benzodiazepines, other CNS depressants), neurologic disorders (e.g., encephalitis, brainstem disease, trauma), primary alveolar hypoventilation
- Other lung and airway diseases: laryngeal and tracheal stenosis
- Lung-protective ventilation in acute respiratory distress syndrome

neuromuscular processes including amyotrophic lateral sclerosis can lead to chronically decreased minute ventilation. Over time, a persistently elevated  $\text{PaCO}_2$  will lead to changes in renal function and a compensatory metabolic alkalosis. The central respiratory drive will still respond to the elevated  $\text{PaCO}_2$ , but because of neuromuscular dysfunction, the muscles of respiration will not be able to adequately increase  $\dot{V}_A$ .

Similarly, patients with advanced COPD may be unable to perform efficient ventilation because of airways obstruction and hyperinflation. Over time, elevated  $\text{PaCO}_2$  leads to a chronic respiratory acidosis and a compensatory metabolic alkalosis.

As in acute respiratory acidosis, treatment of a chronic respiratory acidosis is focused on the underlying cause. Supportive care is typically appropriate, given that many causes of chronic respiratory acidosis are not reversible or easily treatable. Mechanical ventilation, particularly noninvasive positive-pressure ventilation (NIPPV), is appropriate treatment for many causes of chronic respiratory acidosis. Particularly for patients with OHS or other central causes of chronic respiratory acidosis, nocturnal NIPPV can delay the progression of disease and worsening of chronic respiratory acidosis.

For patients with advanced COPD, treatment of the underlying disease with appropriate medical therapy and judicious use of NIPPV is appropriate.

### Respiratory Alkalosis

Respiratory alkalosis is defined as an increased pH resulting from a decreased  $\text{PaCO}_2$ . Whereas respiratory acidosis is caused by decreased alveolar ventilation, increased alveolar ventilation is the cause of respiratory alkalosis. Any process that leads to an increase in minute ventilation without a substantive increase in dead space ventilation will result in a respiratory alkalosis.

### • BOX 43.2 Causes of Respiratory Alkalosis

Iatrogenic

Psychiatric: anxiety, hysteria, stress

Medications: doxapram, aspirin, caffeine

Central nervous system: stroke, subarachnoid hemorrhage, meningitis

Pulmonary disease: pneumonia, pulmonary embolism

General: fever, pregnancy, sexual activity, hepatic failure (high ammonia levels), high altitude

Most respiratory alkaloses are acute (Box 43.2). Increases in respiratory rate and/or tidal volume caused by pain, anxiety, stress, fever (which may stimulate the medullary respiratory centers), drugs (methamphetamines, caffeine, or other stimulant use), or hypoxia can lead to increased elimination of carbon dioxide and an acute respiratory alkalosis. It should be emphasized that in an awake and alert patient with hypoxemia, it is not uncommon for a mild respiratory alkalosis to be present. Aspirin is a unique example because it classically causes a centrally mediated respiratory alkalosis and a metabolic acidosis.

Chronic respiratory alkalosis is a relatively rare phenomenon; chronic causes of persistently increased alveolar ventilation are almost exclusively related to CNS pathologies. Stroke, infection (such as meningitis), and subarachnoid hemorrhage are all potential causes of chronic respiratory alkalosis resulting from direct brainstem stimulation. Additional etiologies of chronic respiratory alkaloses are high-progesterone states, including pregnancy, and advanced liver disease and cirrhosis.

Treatment of an acute respiratory alkalosis focuses on treatment of the underlying process. In an anxious patient, redirection and judicious use of anxiolytics may be appropriate. In a patient with pain, analgesia is appropriate. In a hypoxic patient, treatment of the underlying process and providing supplemental oxygen are appropriate interventions.

Chronic respiratory alkaloses are more difficult to treat because they are typically centrally mediated. Therapeutic efforts are focused on supporting and reversing (if possible) the underlying central process.

### Metabolic Acidosis

Acute metabolic acidosis is defined as a decrease in serum  $\text{HCO}_3^-$  levels with a concomitant decrease in pH.  $\text{HCO}_3^-$  is an important physiologic buffer; when hydrogen ion is increased,  $\text{HCO}_3^-$  is consumed via the following relationship:

where  $\text{H}_2\text{CO}_3$  is a transient, unstable intermediate state.

The relationship between carbon dioxide and  $\text{HCO}_3^-$  can also be described by the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK} + \log \left[ \frac{(\text{HCO}_3^-)}{(0.03 \times \text{PaCO}_2)} \right]$$

The Henderson-Hasselbalch equation demonstrates that pH is dependent on the ratio of  $\text{HCO}_3^-$  to carbon dioxide. This concept explains the importance of so-called “compensatory” mechanisms. In an effort to preserve pH near normal, changes in  $\text{HCO}_3^-$  level lead to changes in respiration and minute ventilation to adjust carbon dioxide levels.

Most metabolic acidoses are acute in nature, as a sudden increase in hydrogen ion production is usually caused by an acute clinical event. Chronic metabolic acidoses are processes in which acids are produced (and buffered) over time. The primary differentiation between an acute and chronic metabolic acidosis is that alternative buffers such as bone and hemoglobin may be used in chronic metabolic acidoses as  $\text{HCO}_3^-$  is depleted.

Metabolic acidoses are divided into anion-gap and nonanion-gap metabolic acidoses. Anion-gap metabolic acidoses are processes in which an unmeasured anion is produced, leading to an increase in the anion gap. The anion gap represents the presence of anions that are not measured in the basic chemistry panel. Negatively charged proteins (particularly albumin) form the majority of unmeasured anions. The anion gap is calculated in the following manner:

$$\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-) = \text{anion gap}$$

A normal anion gap is approximately 10 to 12, largely determined by the serum albumin concentration. When albumin is lower than normal, the upper limit of the anion gap is reduced. This reduction can be approximated by lowering the upper limit of the anion gap by 2 for every 1 g/dL decrease in serum albumin. For example, an anion gap of 10 would be normal in a patient with a normal serum albumin; however, in a patient with a serum albumin of 2 g/dL an anion gap of 10 would be considered elevated (because the upper limit of normal of the anion gap in this patient would be ~6–8).

Processes that produce unmeasured anions cause an anion-gap metabolic acidosis. Methanol ingestion, uremia, diabetic ketoacidosis (DKA), paraldehyde ingestion, iron toxicity, lactic acidosis, ethylene glycol ingestion, and salicylate toxicity are all potential causes of an anion-gap metabolic acidosis (the acronym MUDPILES can be helpful in recalling these conditions).

Nonanion-gap metabolic acidoses result from depletion of  $\text{HCO}_3^-$  without an increase in unmeasured anions. The urine anion gap (UAG) is helpful in the workup of a nonanion-gap metabolic acidosis. The three main causes of nonanion-gap acidosis are (1) loss of  $\text{HCO}_3^-$  from the gastrointestinal (GI) tract (e.g., diarrhea), (2) loss of  $\text{HCO}_3^-$  from the kidneys (e.g., renal tubular acidosis, RTA), and (3) administration of acid. The urine anion gap = unmeasured anions – unmeasured cations, or  $[\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-]$ . In normal subjects, the urine anion gap is usually near zero or is positive. In metabolic acidosis, the excretion of ammonium (which is excreted with  $\text{Cl}^-$ ) should increase markedly if renal acidification is intact. Because of the rise in urinary  $\text{Cl}^-$ , the urine anion gap, which is also called the *urinary net charge*, becomes negative, ranging from –20 to more than –50 mEq/L. The negative value occurs because the  $\text{Cl}^-$  concentration now exceeds the sum total of  $\text{Na}^+$  and  $\text{K}^+$ .

In contrast, if there is an impairment in kidney function resulting in an inability to increase ammonium excretion (e.g., RTA), then  $\text{Cl}^-$  ions will not be increased in the urine, and the urine anion gap will not be affected and will be positive or zero. In a patient with a hyperchloremic metabolic acidosis, a negative UAG suggests GI loss of  $\text{HCO}_3^-$  (e.g., diarrhea), whereas a positive UAG suggests impaired renal acidification (i.e., RTA).

When serum  $\text{HCO}_3^-$  decreases resulting in a decrease in serum pH, alveolar ventilation increases to decrease  $\text{PaCO}_2$  in an effort to maintain the pH near normal. Normally, the  $\text{PaCO}_2$  decreases by 1 mm Hg for each 1 mEq/L decrease in serum  $\text{HCO}_3^-$ .

In most cases, treatment of metabolic acidoses involves treating the underlying disorder. In specific instances, such as in a type 1 RTA, replacement of  $\text{HCO}_3^-$  is appropriate. However, in most cases of metabolic acidosis (particularly anion-gap metabolic acidosis)  $\text{HCO}_3^-$  replacement is not necessary or clinically beneficial. In cases of extreme acidosis such as a pH <7.10 to 7.15,  $\text{HCO}_3^-$  replacement may be considered while the underlying process is addressed.

## Metabolic Alkalosis

Metabolic alkalosis is defined as an increase in serum  $\text{HCO}_3^-$  levels with a concomitant increase in pH. Conceptually, the causes of metabolic alkaloses are loss of hydrogen ion or retention of  $\text{HCO}_3^-$ .

Loss of hydrogen ion may occur because of vomiting or nasogastric suctioning. Normally, when acidic gastric secretions pass into the duodenum, they cause a release of alkalotic pancreatic secretions. However, in the setting of vomiting or gastric suctioning, the release of  $\text{HCO}_3^-$ -rich pancreatic secretions does not occur, and a metabolic alkalosis ensues.

Diuretics such as thiazides or loop diuretics (such as furosemide) cause increased hydrogen ion secretion in the urine and thereby cause a metabolic alkalosis. Hyperaldosteronism may also cause a metabolic alkalosis.

An increase in serum  $\text{HCO}_3^-$  level that causes an increase in pH will result in alveolar hypoventilation with an increase in  $\text{PaCO}_2$  to maintain a near-neutral pH. Typically, the  $\text{PaCO}_2$  will increase by 0.7 mm Hg for every 1 mEq/L increase in the serum  $\text{HCO}_3^-$ .

Treatment of metabolic alkalosis is focused on treatment of the underlying process. Patients with excessive vomiting should receive antiemetics, and the cause of the vomiting should be addressed. Diuretics should be stopped or adjusted when appropriate. Spironolactone (an aldosterone-receptor antagonist) may be considered in patients with hyperaldosteronism.

## Mixed Disorders

### Expected Compensation

As described in the previous sections, carbon dioxide and  $\text{HCO}_3^-$  levels will vary in a predictable fashion in response

to an acid-base abnormality. The Henderson-Hasselbalch equation describes the relationship between carbon dioxide and  $\text{HCO}_3^-$ :

$$\text{pH} = \text{p}K + \log \left[ \frac{(\text{HCO}_3^-)}{(0.03 \times \text{PaCO}_2)} \right]$$

Specifically, in the setting of a metabolic acidosis, the central respiratory centers are stimulated to increase minute ventilation and thereby increase elimination of carbon dioxide. Predictably, carbon dioxide should decrease 1 mm Hg for every 1 mEq/L decrease in  $\text{HCO}_3^-$ .

This anticipated change in carbon dioxide may be estimated by using Winters' formula:

$$\text{estimated PaCO}_2 = [1.5 \times \text{HCO}_3^-] + 8 \pm 2$$

If the measured carbon dioxide varies from the estimated  $\text{PaCO}_2$ , then a secondary independent respiratory acid-base process is occurring.

A metabolic alkalosis causes increased pH, which decreases the respiratory drive and leads to relative hypoventilation. This results in an increase in  $\text{PaCO}_2$ . The carbon dioxide should increase by 0.7 mm Hg for each 1 mEq/L increase in  $\text{HCO}_3^-$ .

Compensation for respiratory disorders may be either acute or chronic. Acute compensation is primarily performed by intracellular buffers and is relatively modest in effect. Chronic compensation is accomplished by alterations in kidney function by either increased excretion of  $\text{HCO}_3^-$  (in respiratory alkalosis) or increased reabsorption of  $\text{HCO}_3^-$  (in respiratory acidosis).

In acute respiratory alkalosis, alveolar hyperventilation leads to increased elimination of carbon dioxide and a decrease in pH. Acutely, serum  $\text{HCO}_3^-$  decreases by 0.1 to 0.2 mEq/L for each 1 mm Hg decrease in  $\text{PaCO}_2$ . By extension, serum  $\text{HCO}_3^-$  decreases by approximately 2 mEq/L for each 10 mm Hg decrease in  $\text{PaCO}_2$ .

Chronic respiratory alkalosis causes increased renal  $\text{HCO}_3^-$  excretion. In the chronic setting, serum  $\text{HCO}_3^-$  is expected to decrease by 0.5 mEq/L for each 1 mm Hg decrease in  $\text{PaCO}_2$  (or a decrease of 5 mEq/L for each decrease of 10 mm Hg).

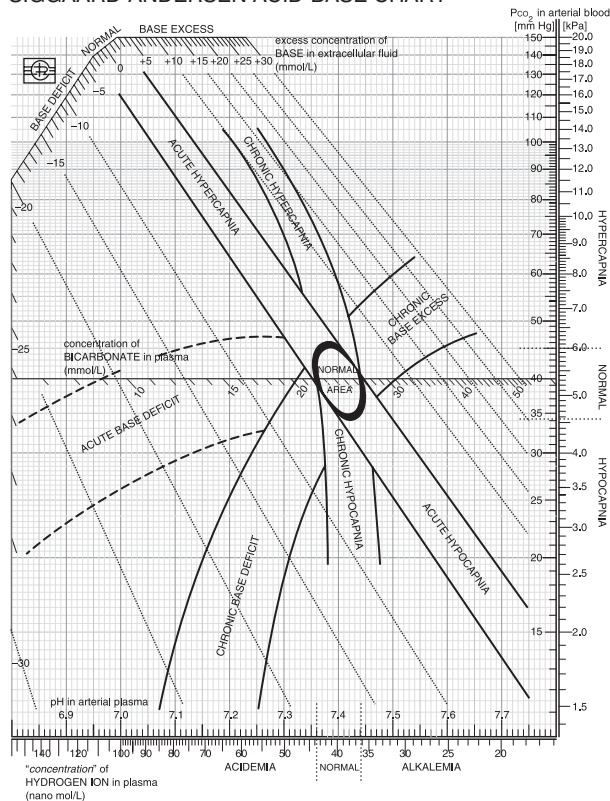

Acute respiratory acidosis is defined by alveolar hypoventilation and an increase in carbon dioxide that results in a decrease in serum pH. In the acute setting,  $\text{HCO}_3^-$  increases by 0.05–0.1 mEq/L for each 1 mm Hg increase in carbon dioxide (or a 1 mEq/L increase for every increase of 10 mm Hg of carbon dioxide).

In response to chronic respiratory acidosis, the serum  $\text{HCO}_3^-$  is expected to rise by 0.4 mEq/L for every 1 mm Hg increase in carbon dioxide (or a rise of 4 mEq/L for every increase of 10 mm Hg of carbon dioxide).

There are more complicated equations for predicting the appropriate compensatory response for a given acid-base situation; however, for practical purposes the simple relationships described are easy to use and relatively accurate.

In addition, graphic representations of the relationship between carbon dioxide and  $\text{HCO}_3^-$  are available as aids to determine expected compensatory responses (Fig. 43.3).

SIGGAARD-ANDERSEN ACID-BASE CHART

• **Fig. 43.3** Acid-base compensation chart. (From Siggaard-Andersen O. The Siggaard-Andersen curve nomogram. *Scand J Clin Lab Invest.* 1962;14:598–604.)

### True Mixed Acid-Base Disorders

True mixed acid-base disorders occur when two or more independent processes are occurring, both of which affect either the  $\text{HCO}_3^-$  or carbon dioxide levels and thereby affect pH (Box 43.3). The simplest manner by which to identify multiple acid-base processes is to recognize when the expected compensatory response is not present. In this instance a second, independent process is likely the cause of the lack of expected compensation. The  $\Delta$ - $\Delta$  is also helpful in sorting out mixed acid-base disorders (Table 43.1).

The delta ratio is calculated as follows:

$$\text{Delta ratio} = \Delta \text{ anion gap} / \Delta [\text{HCO}_3^-]$$

or

$$\text{anion gap} / \downarrow [\text{HCO}_3^-]$$

$$\Delta - \Delta = (\text{measured anion gap} - \text{normal anion gap}) / (\text{normal} [\text{HCO}_3^-] - \text{measured} [\text{HCO}_3^-])$$

A  $\Delta$ - $\Delta$  value below 1:1 indicates a greater fall in  $\text{HCO}_3^-$  than one would expect given the increase in the anion gap. This can be explained by a mixed metabolic acidosis, that is, a combined elevated anion-gap acidosis and a normal

### • BOX 43.3 Red Flags Suggesting a Mixed Acid-Base Disorder

- The expected compensatory response does not occur.
- Compensatory response occurs, but level of compensation is inadequate or too extreme.
- Whenever the  $\text{PCO}_2$  and  $\text{HCO}_3^-$  become abnormal in the opposite direction (i.e., one is elevated while the other is reduced). In simple acid-base disorders, the direction of the compensatory response is always the same as the direction of the initial abnormal change.
- pH is normal, but  $\text{PCO}_2$  or  $\text{HCO}_3^-$  is abnormal.
- In anion-gap metabolic acidosis, if the change in bicarbonate level is not proportional to the change of the anion gap. More specifically, if the  $\Delta$  ratio is  $>2$  or  $<1$ .
- In simple acid-base disorders, the compensatory response should never return the pH completely to normal. If that happens, suspect a mixed disorder.

**TABLE 43.1** Differential Diagnosis of a Delta-Delta

$\Delta$	Differential Diagnosis
$<0.4$	Hyperchloremic normal anion-gap acidosis
$<1$	High-AG and normal-AG acidosis
1 to 2	Pure anion-gap acidosis lactic acidosis
$>2$	High-AG acidosis and a concurrent metabolic alkalosis or a preexisting compensated respiratory acidosis

AG, Anion gap.

anion-gap acidosis as might occur when lactic acidosis is superimposed on severe diarrhea. In this situation, the additional decrease in  $\text{HCO}_3^-$  is caused by further buffering of an acid that does not contribute to the anion gap (i.e., addition of hydrochloric acid to the body as a result of diarrhea).

A  $\Delta$ - $\Delta$  value of 1:2 is usual for an uncomplicated high-anion gap acidosis. In patients with a lactic acidosis the average value is 1.6, whereas in patients with a DKA, the  $\Delta$ - $\Delta$  ratio is more likely to be closer to 1 because of urine ketone loss. A further complication is that patients with DKA are often fluid resuscitated with normal saline, which results in an increase in plasma chloride, a decrease in anion gap, and development of a hyperchloremic normal anion-gap acidosis superimposed on ketoacidosis. The result is a further drop in the  $\Delta$  ratio.

A value above 2:1 indicates a lesser fall in  $\text{HCO}_3^-$  than one would expect given the change in the anion gap. This can be explained by another process that increases the  $\text{HCO}_3^-$ —a concurrent metabolic alkalosis. Another situation to consider is a preexisting high  $\text{HCO}_3^-$  level as would be seen in chronic respiratory acidosis.

## Chapter Review

### Questions

- A 72-year-old man with severe COPD presents to the emergency department (ED) with progressively worsening cough, phlegm, and shortness of breath. He has increased the frequency of his short-acting bronchodilator use without improvement in his symptoms. On examination, he is “tripoding” and in moderate respiratory distress. Vital signs reveal a heart rate of 126 beats per minute, blood pressure 110/62 mm Hg, respiratory rate 22 breaths per minute, O<sub>2</sub> saturation 85% on room air. Pulmonary auscultation demonstrates very little air movement. His heart rate is tachycardic, and he is mildly cyanotic. ABG reveals pH 7.22, P<sub>a</sub>CO<sub>2</sub> 71 mm Hg, P<sub>a</sub>O<sub>2</sub> 55 mm Hg. Chest x-ray shows hyperinflation but no new opacities.

How do you interpret his arterial blood gas?

  - Acute respiratory acidosis
  - Acute metabolic acidosis
  - Metabolic acidosis with superimposed respiratory alkalosis
  - Chronic respiratory acidosis with superimposed acute respiratory acidosis
  - Metabolic acidosis and respiratory acidosis
- A 47-year-old woman with known peptic ulcer disease presents with a 3-day history of epigastric pain, profuse vomiting, and inability to tolerate oral food or fluids. On examination, she is in moderate pain. Blood pressure is 88/42 mm Hg, pulse rate 97 beats per minute, and mucous membranes are dry. Laboratory studies demonstrate a serum sodium 124 mmol/L, serum potassium 3.0 mmol/L, serum chloride 65 mmol/L, serum HCO<sub>3</sub><sup>-</sup> 40 mmol/L, blood urea nitrogen 56 mg/dL, serum creatinine 2.1 mg/dL. Arterial blood studies on room air reveal pH 7.65 and P<sub>a</sub>CO<sub>2</sub> 38 mm Hg.

Which of the following best describes the acid-base disorder in this patient?

  - Metabolic alkalosis and respiratory acidosis
  - Metabolic alkalosis and respiratory alkalosis
  - Metabolic alkalosis, respiratory acidosis, and respiratory alkalosis
  - Metabolic acidosis, metabolic alkalosis, and respiratory alkalosis
  - None of the above
- A 22-year-old woman presents with fatigue and generalized muscle weakness. Blood pressure is 92/65 mm Hg, pulse rate 62 beats per minute, weight 132 lb, height 5 ft 9 in. Laboratory studies yield serum Na<sup>+</sup> 136 mmol/L, serum K<sup>+</sup> 3.3 mmol/L, serum Cl<sup>-</sup> 98 mmol/L, serum HCO<sub>3</sub><sup>-</sup> 32 mmol/L, blood urea nitrogen 12 mg/dL, serum creatinine 0.6 mg/dL.

Arterial blood studies on room air reveal pH 7.46 and P<sub>a</sub>CO<sub>2</sub> 47 mm Hg.

What is the likely cause of this patient’s acid-base disturbance?

  - Surreptitious vomiting
  - Laxative abuse
  - Thiazide diuretic abuse
  - Gitelman syndrome
  - Hepatic encephalopathy
- A 63-year-old woman with hypertension, gastrointestinal reflux disease, type 2 diabetes, and dementia presents to the ED with 4 days of cough, fevers, and right-sided chest pain. Her temperature is 101°F, heart rate 120 beats per minute, blood pressure 100/50 mm Hg, respiratory rate 34 breaths per minute, and blood oxygen saturation (SpO<sub>2</sub>) is 86% on ambient air. She has decreased right basilar breath sounds and right-midlung crackles and rhonchi. Antibiotics have been ordered, a chest x-ray is pending, and an ABG demonstrates a pH of 7.32, P<sub>a</sub>CO<sub>2</sub> 50 mm Hg, P<sub>a</sub>O<sub>2</sub> 56 mm Hg.

What is the most appropriate immediate next step in her care?

  - Repeat the arterial blood gas.
  - Order albuterol nebulizer treatment.
  - Obtain a STAT chest CT angiogram.
  - Initiate supplemental oxygen via face mask.
  - Start noninvasive positive-pressure ventilation.
- A 45-year-old homeless man is brought to the ED after having been found down covered in emesis. He is known to have a history of asthma and heavy alcohol use. His SpO<sub>2</sub> is 89% on ambient air, and his respiratory rate is 11 breaths per minute. Arterial blood gas on room air reveals pH 7.16, P<sub>a</sub>CO<sub>2</sub> 70 mm Hg, and P<sub>a</sub>O<sub>2</sub> 60 mm Hg.

What is the most appropriate next step in his clinical care?

  - Start antibiotics for aspiration pneumonia.
  - Give HCO<sub>3</sub><sup>-</sup> for metabolic acidosis.
  - Intubate and initiate invasive mechanical ventilation.
  - Provide intravenous steroids.
  - Administer inhaled bronchodilators.
  - Both A and B

### Questions

1. A 65-year-old man with a history of insulin-dependent diabetes, hypertension, and end-stage renal disease on hemodialysis is admitted to the hospital for treatment of lower extremity cellulitis. At the registration area of the emergency department (ED), he collapses. The code team is activated, and on arrival he is unresponsive without detectable respirations or blood pressure. A monitor/defibrillator is attached, and the rhythm is shown in Fig. 44.1. The patient has been given effective bag mask ventilation and five cycles of appropriate chest compressions. He remains without detectable blood pressure. Treatment at this point should be:
  - A. Biphasic shock at 200 J
  - B. Monophasic shock at 100 J
  - C. Epinephrine, 1 mg intravenous (IV)
  - D. Lidocaine, 1 mg/kg IV
2. A 50-year-old woman with a history of hypertension is brought to the ED after an extensive house fire. On presentation she is afebrile, her heart rate is 120 beats per minute, blood pressure is 105/45 mm Hg, respiratory rate is 23 breaths per minute and unlabored. Her oxygen saturation is 98% (pulse oximetry). The best next step in her evaluation would be:
  - A. Immediate intubation and bronchoscopy to exclude lower airways thermal injury
  - B. Arterial blood gas (ABG) for partial oxygen pressure (PaO<sub>2</sub>) determination
  - C. Administration of methylene blue and check cyanomethemoglobin level
  - D. ABG with cooximetry
3. Which of the following statements is true regarding central venous catheters?
  - A. The frequency of mechanical complications of central line placement (arterial puncture, hematoma, and pneumothorax) is twice as high for internal jugular catheterizations as for subclavian vein catheterizations.
  - B. Femoral vein cannulation carries a higher risk of arterial puncture than internal jugular or subclavian site.
  - C. Subclavian vein catheterization is associated with a higher infection rate than internal jugular vein catheterization.
  - D. Routine exchanges of catheters every 7 days is associated with a decreased rate of catheter infection.
4. A 35-year-old woman is admitted to the intensive care unit (ICU) with crush injury after a motor vehicle accident. After 48 hours of admission, she develops an increased oxygen requirement. She is intubated, and mechanical ventilation is initiated. Which of the following interventions is not universally recommended to reduce incidence of ventilator-associated pneumonia?
  - A. Continuous aspiration of subglottic secretions
  - B. Selective decontamination of the digestive tract
  - C. Elevation of the head of the bed to >30 degrees
  - D. Changes of ventilator circuit only when visibly soiled
5. A 23-year-old college student is brought to the ED after ingestion of 60 mL of wintergreen oil in a suicidal gesture. She is lethargic and unable to answer questions. On presentation, she has a respiratory rate of 28 breaths per minute with deep respirations. Oral temperature is 100.5°F, heart rate is 128 beats per minute, and blood pressure is 124/60 mm Hg. Skin has no rashes. There is no evidence of external trauma. Lungs are clear. Cardiovascular examination shows a regular rate and rhythm with a normal S1 and S2. Abdomen is soft with mild diffuse tenderness. Neurologic examination is nonfocal. Her laboratory data reveal a serum sodium 136 mEq/L, potassium 3.8 mEq/L, chloride ion 100 mEq/L, bicarbonate 18 mEq/L, creatinine 0.6 mg/dL, glucose 90 mg/dL, white blood count 12,000/μL, hematocrit 42%, and platelet 300,000/μL. ABG on 2 L via nasal canula reveals pH 7.44, partial carbon dioxide pressure (PaCO<sub>2</sub>) 22 mm Hg, PaO<sub>2</sub> 100 mm Hg. Chest x-ray is normal. Electrocardiogram (EKG) reveals normal sinus rhythm without ischemia. The remainder of her laboratory studies is pending. In the ED, she was begun on IV normal saline (NS). Activated charcoal was given. Your next step should be to:
  - A. Administer acetazolamide.
  - B. Begin mechanical ventilation.
  - C. Change IV fluid to bicarbonate-containing solution.
  - D. Begin beta-blocker.
  - E. Administer *N*-acetylcysteine.

• **Fig. 44.1** Rhythm strip of patient in question 1.

6. A decision is made to intubate an asthmatic patient for impending respiratory failure. During intubation, the patient receives sedation and a short-acting paralytic agent. Initial ventilator settings are assist control, respiratory rate is 16 breaths per minute, tidal volume ( $V_T$ ) is 500 mL, positive end-expiratory pressure (PEEP) is 5 cm  $H_2O$ , inspiratory flow rate is 60 L/minute, and fraction of inspired oxygen ( $FiO_2$ ) is 1.0. An end-inspiratory pause is administered, and the peak inspiratory pressure (PIP) and plateau pressure ( $P_{plat}$ ) are measured. Compliance ( $C_{stat}$ ) and airway resistance ( $R_{aw}$ ) are calculated. In this patient with status asthmaticus the most likely findings would be:

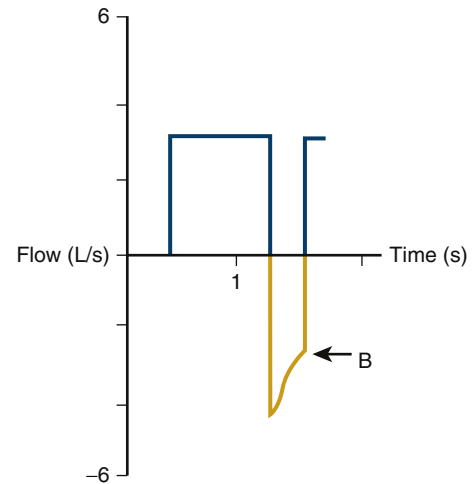

- A. PIP = 35 cm  $H_2O$ ,  $P_{plat}$  = 15 cm  $H_2O$ ,  $C_{stat}$  = 50 mL/cm  $H_2O$ ,  $R_{aw}$  = 20 cm  $H_2O/L/s$
- B. PIP = 17 cm  $H_2O$ ,  $P_{plat}$  = 15 cm  $H_2O$ ,  $C_{stat}$  = 50 mL/cm  $H_2O$ ,  $R_{aw}$  = 2 cm  $H_2O/L/s$
- C. PIP = 32 cm  $H_2O$ ,  $P_{plat}$  = 30 cm  $H_2O$ ,  $C_{stat}$  = 20 mL/cm  $H_2O$ ,  $R_{aw}$  = 2 cm  $H_2O/L/s$
- D. PIP = 35 cm  $H_2O$ ,  $P_{plat}$  = 15 cm  $H_2O$ ,  $C_{stat}$  = 40 mL/cm  $H_2O$ ,  $R_{aw}$  = 2 cm  $H_2O/L/s$

7. After 4 hours on these ventilator settings, the PIP is noted to now be 50 cm  $H_2O$ . Review of the ventilator waveforms indicates the flow-time curve graphic shown in Fig. 44.2.

Which ventilator change should be considered next?

- A. Increase the set respiratory rate.
  - B. Decrease the  $FiO_2$ .
  - C. Decrease the set inspiratory time.
  - D. Increase the inspiratory flow rate.
  - E. Decrease the  $V_T$ .
8. Which of the following statements is false regarding the fat embolism syndrome (FES)?
- A. FES refers to the triad of respiratory dysfunction, neurologic changes, and renal failure caused by entry of fat particles into the microcirculation.
  - B. FES occurs in 5% to 10% of patients with multiple long bone fractures or concomitant pelvic fractures.
  - C. There is commonly a latent period after the injury before clinical manifestation is noted.
  - D. FES without pulmonary involvement is uncommon.

PIP = 35 cm  $H_2O$ ,  $P_{plat}$  = 15 cm  $H_2O$ ,  $C_{stat}$  = 50 mL/cm  $H_2O$ ,  $R_{aw}$  = 20 cm  $H_2O/L/s$

• **Fig. 44.2** Ventilator waveform (flow-time curve) for patient in question 7.  $C_{stat}$ , Compliance; PIP, peak inspiratory pressure;  $P_{plat}$ , plateau pressure;  $R_{aw}$ , airway resistance.

9. A 50-year-old male smoker with chronic obstructive pulmonary disease and diabetes mellitus (DM) type 2 is admitted to the ICU with pneumonia and respiratory failure. He is intubated, and mechanical ventilation is initiated. Laboratory studies on presentation reveal serum sodium 140 mEq/L, white blood count 19,000/ $\mu$ L (89% polys, 4% bands), potassium 4.6 mEq/L, hematocrit 38%, chloride 110 mEq/L, platelet 190,000/ $\mu$ L, bicarbonate 26 mEq/L, and glucose 230 mg/dL. Vancomycin IV, levofloxacin, Solu-Medrol, and bronchodilator therapy are ordered. A ventilator bundle is implemented including elevation of head of bed, daily assessment of readiness to extubate, daily sedation holiday, gastrointestinal (GI) prophylaxis with IV Pepcid, and deep vein thrombosis prophylaxis with heparin subcutaneously. An IV insulin infusion is begun with goal glucose of  $\leq$ 180 mg/dL. On hospital day 7, the patient remains intubated. He has new right lower extremity pain. Right dorsalis pedis and posterior tibialis pulses are newly absent. Laboratory values reveal serum sodium 136 mEq/L, white blood count

- 12,000/ $\mu$ L (93% polys, 0% bands), potassium 3.6 mEq/L, hematocrit 36%, chloride 106 mEq/L, platelet 40,000/ $\mu$ L, bicarbonate 22 mEq/L, and glucose 114 mg/dL. Platelet factor-4 antibodies and vascular imaging studies are ordered. In addition to surgical consultation, appropriate treatment includes:
- Stop unfractionated heparin and begin platelet infusion.
  - Stop unfractionated heparin and monitor platelets daily.
  - Stop unfractionated heparin and begin low-molecular-weight heparin (LMWH).
  - Stop unfractionated heparin and begin argatroban.
  - Stop unfractionated heparin and begin warfarin.
- A 60-year-old man is admitted with severe midepigastic abdominal pain radiating to the back. Oral temperature is 103°F. Heart rate is 100 beats per minute, and current blood pressure is 110/60 mm Hg. Lipase is elevated. Abdominal CT scan reveals pancreatic inflammation with areas of necrosis. Biliary ducts are not dilated. The best next step in management would be:
    - Begin enteral nasojejunal feeds
    - NS
    - Empirical antibiotic treatment with aminoglycoside
    - Empirical antifungal therapy
  - Decisions regarding end-of-life care are guided by which of the ethical principles outlined below?
    - Autonomy
    - Nonmaleficence
    - Beneficence
    - All the above
  - A 75-year-old man is admitted to the ICU with increased respiratory distress. He is a current smoker (75-pack-year history). Most recent outpatient spirometry revealed a forced respiratory volume in 1 second ( $FEV_1$ ) of 50% of predicted and presence of an obstructive ventilatory defect. At home, he is on inhaled tiotropium and an albuterol inhaler as needed. Treatment was initiated with supplemental oxygen, 4 L/min via nasal cannula, IV steroids, inhaled bronchodilators, and broad-spectrum antibiotics. He notes progressive dyspnea. On evaluation, he appears fatigued but follows all commands. He is currently afebrile, his heart rate is 96 beats per minute, his blood pressure is 104/62 mm Hg, and his respiratory rate is 32 breaths per minute with use of accessory muscles. Oxygen saturation is 92%. Auscultation of lungs reveals bilateral expiratory wheezes. ABG reveals pH 7.29,  $P_{CO_2}$  60 mm Hg, and  $PO_2$  66 mm Hg. What would be the best next treatment?
    - Increase  $F_{iO_2}$  to 6 L via nasal cannula
    - Diuresis
    - Initiation of noninvasive ventilation
    - Intubation and initiation of mechanical ventilation
  - A 67-year-old woman with a history of hypertension and coronary artery disease presents with 72 hours of progressive lethargy, fever, and dysuria. On evaluation in the ED, she is lethargic but arousable. Her heart rate is 126 beats per minute and regular, blood pressure is 70/46 mm Hg, and respiratory rate is 24 breaths per minute unlabored. Jugular venous pressures do not appear to be elevated. Lungs are clear to percussion and auscultation. Cardiac examination reveals a tachycardia but regular rate and rhythm. There are no murmurs noted. Abdomen is soft and nontender. Laboratory values are as follows: white blood count 13,000/ $\mu$ L with a left shift. Hematocrit is 42%. Urinalysis reveals white blood cells too numerous to count. EKG is unremarkable. Urine and blood cultures are obtained. Broad-spectrum antibiotics are initiated. What is the most appropriate next step in treatment?
    - Initiation of vasopressin drip
    - Administration of IV NS
    - Empirical stress-dose steroids
    - Initiation of norepinephrine drip
  - The 67-year-old woman with presumed urinary tract infection and sepsis (from question 13) remains hypotensive despite 8 L of NS. Her urine output is poor. Blood pressure is 80/50 mm Hg, and central venous pressure (CVP) has been measured at 12 mm Hg. Blood cultures have grown gram-negative rods (speciation pending). What would the best treatment for hypotension be now?
    - Intubation and mechanical ventilation
    - Additional fluid resuscitation with NS
    - Placement of a Swan-Ganz catheter
    - Initiation of vasopressors
  - Which of the following medications has the least amount of alpha activity?
    - Dopamine
    - Dobutamine
    - Epinephrine
    - Norepinephrine
    - Phenylephrine
  - A 64-year-old man is admitted to the ICU with nausea, hematemesis, and melena. Upon arrival, he is alert. He is afebrile, his heart rate is 126 beats per minute, and his blood pressure is 92/58 mm Hg. Which treatment has been shown to reduce the need for endoscopic therapy?
    - Continuous IV  $H_2$  blocker
    - Intermittent bolus dose  $H_2$  blocker
    - Continuous IV proton pump inhibitor
    - Continuous IV octreotide
  - Which of the following represented a significant risk of administration of activated protein C?
    - Anaphylaxis with repeated use
    - Intracranial hemorrhage
    - Congestive heart failure
    - Pneumonia

18. You are asked to evaluate a 50-year-old man (70 kg) admitted to the ICU with alcoholic pancreatitis 72 hours earlier. He has now developed bilateral pulmonary infiltrates requiring mechanical ventilation. His  $F_{iO_2}$  is 0.8. Vent settings: Volume cycled continuous mandatory ventilation (CMV) rate is 12/min,  $V_T$  is 1000 mL, and PEEP is 10. ABG reveals pH 7.32,  $P_{aCO_2}$  56 mm Hg, and  $P_{aO_2}$  68 mm Hg. CVP is 12 mm Hg. Echocardiogram reveals normal left ventricular function. The next step in management should be:
- Initiation of prone-positioning ventilation
  - Increase PEEP to 15 cm  $H_2O$
  - Reduce  $V_T$  to 500 mL
  - Convert to pressure-cycle CMV (pressure control)
  - Trial of diuresis
19. Therapeutic hypothermia has been shown to be effective in which of the following clinical situations?
- A 60-year-old male now unresponsive 30 minutes status post asystolic arrest on postoperative day 2 after colon resection for newly diagnosed colon carcinoma in the setting of active GI bleeding
  - A 19-year-old female intubated, unresponsive status post lorazepam overdose 2 hours earlier
  - An 82-year-old female with history of DM type 2 now comatose status post ventricular fibrillation (VF) arrest 4 hours earlier
  - A 50-year-old male transferred from an outside hospital unresponsive status post pulseless electrical activity (PEA) arrest at home 24 hours earlier
20. A 50-year-old woman with insulin-dependent diabetes presents to the ED with 24 hours of rhinorrhea, cough, and crampy abdominal pain. On physical examination, she appears ill with temperature 100.4°F, heart rate 130 beats per minute, blood pressure is 100/64 mm Hg, and  $S_{aO_2}$  96% on right atrium. There is mild abdominal tenderness without rebound or guarding. Laboratory values reveal serum sodium 134 mEq/L, potassium 4.9 mEq/L, chloride 86 mEq/L, bicarbonate 14 mEq/L, glucose 660 mg/dL; ABG pH 7.20,  $P_{aCO_2}$  25 mm Hg, and  $P_{aO_2}$  80 mm Hg. Treatment is initiated with NS, 250 mL/h. Insulin is begun at 4 units per hour. Six hours later, laboratory values reveal serum sodium 138 mEq/L, potassium 3.6 mEq/L, chloride 100 mEq/L, bicarbonate 18 mEq/L, and glucose 160 mg/dL. What should you do next?
- Decrease insulin infusion rate to 3 U/h.
  - Administer neutral protein Hagedorn (NPH) insulin (patient's home dose).
  - Change NS to D5NS.
  - Change NS to ½NS with bicarbonate.
  - Continue the current therapy.

### Answers

- C. The patient has no detectable pulse in the setting of continued electrical activity and therefore has PEA. PEA accounts for about 20% of out-of-hospital cardiac arrests and about 60% of in-hospital cardiac

arrests. The differential diagnosis for underlying contributing conditions to a PEA arrest include the “H”s and the “T”s—i.e., hypoxemia hyperkalemia or hypokalemia, hypovolemia, hypoglycemia, hydrogen ions (acidosis), hypothermia, and hypocalcemia and tension pneumothorax, tamponade, thrombosis (cardiac or pulmonary), toxins (e.g., tablets), and trauma. There is no indication for administration of shocks or for administration of lidocaine.

In summary, PEA can be caused by many underlying conditions, and primary treatment should be directed toward alleviating the underlying problem. In addition to effective cardiopulmonary resuscitation with minimal interruptions, and with a focus on high-quality chest compressions of adequate depth and rate, adjunctive support for a PEA arrest can include administration of epinephrine and other advanced cardiac life support (ACLS) code algorithm medications. (ACLS 2015 Guidelines. *Circulation*. 2015;132(18 suppl 2):S313-S314.)

- D. Smoke inhalation injury can arise from a variety of mechanisms, including thermal damage (oropharyngeal injury or lower airways injury from steam or explosive gases), asphyxiation (hypoxemia as a result of reduced oxygen tensions from combustion; carbon monoxide [CO] toxicity resulting in decreased oxygen-carrying capacity of hemoglobin; cyanide toxicity as a result of interfering with cellular respiration, particularly as a result of burning of polyurethane or wool; and methemoglobinemia), and pulmonary parenchymal inflammation. The most common toxic inhalation as a result of house fires is CO toxicity. Standard pulse oximetry will not distinguish between oxygenated hemoglobin and CO-bound hemoglobin, so cooximetry is required for detection of CO intoxication.

In summary, a variety of injuries can occur as a result of smoke inhalation, including direct thermal injury and toxic inhalations. Detection of CO toxicity requires an ABG with cooximetry.

- B. A variety of complications can arise from central line placement, including bleeding (hematoma, arterial puncture), pneumothorax, air embolization (0.5%), loss/migration of catheter or wire, arrhythmia (68% ectopy, 6% to 12% right bundle branch block), cardiac tamponade, injury to nonvascular structures (e.g., nerves, thoracic duct), line misplacement, thrombosis (21% femoral, 1.9% subclavian), infection. Risks of central line insertion vary by site, and it was traditionally believed that infection risks were highest at the femoral site (femoral > internal jugular > subclavian), arterial puncture risk highest at femoral site (femoral > internal jugular > subclavian), and pneumothorax risk higher at subclavian than at internal jugular vein site. A more recent study (Parienti J-J et al. *N Engl J Med* 2015;373:1220-1229) showed that the subclavian site posed a lower

risk of bloodstream infection and thrombosis compared with the jugular and femoral sites, while carrying with it a higher incidence of pneumothorax. Catheter-associated bloodstream infections can cause significant morbidity in the ICU, and mechanisms of line-site infection can include subcutaneous skin tract colonization (85%), contamination of the catheter hub or stopcock, infusate contamination, or seeding of the blood from a remote site. Adoption of standardized techniques in line insertion has been shown to reduce rates of line-associated infections, and these protocols include hand hygiene, use of chlorhexidine skin prep, full barrier precautions and full body draping, avoidance of the femoral site, strict maintenance of sterile field during insertion, and removal of catheters when no longer necessary (rather than routine exchange of catheters).

In summary, risks of arterial puncture and line-associated infection are highest at the femoral site for line insertion. The use of protocolized checklists for line insertion can reduce development of line-associated infections.

4. B. Ventilator-associated pneumonia (VAP) has a reported incidence of 7% to 40% and results in prolonged time on the ventilator, longer ICU stays, and higher morbidity. A number of strategies have been proven to decrease development of VAP, presumably through decreasing entrance of oral and GI microbes into the lower respiratory tract. These include elevation of the head of the bed >30 degrees (at least 3× risk reduction in VAP), use of oral hygiene with chlorhexidine, and continuous suctioning of subglottic secretions. Although selective digestive tract decontamination using topical and IV antibiotics has been shown to reduce mortality, significant concern has been raised for this technique resulting in development of increased drug resistance. No benefit has been demonstrated for prophylactic changes of the ventilator circuit tubing.

In summary, VAP results in significant morbidity in the ICU, and extubation as soon as is feasible should be a primary goal of ICU care. Strategies such as elevation of the head of the bed >30 degrees and continuous subglottic suctioning should be used to minimize the risk of VAP development.

5. C. Oil of wintergreen (methyl salicylate) is a plant product that has been used in topical pain relief products and as a flavoring in small doses. Salicylate is the major metabolite of methyl salicylate, and one teaspoon of this substance contains approximately 7 g of salicylate, which is approximately equivalent to 23 tablets of 325 mg aspirin. Thus ingestion of 60 mL of oil of wintergreen likely has resulted in salicylate toxicity in this patient. Consistent with salicylate toxicity is the presence of an anion-gap metabolic acidosis and a respiratory alkalosis. Other features of salicylate intoxication

can include lethargy, depressed mental status, tinnitus, noncardiogenic pulmonary edema, hepatic failure, and coma. In addition to supportive care, treatment for salicylate toxicity includes alkalinization of the urine to increase renal clearance of the drug and hemodialysis in severe cases of toxicity.

In summary, salicylate intoxication classically presents with a combined anion-gap metabolic acidosis and respiratory alkalosis. The treatment for salicylate toxicity includes standard supportive care and urine alkalinization to enhance clearance of the drug.

6. A. Patients with severe asthma usually exhibit elevated airways resistance with reasonably conserved lung compliance, and option A is the only choice with this combination. Resistance and compliance are calculated using a plateau pressure measured at end inspiration (in a patient not actively exhaling against the ventilator). Resistance is equal to the difference between the PIP and  $P_{plat}$ , divided by the flow, with a normal resistance being in the range of 5 to 12 cm H<sub>2</sub>O/L/s. Compliance is equal to the  $V_T$  divided by the difference between the  $P_{plat}$  and PEEP, with a normal compliance being in the range of 40 to 70 mL/cm H<sub>2</sub>O.

In summary, patients with obstructive lung diseases (such as asthma or chronic obstructive pulmonary disease) often exhibit an increased resistance, whereas patients with diseases predominantly affecting the alveolar space (such as pneumonia or congestive heart failure) may exhibit reduced compliance. Resistance and compliance can be calculated from the ventilator with use of an end-inspiratory pause to measure the  $P_{plat}$  (see previous equations).

7. E. The waveform demonstrates inadequate time for exhalation (as seen by the yellow waveform not reaching baseline before the next breath, labeled “B”). This pattern of breathing is likely to result in development of intrinsic PEEP (i.e., auto-PEEP) and risk of barotrauma if not addressed. Increasing the respiratory rate will likely worsen gas trapping with a further reduction in exhalation time. Although increasing the inspiratory flow rate and decreasing inspiratory time might also lead to increased time for exhalation, it is generally felt that these maneuvers are not as effective as decreasing the respiratory rate and/or  $V_T$  in minimizing gas trapping.

In summary, patients with severe airflow obstruction are at risk for development of auto-PEEP as a result of gas trapping. In addition to treatment of the underlying cause (e.g., bronchodilators, steroids, etc., for asthma) and adequate sedation on the ventilator, initial maneuvers to minimize auto-PEEP include decreasing the respiratory rate and the  $V_T$  with careful monitoring of acid-base status and the overall clinical condition.

8. A. The classic triad of fat embolism syndrome is respiratory failure, mental status changes, and a petechial rash that results most often from long-bone and pelvic fractures (more often with closed than open fractures) and usually develops 24 to 72 hours after the insult. Neurologic symptoms often develop after respiratory symptoms and can include confusion, lethargy, seizures, and focal deficits. Mortality has been reported to range from 5% to 15%. Renal failure is not included in the classic triad of fat embolism.
- In summary, consider fat embolism syndrome in patients who develop respiratory failure, mental status changes, and a petechial rash in the 24-hour to 72-hour window after long-bone fracture.
9. D. The patient has developed >50% reduction in his platelet count over a 7-day period, during which time he was treated with subcutaneous unfractionated heparin and thus most likely had developed heparin-induced thrombocytopenia with thrombosis (HITT). Treatment includes discontinuation of unfractionated heparin and initiation of a direct thrombin inhibitor such as argatroban. Newer oral direct thrombin inhibitors have gained attention for a variety of conditions but have not been adequately studied in HITT. Solely stopping unfractionated heparin will not be sufficient to treat the thrombosis. Although LMWH is associated with a lower risk of developing heparin-induced thrombocytopenia (HIT), once HITT has developed, LMWH has sufficient cross-reactivity with unfractionated heparin that it cannot be used. Transfusing platelets is not advised, given the theoretical risk of worsening thrombosis. Transition to longer-term warfarin (with at least 5 days of overlap with a direct thrombin inhibitor) should be considered only once the platelet count has recovered and once the patient has been stably anticoagulated on a direct thrombin inhibitor.
- In summary, suspect HIT in patients who develop a >50% drop in their platelet count in the setting of receiving heparin products. The treatment for HITT includes discontinuation of heparin and initiation of anticoagulation with an alternative agent such as a direct thrombin inhibitor.
10. B. The patient likely has necrotizing pancreatitis, and the primary initial approach involves aggressive fluid resuscitation given the intravascular volume depletion that arises from third-space fluid. Inadequate fluid resuscitation can result in the development of acute tubular necrosis, and there is concern that volume depletion can worsen the pancreatic microcirculation and further aggravate pancreatic necrosis. The other answer choices might be treatment considerations during therapy, but the primary initial goal of management involves adequate rehydration.
- In summary, patients with necrotizing pancreatitis require aggressive fluid resuscitation and close monitoring, given third-space fluid and intravascular volume depletion.
11. D. There are a number of important ethical principles that guide decisions regarding end-of-life care. Autonomy means the patient has the right to choose among offered therapies and the right to refuse any treatment even though this decision could result in the patient's death. Beneficence means that the physician ought to do and promote good and must remove evil or harm. Nonmaleficence is a companion of beneficence and means not inflicting evil or harm. Physicians must refrain from providing interventions that are more likely to be of harm than benefit.
12. C. The patient likely has chronic obstructive respiratory disease (COPD) and is experiencing an exacerbation, with increased respiratory distress, increased work of breathing, and hypercapnic acidosis. *Non-invasive positive-pressure ventilation* refers to delivery of positive-pressure ventilation via face mask, and appropriate patients with COPD exacerbations (especially those with hypercapnic acidosis) have been shown to respond well to this support, with the goal of avoiding mechanical ventilation if at all feasible. Contraindications to noninvasive ventilation use include cardiac/respiratory arrest, inability to protect the airway, copious secretions, altered mental status, facial trauma/deformity, and high risk of aspiration. Patients receiving noninvasive ventilation require close monitoring.
- In summary, noninvasive ventilation can improve outcomes in patients with COPD exacerbations who are appropriate candidates for this type of support. Altered mental status, copious secretions, and significant aspiration risk are contraindications to use of noninvasive ventilation.
13. B. This patient has presented in septic shock, likely from urosepsis. In addition to source control and administration of early appropriate antibiotics, initiation of early goal-directed therapy (EGDT) demonstrated an improvement in mortality from severe sepsis and septic shock in a study published in 2001. The algorithm involved a number of steps, beginning with catheter-guided fluid resuscitation, using colloid or crystalloid to target a CVP >8 mm Hg. Once the CVP goal was met, use of vasoactive agents (norepinephrine was used in the study) was advised to target the mean arterial pressure (MAP) in the 65- to 90-mm Hg range. The protocol next used a central venous saturation target of 70% to guide use of packed red blood cells and inotropic agents. Although all the subjects received a significant volume of IV fluids by the end of the protocol, subjects in the EGDT arm of the study received a significantly larger volume of fluid in the first 6 hours of the protocol compared with the control group. Beginning in 2014 three studies were published demonstrating that EGDT did not provide benefit over other early resuscitation algorithms,

including institution of usual care. However, given that usual care has evolved substantially for sepsis since 2001, many intensivists agree that early targeted fluid resuscitation was the most critical part of the EGDT management algorithm and, along with early broad-spectrum antibiotics, should remain a cornerstone of early sepsis management.

In summary, early source control, appropriate antibiotics, and early targeted fluid resuscitation in patients with sepsis are key management strategies.

14. D. The patient has been adequately fluid resuscitated, and she remains hypotensive with an MAP <65 mm Hg. Therefore the next appropriate step would be addition of vasoactive agents.
15. B. Vasopressors (such as dopamine, norepinephrine, and epinephrine) increase MAP through vasoconstriction and exert actions, to varying degrees, via alpha-adrenergic receptors and beta-adrenergic receptors (with dopamine at low doses acting as well through dopamine receptors). Although phenylephrine has sole alpha-adrenergic activity, inotropes (such as dobutamine) act to increase cardiac contractility predominantly through beta-1 adrenergic receptors. A 2010 study (de Backer D et al. *N Engl J Med.* 2010;362:779-789) compared dopamine and norepinephrine as first-line vasopressors in the treatment of shock and found no difference in mortality but observed higher rates of adverse events in the subjects receiving dopamine.
16. C. A 2007 article (Lau JY et al. *N Engl J Med.* 2007;356:1631-1640) evaluated the effect of IV omeprazole (bolus followed by infusion) versus placebo before endoscopy in decreasing the need for endoscopic intervention. Omeprazole significantly reduced the need for endoscopic therapy at the first endoscopy (primary endpoint), as well as length of hospital stay and the number of actively bleeding ulcers (secondary endpoints).

In summary, high-dose omeprazole infusion before endoscopy reduced the need for endoscopic intervention and accelerated resolution of signs of bleeding.

17. B. Although there was initial enthusiasm for use of activated protein C as therapy in the sickest subgroup of sepsis patients after analyses of trials in 2001 and 2005, a subsequent trial (Ranieri VM et al. *N Engl J Med.* 2012;366:2055-2064) did not support efficacy of activated protein C. Thus given risks of life-threatening hemorrhage with activated protein C, the manufacturer withdrew activated protein C from the market in October 2011.
18. C. This patient has developed acute respiratory distress syndrome (ARDS) likely as a result of pancreatitis. The American European Consensus Conference criteria for ARDS definition reported in 1994 (Bernard GR et al. *Am J Respir Crit Care Med.* 1994;149:818-824) included acute onset of bilateral

infiltrates,  $P_{aO_2}/F_{iO_2}$  ratio <200, and absence of heart failure or LV dysfunction as contributors. The more recently updated Berlin Criteria (ARDS Definition Task Force et al. *JAMA.* 2012;307:2526-2533) better predicted mortality and further subdivided ARDS into categories of mild ( $P_{aO_2}/F_{iO_2}$  ratio 200–300), moderate ( $P_{aO_2}/F_{iO_2}$  ratio 100–200), and severe ( $P_{aO_2}/F_{iO_2}$  ratio  $\leq$ 100). The ARDSnet ARMA trial (Acute Respiratory Distress Syndrome Network et al. *N Engl J Med.* 2000;342:1301) demonstrated a mortality benefit in ARDS patients ventilated with 6 cc/kg  $V_T$ , as compared with 12 cc/kg  $V_T$ . They targeted a maximal plateau pressure of <30 cm H<sub>2</sub>O and adjusted  $F_{iO_2}$  and PEEP per protocol to target  $P_{aO_2}$  values of 55 to 80 mm Hg. Despite multiple trials, optimal PEEP in ARDS is not clear. Although a recent trial demonstrated a mortality benefit of prone positioning in severe ARDS (Guérin C et al. *N Engl J Med.* 2013;368:2159-2168) and the FACTT trial demonstrated that a conservative fluid management strategy reduced the duration of ventilator dependence and ICU length of stay (National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network et al. *N Engl J Med.* 2006; 354:2564-2575), use of low  $V_T$  ventilation would be the preferred initial step in ARDS management.

In summary, low  $V_T$  ventilation in ARDS (6 cc/kg) reduced mortality compared with higher  $V_T$  (12 cc/kg).

19. C. Two randomized controlled trials (Hypothermia after Cardiac Arrest Study Group. *N Engl J Med.* 2002;346:549-556 and Bernard SA et al. *N Engl J Med.* 2002; 346:557-563) demonstrated improved neurologic outcomes for patients resuscitated after VF or pulseless  $V_T$  arrests who were subjected to mild to moderate hypothermia for a period of 12 to 24 hours after arrest. Although there may be similar benefits for patients who have suffered from other precipitants resulting in cardiac arrest (and the 2015 ACLS guidelines suggest that therapeutic hypothermia be considered in comatose patients following PEA or asystole arrests), rigorous data are not available for these other groups of patients. Interestingly, a more recent study did not find that targeting a temperature of 91.4°F (33°C) conferred a benefit beyond targeting a temperature of 96.8°F (36°C) (Nielsen N et al. *N Engl J Med.* 2013;369:2197-2206). Because cooling can induce a coagulopathy, there is concern for inducing therapeutic hypothermia in patients with active bleeding, especially if they are hemodynamically unstable and are bleeding from a noncompressible site.

In summary, therapeutic hypothermia has been shown to improve neurologic outcomes in patients who have been successfully resuscitated after a VF or pulseless  $V_T$  arrest, ideally within 6 hours after the arrest.

20. C. This patient has diabetic ketoacidosis (DKA), perhaps triggered by a viral syndrome. Key aspects of DKA management include fluid resuscitation (usually with 0.9% NS) to replete intravascular volume and insulin administration with close glucose monitoring. Once the glucose level falls below 200 mg/dL, it is advised to add D5 to the administered fluids. This is done to ensure that glucose levels do not fall precipitously (with risk of cerebral edema) and to facilitate continuation of the IV insulin drip (even at a low level) so that DKA is not reprecipitated by discontinuation of insulin (as this patient had not yet closed her anion gap).

In summary, fluid resuscitation and insulin administration with close glucose monitoring are key aspects of DKA management. Careful attention also needs to be paid to potassium levels in patients with DKA, as these patients usually have marked potassium depletion.

CHRISTOPHER H. FANTA

### Questions

1. An elderly woman is admitted to a nursing home. She feels well; hypertension is the only medical problem identified in her history. As part of her initial evaluation, a purified protein derivative (PPD) skin test is performed. It demonstrates 12 mm of induration. Her physical examination is normal, and routine laboratory studies (complete blood count and chemistry profile) are likewise normal. A chest x-ray (CXR) is obtained and reveals minor apical scarring on the right and a localized, poorly defined area of opacity in the right upper lobe posteriorly. Prior chest films are not available for comparison. As the patient's physician, which of the following do you recommend?
  - A. Follow-up evaluation with repeat CXR in 3 months to assess for change.
  - B. Administer isoniazid (INH), 300 mg/d, for 9 months to treat for latent tuberculous infection.
  - C. Obtain three induced sputum samples, and await the results of mycobacterial culture and smear.
  - D. Obtain three induced sputum samples, and immediately begin antituberculous therapy with INH, rifampin, and ethambutol.
  - E. Empirically begin treatment for tuberculosis with INH and ethambutol.
2. The lung disease typically associated with cystic fibrosis is:
  - A. Bronchiectasis
  - B. Interstitial lung disease
  - C. Diaphragmatic weakness
  - D. Antinuclear cytoplasmic antibody-associated vasculitis
  - E. Pleural effusion
3. In a 65-year-old construction worker with a long-standing history of asbestos exposure, which of the following findings/diagnoses suggests that his lung disease is unrelated to his asbestos exposure?
  - A. Fibrocalcific parenchymal disease, predominantly involving the upper zones of the lung
  - B. Pleural plaques
  - C. Malignant mesothelioma
  - D. Benign pleural effusions
  - E. Bronchogenic carcinoma
4. A 65-year-old woman with a 60-pack-year history of cigarette smoking presents with cough and shortness of breath. She reports an increase in her usual amount of sputum production with yellow discoloration of the sputum. She has a low-grade fever (99.6°F). Chest examination reveals scattered expiratory rhonchi, and a CXR is normal. A sample of sputum is sent for routine culture. The sputum Gram stain describes 4+ polys and many gram-negative cocci in pairs. Based on the history and Gram stain, an appropriate choice of antibiotics would be which of the following?
  - A. Ampicillin, orally
  - B. Amoxicillin-clavulanic acid, orally
  - C. Procaine penicillin G, intramuscularly twice a day
  - D. Cefotaxime, intravenously
  - E. Cephalexin, orally
5. Which of the following outcomes can one expect from an outpatient pulmonary rehabilitation program in a patient with severe chronic obstructive pulmonary disease?
  - A. Increased survival
  - B. Improved cardiovascular function
  - C. Increased exercise tolerance
  - D. Increased expiratory airflow (forced expired volume in 1 second [FEV<sub>1</sub>])
  - E. Decreased use of inhaled bronchodilators and/or corticosteroids
6. A 23-year-old man presents with nosebleeds and a petechial rash. A complete blood count reveals pancytopenia with a white blood cell count of 400 cells/μL, hematocrit of 24%, and platelet count of 12,000/μL. A diagnosis of acute myelogenous leukemia is made, and chemotherapy is begun. Ten days into his course of induction chemotherapy he develops a fever (101°F) and cough. He expectorates minimal mucoid sputum. A CXR reveals new localized nonhomogeneous opacities in the left lower lobe. A sample of induced sputum is obtained; Gram stain shows no polys or microorganisms. The pathogen most likely to cause this illness is which of the following?
  - A. *Aspergillus*
  - B. *Cytomegalovirus*

- C. *Nocardia*  
 D. Gram-negative bacteria  
 E. *Candida*
7. Five potential diagnoses are provided subsequently. Which diagnosis fits best with the following set of arterial blood gases obtained with the patient breathing air:  $PO_2$  40 mm Hg,  $PCO_2$  80 mm Hg, and pH 7.10?  
 A. Adult respiratory distress syndrome  
 B. Severe attack of asthma  
 C. Severe bilateral bacterial pneumonia  
 D. Acute exacerbation of severe chronic obstructive pulmonary disease  
 E. Sedative drug overdose
8. A 60-year-old man was recently seen in the emergency department following a fall from a ladder. No rib fracture or lung contusion was sustained, but CXR revealed a 1.8 by 1.4 cm nodule in the left lower lobe. A chest CT scan was obtained, which confirmed the presence of the nodule within the lung parenchyma. No other nodules were seen, and no abnormal hilar or mediastinal lymph node enlargement was found. The nodule has sharp margins without calcification.  
 The patient smoked cigarettes only briefly in college. He grew up in Arkansas until age 15 and then moved to New England. He works as a college administrator. Which of the following would you recommend as the next step in his workup?  
 A. Obtain a positron emission tomography (PET)-CT scan.  
 B. Order a transthoracic needle aspirate.  
 C. Ask a pulmonologist to perform bronchoscopy.  
 D. Review prior CXRs for comparison.  
 E. Order chest MRI.
9. A 56-year-old man presents with a 6-week history of nonproductive cough, moderate exertional dyspnea, and intermittent low-grade fevers (to 100.4°F). He had been in good health but smoked a pack of cigarettes each day for the last 35 years. The patient has received two courses of clarithromycin (500 mg orally twice daily for 10 days) without improvement in symptoms. He denies any history of ocular inflammation, skin rash, or arthritis.  
 The physical examination shows no clubbing or cyanosis. There is no peripheral lymphadenopathy or jugular venous distension. Chest examination reveals inspiratory crackles in the lower posterior lung zones bilaterally and no wheezing.  
 Laboratory studies include the following: hematocrit 34%; white blood cell count, 11,100/ $\mu$ L with 18% lymphocytes, 64% polys, 7% bands, 6% monocytes, and 5% eosinophils; platelets 250,000/ $\mu$ L. Serum blood urea nitrogen is 22 mg/dL, and creatinine is 0.8 mg/dL.  
 Urinalysis is normal.  
 The CXR shows airspace disease at both lung bases (Fig. 45.1).

The most likely diagnosis is:

- A. Pneumococcal pneumonia  
 B. Legionnaires disease  
 C. Granulomatosis with polyangiitis (Wegener's granulomatosis)  
 D. Idiopathic pulmonary fibrosis  
 E. Cryptogenic organizing pneumonia (COP) (bronchiolitis obliterans organizing pneumonia [BOOP])
- Questions 10 to 14.
- For each of the five following statements (10–14), indicate whether it pertains to patients with asthma, chronic obstructive pulmonary disease (COPD), neither, or both.
- A. Asthma  
 B. COPD  
 C. Neither  
 D. Both
10. Disease severity correlates directly with the reduction in the  $FEV_1$ .
11. Leukotriene receptor antagonists such as montelukast (Singulair) are indicated in patients with mild or moderate disease.
12. Inhaled anticholinergic bronchodilators are appropriate first-line therapy.
13. Alpha-1 antitrypsin augmentation therapy may improve lung function (increase  $FEV_1$ ) in some patients.
14. Antibiotics are generally indicated for exacerbations of the disease when the patient reports cough and discolored sputum.

Questions 15 to 19.

- For each of the five following phrases or statements (15–19), indicate whether it pertains to patients with sarcoidosis, idiopathic pulmonary fibrosis, neither, or both.
- A. Sarcoidosis  
 B. Idiopathic pulmonary fibrosis  
 C. Neither  
 D. Both

• Fig. 45.1 Posteroanterior chest x-ray for question 9.

15. Rarely seen in children
16. May be a cause of chronic airflow obstruction on pulmonary function testing
17. Associated with an increased risk of lung cancer
18. Predominantly involves the lower lung zones
19. A definitive infectious pathogen has been identified as the cause

#### Questions 20 to 24.

INH treatment for latent tuberculous infection (INH 300 mg daily for 9 months) should be given to which of the following patients?

20. A 21-year-old health care worker with a PPD skin test reaction of 12 mm of induration. His CXR is normal. His skin test reaction last year had 10 mm of induration.
  - A. Yes
  - B. No
21. A 45-year-old former intravenous drug abuser known to be HIV positive has a clear CXR, and the PPD skin test shows 5 mm of induration. Prior skin tests are reported as equivocal.
  - A. Yes
  - B. No
22. A 74-year-old man with no known tuberculosis exposure and a clear CXR has a PPD skin test showing 5 mm of induration. The patient does not recall any previous tuberculin skin tests. Repeat testing 1 week later now shows 15 mm of induration.
  - A. Yes
  - B. No
23. A 53-year-old woman with no known medical illnesses and a clear CXR has a PPD skin test reaction with 8 mm of induration. She had no previous skin testing but has been tested now because her husband has just had active tuberculosis diagnosed after a 6-month illness.
  - A. Yes
  - B. No
24. A 26-year-old homeless man has a PPD skin test demonstrating 15 mm of induration. He has no symptoms, but his CXR shows nonhomogeneous opacities with some nodularity in the left upper lobe.
  - A. Yes
  - B. No

#### Answers

1. D. An elderly woman admitted to a nursing home has a positive PPD skin test and an abnormal CXR with evidence of a localized, poorly defined area of opacity in the right upper lobe posteriorly. This description is suspicious for reactivation tuberculosis with a tuberculous pneumonia in the right upper lobe. The anatomic location is typical for reactivation tuberculosis, which most often begins in the posterior and apical segments of the upper lobes or in the superior segment of the lower lobes. A pneumonia localized to the anterior segment of the upper lobe is unlikely to be tuberculosis.

What is surprising in the brief description of her condition, and what may cause some doubt about the correct answer, is that she is asymptomatic, free of cough, sputum production, fever, or weight loss. Do not let this observation dissuade you from the possibility that she has active pulmonary tuberculosis. In its early stages, active tuberculosis may be asymptomatic. Nor should it be reassuring to those around her that she has no cough. She may develop a cough any day, and the risk of contagion is real, especially in a nursing home residence where she will likely be in contact with a vulnerable population of people, many with chronic illness.

With active tuberculosis as a possibility, your proper management plan is to attempt diagnosis (such as with analysis of sputum induced by inhalation of nebulized hypertonic saline or with bronchoscopy with bronchoalveolar lavage) and, while awaiting the results of sputum acid-fast stain and culture (possibly with nucleic acid amplification to detect *Mycobacterium tuberculosis* and primary rifampin resistance), initiate therapy for presumed active tuberculosis (answer D). The patient will also need to be kept in respiratory isolation until either three sputum samples have returned negative for acid-fast bacilli on smear or until she has completed 2 weeks of antimycobacterial therapy. A three-drug regimen of antituberculous medications, such as offered in answer D, is appropriate if she is a patient at low risk for primary drug-resistant tuberculosis.

The other proposed options for her management are not appropriate. Watchful waiting, as in answer A, puts both the patient and those around her at risk. It might be an appropriate course if an old CXR from a year or two previously had been identical, indicating that the right upper lobe abnormality was a chronic radiographic finding, but not in the absence of such information.

Until you are certain that this patient does not have active pulmonary tuberculosis, it would be inappropriate to treat with a single antituberculous medication for latent tuberculous infection (answer B). Doing so might induce an INH-resistant strain of *Mycobacterium tuberculosis*. Besides, the indication for chemoprophylaxis in this elderly woman with a positive PPD skin test is unclear. We will discuss these indications further in a subsequent portion of the Board Simulation exercise (questions 20–24).

Identification of *M. tuberculosis* by traditional culture techniques can take up to 6 to 8 weeks. Waiting several weeks without initiating antituberculous therapy (answer C) again places the patient at risk for worsening disease and those around her at risk for acquiring tuberculous infection. Finally, immediate treatment with a two-drug regimen (answer E) is wrong because (1) it fails to obtain a diagnostic sample for culture and sensitivity testing; (2) it uses

• **Fig. 45.2** Fibrocalcific parenchymal disease predominantly involving the upper zones of the lung.

an old-fashioned treatment regimen that requires 18 months of therapy; and (3) it does not address the possibility of infection with a primary INH-resistant strain of tuberculosis.

2. A. Cystic fibrosis is associated with widespread bronchiectasis. Characteristic features include chronic productive cough with purulent sputum and intermittent hemoptysis. Bronchiectasis is an airway disease, not an interstitial lung disease (answer B), respiratory muscle disease (answer C), vasculitis (answer D), or pleural disease (answer E).
3. A. The description offered as answer A (fibrocalcific parenchymal disease, predominantly involving the upper zones of the lung) does not evoke asbestos-related lung disease. It is rather a description of chronic granulomatous lung disease, such as tuberculosis. A sample CXR with this pattern is seen in Fig. 45.2. It shows bilateral upper lobe scarring, calcified nodules in the right upper lobe, and cephalad retraction of the hila in a patient with treated reactivation tuberculosis. Asbestosis, the diffuse interstitial lung disease that results from many years (decades) of intense asbestos exposure, typically manifests radiographically as a pattern of interstitial opacities (linear and nodular shadows) predominantly in the lower lung zones bilaterally. Calcification, if present, involves pleural surfaces.

The other choices (pleural plaques, mesothelioma, benign pleural effusions, and bronchogenic carcinoma) are indeed all potential consequences of chronic asbestos fiber inhalation. Perhaps least well known is answer D, benign pleural effusions. Benign exudative effusions, often bloody and often bilateral, may develop

• **Fig. 45.3** Asbestos-related pleural plaques on posteroanterior chest x-ray.

with a latency period of  $\geq 10$  years after asbestos inhalation, a relatively short latency period compared with other asbestos-related diseases. Because mesothelioma often manifests as a unilateral pleural effusion, the challenge for the clinician of a patient with unilateral pleural effusion and a history of asbestos exposure is to exclude malignancy as the cause. Pleural fluid mesothelin, if present, is a useful marker of malignant mesothelioma.

The radiographic images of asbestos-related pleural plaques and of mesothelioma can be distinctive. Fig. 45.3 is the posteroanterior CXR of a patient with asbestos-related pleural plaques. It shows multiple bilateral nodular opacities, and one's immediate response to the image may well be to think of metastatic lung nodules. However, many of the opacities are pleural based, and at least one (on the lateral margin of the left lung) is not spherical but rather is shaped like a bluff or plateau with its long diameter paralleling the pleural surface, a clue to its pleural origin. Adjacent and more medial to this plaque is a round-appearing nodule. It too is a pleural plaque, not located in the substance of the lung but along the pleural surface. It is located along an anterior or posterior portion of the pleura and when seen *en face* gives a rounded appearance. The pleural location of these asbestos-related plaques is best visualized on the transverse image of a chest CT scan, as seen in Fig. 45.4 (in a chest CT image from a different patient). Although not illustrated by these images, pleural plaques may become calcified. They are not precancerous lesions and do not evolve into mesothelioma.

• **Fig. 45.4** Asbestos-related pleural plaques on chest CT image.

Fig. 45.5 is the posteroanterior CXR of a patient with mesothelioma. There is a large right pleural effusion. In addition, one sees distinctive lobulated opacities along the upper portion of the lateral pleural surface of the right lung. These opacities may represent loculated pleural fluid, but their nodularity suggests more mass-like tissue invasion along the chest wall. We are likely visualizing both tumor mass growing along the pleural surface as well as associated malignant pleural effusion. Mesothelioma is the disease manifestation related to asbestos fiber inhalation that may develop with relatively minor exposure, such as a summer or two spent working closely with asbestos in a shipyard 20 years earlier.

4. B. This 65-year-old cigarette-smoking woman with a chronic productive cough most likely has chronic bronchitis (chronic productive cough related to cigarette smoking) and possibly also has COPD related to cigarette smoking. She has developed shortness of breath, increased cough, discolored sputum production, and a low-grade fever. You readily diagnose a respiratory tract infection and attribute her symptoms to an acute exacerbation of her COPD. Her chest examination is confirmatory (expiratory low-pitched wheezes or rhonchi indicative of accumulated central airway secretions), and her CXR helps to exclude pneumonia.

In most instances, you will treat this condition with empirical antibiotics chosen to cover the common pathogens that cause acute infectious exacerbations of COPD, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and gram-negative rods. In this instance, a sputum sample was sent for culture, and you are asked to interpret the significance of the many gram-negative cocci in pairs seen on Gram stain. Although perhaps tempted to dismiss this finding as typical of the *Neisseria* species that are normal flora of the oropharynx, in fact gram-negative cocci can be pathogenic. This is the Gram-stain appearance of *Moraxella catarrhalis* (formerly *Branhamella*

• **Fig. 45.5** Mesothelioma.

*catarrhalis*), a potential cause of bronchitis and pneumonia, particularly in patients with COPD.

- Not satisfied with your knowledge of the microscopic appearance of *Moraxella*, the question further asks about this pathogen's usual pattern of antibiotic sensitivities. In particular, you are asked to remember that, almost universally, these are beta lactamase-producing bacteria. Consequently, they will be resistant to ampicillin and penicillin (answers A and C) but sensitive to ampicillin combined with clavulanic acid (Augmentin), answer B. They are likely also to be sensitive to cephalosporin antibiotics, but intravenous antibiotics such as cefotaxime (answer D) are not indicated, and the orally administered cephalexin (Keflex) has poor lung penetration and would be a second-best option (answer E).
5. C. Outpatient pulmonary rehabilitation is recommended for patients with disabling exertional dyspnea caused by their COPD. It is designed to interrupt the vicious cycle by which shortness of breath on exercise (because of severe airflow obstruction) leads to physical inactivity, which promotes decreased physical conditioning and consequent worsened exertional dyspnea. Most pulmonary rehabilitation programs include supervised upper and lower body exercising, typically two to three times per week for a period of 8 to 12 weeks. Additional components of most programs include education about lung diseases and psychosocial support, not the least of which comes from sharing experiences with other people in a group with similar medical problems.
- The most consistent benefit at the end of such training programs is an improved exercise capacity (answer C) with associated reduced sense of dyspnea, the result of

improved oxygen uptake and use by exercising muscles. Some studies have also found a reduction in the number of hospitalizations and urgent care visits following outpatient pulmonary rehabilitation. Long-term benefit depends on the patient's commitment to continue regular exercise after completing the formal, supervised pulmonary rehabilitation program. Patients with severe COPD cannot achieve normal age-adjusted maximal heart rate targets for exercise and do not stimulate improved cardiac output (answer B). No study has been able to demonstrate improved long-term survival in COPD as the result of outpatient pulmonary rehabilitation (answer A). Expiratory airflow in COPD is not limited by muscle strength and does not improve with improved conditioning (answer D). Although a reduced sense of dyspnea may conceivably lead patients to rely less on their bronchodilator inhalers, decreased medication use has not been a well-documented benefit of pulmonary rehabilitation (answer E).

6. D. A young man with newly diagnosed acute myelogenous leukemia, 10 days into his course of induction chemotherapy, develops a fever and localized pulmonary opacities consistent with a diagnosis of pneumonia. In this question, we are asked to consider the most likely pathogens causing pneumonia in this context. We can readily invoke the rubric of pneumonia in an immunocompromised host, but we must also acknowledge that not all immunocompromising conditions are the same. The patient with compromised immunity resulting from splenectomy will be prone to one set of pathogens (such as *Streptococcus*, *Klebsiella*, and *Haemophilus*); another patient with immunocompromise following solid organ transplant will be vulnerable to other pathogens (including certain viruses such as cytomegalovirus and fungi such as *Pneumocystis*, *Nocardia*, or *Cryptococcus*).

The patient in this question is susceptible to a broad array of pathogens primarily because of his neutropenia, plus whatever other direct immunosuppressive effects his chemotherapeutic medications may have. Neutropenic patients are especially vulnerable to bacterial infections, especially *Staphylococcus* and gram-negative bacilli, and fungal infections including *Aspergillus* and *Mucormycosis*. The fact that his sputum is scant and mucoid should not dissuade us from an infectious etiology for his pulmonary disease. Because of his severe neutropenia he lacks sufficient numbers of polymorphonuclear leukocytes to generate sputum purulence, and often microorganisms do not appear in expectorated (or induced) sputum despite true lower respiratory tract infection.

The timing of the onset of this infection provides helpful information. Among neutropenic patients, fungal infections typically do not develop within the first 30 days of illness. Gram-negative bacilli are the most common cause of pneumonia in this timeframe (answer D). Thereafter, *Aspergillus* pneumonia (answer A)

would be plausible, especially in a patient who might have recently received broad-spectrum antibiotics. On the other hand, *Candida* pneumonias (answer E) are rare, except perhaps preterminally, typically following aspiration in a patient with oropharyngeal candidiasis or as a complication of candidemia. Pneumonia caused by cytomegalovirus (answer B) or *Nocardia* (answer C) is statistically far less common in this setting than gram-negative bacterial pneumonia. They are found more commonly in disorders with profound lymphopenia (such as certain lymphomas/leukemias, acquired immunodeficiency syndrome, and treatment with antirejection medications following solid organ transplantation).

7. E. This question is strictly an exercise in arterial blood gas interpretation. It does not involve clinical decision making because we are not provided with any other patient information, such as symptoms, past medical history, physical examination, or other laboratory data. Some physicians may be able simply to look at these arterial blood gas results and intuit the correct answer. Here is how I come to this conclusion.

The patient with these arterial blood gases has profound hypoxemia, hypercapnia, and acidemia. The acidemia is respiratory in etiology, a consequence of the profound carbon dioxide (CO<sub>2</sub>) retention. Although all five of the disease states offered as potential answers can cause profound hypoxemia, acute respiratory distress syndrome (ARDS) (answer A) and severe bilateral bacterial pneumonia (answer C) are far less likely than the others to cause hypercapnia. Alveolar hyperventilation with hypocapnia would be the norm in ARDS and severe pneumonia, except perhaps in patients with very advanced disease or with other underlying cardiorespiratory illness.

Of the remaining choices, an acute asthmatic attack (answer B) and sedative drug overdose (answer E) would be expected to cause an acute respiratory acidosis, whereas an acute exacerbation of severe COPD (answer D) would more likely be associated with chronic hypercapnia or perhaps acute worsening of chronic hypercapnia (acute-on-chronic respiratory acidosis). It is helpful, then, to determine whether this set of arterial blood gases suggests an acute or an acute-on-chronic respiratory acidosis. One method to calculate the distinction is as follows:

- Acute respiratory acidosis: Predicted fall in pH below 7.40 = rise in Pco<sub>2</sub> above 40 mm Hg × 0.008
- Chronic respiratory acidosis: Predicted fall in pH below 7.40 = rise in Pco<sub>2</sub> above 40 mm Hg × 0.003
- Acute-on-chronic respiratory acidosis: Predicted fall in pH below 7.40 = rise in Pco<sub>2</sub> above 40 mm Hg × 0.005

In our example, the patient's Pco<sub>2</sub> of 80 mm Hg represents a rise in Pco<sub>2</sub> above 40 mm Hg of 40. The pH of 7.1 is 0.3 units below 7.4. The best approximation for this value is 40 × 0.008 (= 0.32), consistent

with an acute respiratory acidosis. A patient with a  $P_{CO_2}$  of 80 mm Hg caused by chronic  $CO_2$  retention with appropriate renal compensation would be expected by these calculations to have a pH of approximately 7.28 ( $40 \times 0.003 = 0.12$  units below 7.4); and a patient with a  $P_{CO_2}$  of 80 mm Hg arising from acute-on-chronic hypercapnia would be expected to have a pH of approximately 7.2 ( $40 \times 0.005 = 0.2$  units below 7.4). Our patient's profound acidemia reflects the acuteness of this pulmonary process, without time for compensatory renal retention of bicarbonate.

We still need to choose between answers B (acute asthmatic attack) and E (sedative drug overdose). The former is associated with airway disease and hypoxemia that is at least in part caused by mismatching of the distribution of ventilation and perfusion. Besides hypoventilation, lung zones with low ventilation for the amount of perfusion that they are receiving contribute to hypoxemia. The latter (sedative drug overdose) may have no intrinsic lung disease; the hypoxemia may be entirely caused by depressed respiratory drive with central hypoventilation. We can use the alveolar gas equation to distinguish between these two possibilities. The alveolar gas equation allows us to calculate a predicted alveolar partial pressure of oxygen ( $PAO_2$ ). We can then compare our predicted  $PAO_2$  with the measured arterial blood oxygen ( $PaO_2$ ) to derive an alveolar-to-arterial difference (or gradient) for oxygen (A-a $DO_2$ ). In the absence of intrinsic lung disease with ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) mismatching, the A-a $DO_2$  will be normal ( $\leq 25$  mm Hg); in the presence of  $\dot{V}/\dot{Q}$  mismatching or shunt, the A-a $DO_2$  will be increased.

An abbreviated version of the alveolar gas equation is the following:

$$PAO_2 \text{ (mm Hg)} = [(P_B - 47) \times FiO_2] - PCO_2/R$$

where  $P_B$  is ambient barometric pressure,  $FiO_2$  is the fraction of oxygen in the inspired gas, and  $R$  is the respiratory exchange ratio, in most instances presumed to be 0.8. For patients breathing air at sea level, this equation simplifies to:

$$\begin{aligned} PAO_2 \text{ (mm Hg)} &= [(760 - 47) \times 0.21] - PCO_2/0.8 \\ &= 150 - PCO_2/0.8 \end{aligned}$$

For our patient, the calculated alveolar  $PO_2$  is as follows:

$$\begin{aligned} PAO_2 &= 150 - 80/0.8 \\ &= 50 \text{ mm Hg} \end{aligned}$$

The measured arterial  $PO_2$  in this example is 40 mm Hg, giving an A-a $DO_2$  (i.e.,  $PAO_2 - PaO_2$ ) of 10 mm Hg, a normal value. The absence of a widened A-a gradient for oxygen fits best with answer E, a sedative drug overdose with pure alveolar hypoventilation as the cause of hypoxemia.

• **Fig. 45.6** Ground-glass nodule (also referred to as a *subsolid nodule*) in the lung apex on transaxial chest CT image. If observed for growth over time with serial chest CT imaging, this nodule will require more than 2 years of follow-up (as many as 5 years or more) to exclude malignancy.

8. D. This 60-year-old man is discovered by serendipity to have an asymptomatic solitary pulmonary nodule on CXR. Our task is to determine whether the nodule is benign or malignant. Features favoring benignity are its sharp margins and the patient's lack of a significant cigarette smoking history. His prior residence in Arkansas raises the possibility of a lung nodule related to endemic fungal infection, specifically a histoplasma. Features that raise the possibility of malignancy are his age (lung cancer is uncommon below the age of 40 but increases in incidence with increasing age) and the relatively large size (greatest diameter  $>1$  cm) of the nodule. A completely calcified lung nodule or a nodule with a characteristic pattern of calcification (e.g., "bull's-eye" lesion with dense central calcification, as in granulomas, or "popcorn-ball" calcifications, as in hamartomas) would clinch a benign diagnosis, but his nodule is noncalcified.

The decision regarding further workup should be easy.

If available, obtain prior chest images for comparison.

This search for old films may be labor intensive or time consuming, but it is cost effective and safe. A nodule such as this one that can be shown not to have grown over a period of 2 years or more is benign; no further evaluation will be necessary. Rare exceptions to this rule that lack of growth over 2 years indicates benign lesions may be very slow-growing adenocarcinomas of the bronchoalveolar cell type, but their radiographic appearance is not that described here. They tend to be less uniformly dense and less well circumscribed; they may have a ground-glass texture, air bronchograms within their margins, or focal, persistent consolidation. An example of an indolent bronchoalveolar cell cancer

(adenocarcinoma in situ or minimally invasive adenocarcinoma) is shown in Fig. 45.6.

If old chest images are not available for comparison, a PET scan combined with chest CT imaging (PET-CT scan) (answer A) would be an appropriate next step. A negative PET-CT scan in this patient (uptake of glucose in the nodule no greater than in surrounding normal lung tissue) would indicate with 95% certainty that the nodule is benign (again, the exceptions to this rule, giving the test a false-negative rate of approximately 5%, are predominantly bronchoalveolar-type adenocarcinomas).

A transthoracic needle aspirate (answer B) is tempting in an effort to establish a definitive diagnosis without surgery, and in some centers with special expertise this procedure would routinely be attempted. However, at most institutions the false-negative rate for needle aspirates reported as “nondiagnostic, with no malignant cells seen” is unacceptably high, on the order of 20%. The procedure carries with it a risk of iatrogenic pneumothorax of 7% to 10%. The accuracy of fiberoptic bronchoscopy (answer C) in the evaluation of peripheral lung nodules is even lower than that of transthoracic needle aspirates. Specific benign etiologies (such as histoplasmosis) are rarely established (<5%), and the risk of false-negative results (no malignant cells identified in a patient with a malignant lung nodule) is high (well above 20%). Bronchoscopic techniques designed to improve the yield of sampling peripheral lung lesions (electromagnetic navigational bronchoscopy combined with three-dimensional reconstructions of the lung from chest CT imaging) are starting to be introduced at some centers. Thoracic MRI (answer E) has no role in the evaluation of lung nodules or parenchymal lung abnormalities in general.

9. E. For this question, we are asked to make a diagnosis. The patient, a middle-aged cigarette smoker, has had a nonproductive cough, dyspnea on exertion, and intermittent fevers for the last 6 weeks, persistent despite two courses of macrolide antibiotics (clarithromycin). His chest examination reveals bilateral inspiratory crackles in the lower lung zones, and his CXR has extensive bilateral lower-lobe airspace opacities. On the image shown (see Fig. 45.1), one can make out air bronchograms, evidence of lung consolidation with an alveolar-filling process.

We would expect that after two courses of antibiotics, pneumococcal pneumonia (answer A) would have resolved, or were this a macrolide-resistant strain of *Streptococcus pneumoniae*, it would have worsened considerably over this time period. Similarly, pneumonia caused by *Legionella pneumophila* (answer B) should have been adequately treated with clarithromycin; we would expect the patient to be on the mend after two rounds of antibiotics. The clinical

features (and remaining three answers from which to choose) encourage us to think about noninfectious causes for his illness.

History and physical examination offer no additional clues: he denies ocular, cutaneous, or joint manifestations that might point to a diagnosis of sarcoidosis, vasculitis, or lung disease associated with collagen-vascular disease. He has no clubbing, as may be seen in chronic inflammatory lung diseases, especially idiopathic pulmonary fibrosis (IPF) (answer D). In fact, the subacute duration of his illness (6 weeks) does not invoke chronic inflammatory lung diseases such as IPF, which tend to have a time course of many months to years. The radiographic pattern of IPF is likewise very different from that of our patient, with linear and nodular opacities and sometimes honeycombing, rather than consolidation with alveolar filling.

Granulomatosis with polyangiitis (Wegener’s granulomatosis) (answer C) can present with diffuse alveolar hemorrhage, giving airspace opacities as seen in this patient. More often, however, it presents with lung nodules, with or without cavitation, and in this patient, the absence of renal abnormalities on blood studies and urinalysis further dissuade us from a systemic vasculitis with pulmonary and renal involvement, such as granulomatosis with polyangiitis.

By process of elimination, we are drawn to the diagnosis of COP, also known as BOOP. In fact, we may recognize that this diagnosis is compelling: a pulmonary process with (1) bilateral airspace pulmonary opacities, (2) mimicking an infectious pneumonia, (3) unresponsive to antibiotics, and (4) with a time course of several weeks. A bronchoscopy might be useful to rule out infection, hemorrhage, and malignancy. A transbronchial lung biopsy occasionally provides sufficient lung tissue to see the characteristic pathologic features of COP: organizing pneumonia plus bronchiolar inflammation with endobronchial polypoid tissue. Some physicians might make a presumptive diagnosis of COP and begin systemic steroids, observing for a clinical response over the next few days. COP tends to be highly responsive to treatment with systemic steroids (with resolution of symptoms and clearing of pulmonary opacities), although in up to one-third of cases the disease may recur with steroid dose reduction and withdrawal.

It is important to emphasize the distinction between bronchiolitis obliterans (or constrictive bronchiolitis), an obstructive lung disease often refractory to treatment with systemic steroids, and BOOP, a steroid-responsive inflammatory lung disease as described earlier. Some of the differences between the two entities are summarized in Table 45.1. Part of the confusion between these two conditions is based on nomenclature; hence the preference of some physicians for the term *COP*.

TABLE  
45.1**Differentiation Between Bronchiolitis Obliterans Organizing Pneumonia and Bronchiolitis Obliterans**

	Bronchiolitis Obliterans Organizing Pneumonia	Bronchiolitis Obliterans
Presentation	Pneumonia-like	Emphysema-like
Chest x-ray	Multifocal or diffuse pulmonary opacities	Hyperinflation
Physiology	Restrictive	Obstructive
Response to steroid treatment	Good	Poor

10. D. Questions 10 to 14 ask us to compare and contrast asthma with COPD.

Both asthma and COPD are characterized by airflow obstruction: intermittent in the former, chronic in the latter. The presence of airflow obstruction is identified on spirometry by a reduction in the ratio of FEV<sub>1</sub> to forced vital capacity (FVC) (FEV<sub>1</sub>/FVC). On the other hand, the severity of airflow obstruction is characterized by the extent of the reduction in FEV<sub>1</sub>. In both asthma and COPD, the frequency and severity of symptoms, need for medications, and frequency of urgent care visits and hospitalizations correlate directly with the degree to which FEV<sub>1</sub> is decreased.

11. A. Leukotriene receptor antagonists such as montelukast (Singulair) and zafirlukast (Accolate) have proven effective in the treatment of mild-to-moderate asthma. They have not been found to be effective in COPD. Our understanding of the pathobiology of these two diseases would lead us to predict that leukotrienes (released by mast cells, eosinophils, and, to some extent, epithelial lining cells) play an important role in some patients with asthma but have little pathogenic role in COPD.
12. B. Short-acting anticholinergic bronchodilators such as ipratropium (Atrovent) provide quick relief in COPD. Long-acting anticholinergic bronchodilators (also referred to as *long-acting muscarinic antagonists*) such as tiotropium (Spiriva), aclidinium (Tudorza), umeclidinium (Incruse), and glycopyrronium (Seebri) are effective for maintenance therapy and prevention of exacerbations of COPD. One appeal of anticholinergic bronchodilators in the older-aged population in which COPD tends to develop is their lack of cardiovascular stimulatory side effects. In asthma, short-acting beta-agonists such as albuterol provide more potent bronchodilation with quicker onset of action than anticholinergic bronchodilators. Recent evidence suggests a potential role for tiotropium among persons with

asthma still poorly controlled on inhaled corticosteroids alone. However, anticholinergic bronchodilators would not be considered first-line therapy in asthma.

13. C. It is estimated that approximately 1% of patients with COPD have a genetic deficiency of alpha-1 antitrypsin protein causing emphysema. Those who are homozygous for this abnormality may benefit from alpha-1 antitrypsin augmentation therapy, with concentrated alpha-1 antitrypsin protein given as an intravenous infusion once weekly. The benefit, however, is one of slowing or arresting the accelerated decline in lung function observed in patients with alpha-1 antitrypsin deficiency. One would not expect improvement in lung function. Persons who have only one abnormal allele and are therefore heterozygous for this deficiency are thought in general not to have a significantly accelerated decline in lung function and are not candidates for alpha-1 antitrypsin augmentation therapy.
14. B. Antibiotics are recommended for acute exacerbations of COPD. Many of these exacerbations are caused by bacterial tracheobronchitis. Although there are other potential causes for increased cough and discolored sputum production in patients with COPD, both viral and noninfectious, withholding antibiotics in this setting puts the patient at risk for serious deterioration. On the other hand, most infectious exacerbations of asthma are caused by viral infections. Antibiotics are not recommended for treatment of exacerbations of asthma in the absence of comorbidities such as pneumonia or bacterial sinusitis.
15. D. Questions 15 to 19 ask us to compare and contrast sarcoidosis with IPF. Both sarcoidosis and IPF are rare in childhood. The incidence of sarcoidosis is highest in young adults between ages 20 and 40 years; IPF most commonly begins after age 50 years.
16. A. Approximately 25% to 30% of patients with sarcoidosis will have predominantly obstructive physiology. The mechanism is presumably airway narrowing because of endobronchial and peribronchial granuloma formation. By contrast, IPF is a quintessential restrictive lung disease, with low lung compliance and extensive interstitial inflammation and fibrosis.
17. B. Patients with IPF are at increased risk for the development of bronchogenic carcinoma, even in the absence of prior cigarette smoking. Sarcoidosis is not associated with an increased risk of lung cancer.
18. B. Sarcoidosis is protean in its thoracic radiographic presentations, but it is more likely to present with bilateral upper lobe opacities than lower lobe opacities. IPF, on the other hand, typically predominates in the lower lobes, although it frequently progresses to diffuse lung involvement.
19. C. No infectious pathogen has been found as the causative agent for either sarcoidosis or IPF; both remain idiopathic in etiology. Much research has attempted to identify a microbiologic cause of sarcoidosis, with interest

focusing on mycobacterial antigens and cell wall-deficient bacteria such as mycoplasma. However, confirmation of a causative role for these organisms is lacking.

20. A. The patients in questions 20 to 24 have all undergone skin testing with PPD using the intermediate strength (5 tuberculin units). In follow-up, a CXR was obtained. You are then asked to consider whether, based on the information given, you would recommend treating this patient for latent tuberculosis infection with INH.

The following rules have been recommended to guide your decision making. First, what constitutes a positive PPD skin test reaction? These measurements, based on the longest diameter of induration recorded approximately 48 hours after intradermal administration, are designed to maximize identification of true-positive reactions to *M. tuberculosis* and minimize misreading of false-positive cross-reactivity caused by infection with other mycobacterial species; that is, to maximize the sensitivity and specificity of the test for latent tuberculosis infection.

- **High-risk** populations with  $\geq 5$  mm of induration: patients with HIV/AIDS or other immunosuppressing illness or treatment; patients who have recently been in close contact with a patient with active pulmonary tuberculosis; or patients with prior pulmonary tuberculosis and residual pulmonary scarring on chest imaging who have never received adequate antituberculous drug therapy.
- **Moderate-risk** populations with  $\geq 10$  mm of induration: patients who are at increased risk of having had exposure to tuberculosis (recent immigration from countries with a high prevalence of tuberculosis; intravenous drug abusers; persons living in shelters; nursing home residents; health care workers; and children exposed to high-risk adults); or patients who are at increased risk of activation of their tuberculous infection (diabetes; chronic renal failure; loss of weight of  $>10\%$  of ideal body weight; post gastrectomy; underlying malignancies; and treatment with tumor necrosis factor- $\alpha$  blockers.).
- **Low-risk** populations with  $\geq 15$  mm of induration: all other patients.

Second, which patients with evidence for latent tuberculous infection (based on a positive PPD skin test) should be treated with antituberculous medication to prevent activation of infection and development of disease? Here the decision making tries to weigh the risks in an asymptomatic patient of activation of tuberculosis (over the course of a lifetime) versus drug-induced toxicity, particularly hepatotoxicity, from antituberculous treatment (over the duration of therapy). The usual recommended treatment is INH, 300 mg/d for 9 months. The following are considered indications for treatment of latent tuberculous infection, regardless of the age of the patient:

- Household contact of a patient with active pulmonary tuberculosis
- Recent converter; that is, a person whose PPD skin test has gone from negative on prior testing within the

past 2 years to positive with an increase of at least 10 mm in diameter

- Patient with prior pulmonary tuberculosis and residual pulmonary scarring on chest imaging who has never received adequate antituberculous drug therapy
- Patient with special circumstances increasing the risk of activation of infection, such as diabetes, HIV infection, dialysis, receiving immunosuppressing drugs, major weight loss, silicosis, or recent immigration from an endemic area. More recently added to this list are persons for whom treatment with a tumor necrosis factor- $\alpha$  inhibitor is planned.

A more controversial indication, previously recommended by panels of experts and now left to the discretion of the treating physician, is treatment of any patient under age 35 years with a positive PPD skin test (regardless of special risk factors). The motivation to treat this population of patients with latent tuberculous infection is that their lifetime risk of activation of tuberculosis spans many decades, whereas their risk of INH hepatotoxicity (which increases with increasing age) is  $<0.1\%$ .

Based on these recommendations, I would choose to treat the 21-year-old health care worker with 12 mm of induration on his PPD skin test (question 20). Because of his increased risk of exposure to active tuberculosis in his work, 12 mm of induration is considered a positive result. His CXR shows no evidence for active pulmonary tuberculosis. He is not a recent converter; the 2-mm difference between the diameter of his previous skin test response and the current one is inconsequential. However, he is under 35 years of age, with very low risk of INH hepatotoxicity during treatment. One can make the argument that protecting this young man from activation of tuberculosis may benefit not only him but others to whom he might spread infection should he remain in the health care profession and ever develop active pulmonary tuberculosis.

21. A. In a patient with HIV infection, a skin test reaction of only 5 mm of induration is considered positive, sufficient in size to suggest latent tuberculous infection. Because of his or her HIV-related immunodeficiency, treatment of latent tuberculous infection is indicated regardless of age.
22. B. This 74-year-old man without known risk factors for tuberculosis exposure or activation has an initial negative skin test (5 mm of induration) that on repeat testing 1 week later is positive (15 mm of induration). This is not a recent converter; he did not develop cellular immunity to tuberculosis in the week between the two skin tests. Rather, he has a latent tuberculous infection that was not detected on the first skin test (false-negative result) but became apparent on the repeat test (true-positive result). Skin testing was repeated after just 1 week because of the well-known tendency of cellular immunity to mycobacterial infection (as judged

by cutaneous reactions) to wane with advancing age. The initial skin test with its intradermal administration of a small amount of tuberculin protein is sufficient to revive an amnestic immune response, with an appropriate cutaneous response (positive skin test) on repeat intradermal exposure to tuberculin protein. This two-step testing is widely practiced in older-aged persons (in some institutions, in any person over age 50 years), and the eliciting of a true-positive result after an initial false-negative response is referred to as the *booster phenomenon*. Note that in a patient without latent tuberculous infection, repeat PPD skin testing, even if done multiple times in a relatively short period, will not provoke a positive result.

Now that it has been established that this 74-year-old man without known tuberculosis exposure has latent tuberculous infection and a normal CXR, should he receive treatment with INH? No. He has no known indication for treatment, as listed previously. We do not know the duration of his latent tuberculous infection. The risk of activation of infection is greatest in the 2 to 3 years after initial exposure. If he has had latent tuberculous infection for many decades, his risk of reactivation at this age is very low, whereas the risk of INH toxicity is not negligible. Risk-benefit analysis suggests that he not receive treatment.

23. A. This patient is at high risk for latent tuberculous infection; she has been intensely exposed to someone with active pulmonary tuberculosis (as a household contact) over a period of several months. Based on her high risk for exposure, a PPD skin test with 8 mm of induration should be considered a positive test result. Given her likely recent acquisition of tuberculous infection, she is currently in the period when the risk for progressing to active disease is greatest. She meets the criteria for treatment of latent tuberculous infection (regardless of age).
24. B. This patient, at increased risk for tuberculous infection because of his homelessness, has a positive skin test ( $\geq 10$  mm of induration, given his moderate-risk status). However, the next step in evaluating a patient with a positive PPD skin test reaction is to obtain a CXR. This patient's CXR reveals nonhomogeneous opacities with some nodularity in the left upper lobe. We are left wondering if his positive PPD skin test is evidence for latent tuberculous infection or active tuberculous pneumonia (reactivation tuberculosis in the upper lobe). If it is possible that he has active pulmonary tuberculosis, treatment with INH alone would be anathema. It would be inadequate treatment for active tuberculosis and might induce INH-resistant *M. tuberculosis*. Before initiating treatment for latent tuberculous infection, it is imperative to exclude active disease.

## Pulmonary and Critical Care Medicine Summary

ELIZABETH GAY

**D**yspnea and cough represent cardinal and initial presenting symptoms of many respiratory illnesses. Acute dyspnea and cough are often associated with infections such as bronchitis or pneumonia, whereas more chronic symptoms may suggest asthma or chronic obstructive pulmonary disease (COPD). Although obstructive lung diseases are often the first diagnoses considered, there is a wide differential for these symptoms, including the diffuse parenchymal lung diseases (DPLD), malignancies affecting the lung, pleural disease, and pulmonary vascular disease. For many patients, a diagnostic evaluation including history and physical examination as well as a combination of chest imaging, pulmonary function testing, and arterial blood gas (ABG) sampling are required to reveal the underlying cause of dyspnea or cough.

### Diagnostic Evaluation of Lung Disease

Initial evaluation of a patient with respiratory symptoms begins with a comprehensive history and physical examination. A history of cigarette smoking or inhalational occupational exposures can provide clues to the diagnosis. On examination, focus on signs of small airway obstruction (wheezes), evidence of alveolar filling or interstitial fibrosis (crackles), or secretions in the larger airways (rhonchi) in addition to looking for signs of pleural disease or heart failure. Even with a thorough initial evaluation, many patients will require chest imaging as well as pulmonary function testing for diagnosis.

### Chest Radiography

The chest radiograph is a simple and powerful diagnostic tool in the evaluation of lung disease. A systematic approach to the interpretation of a chest radiograph is important because subtle abnormalities are missed when one jumps immediately to the most obvious finding. Evaluation of a film begins with ascertainment of the correct patient name and the date of the study. The technique of the film should be reviewed. The gold standard film is a

posteroanterior (PA) film with accompanying lateral film. When a patient is too ill to stand, a portable anteroposterior film (AP) is often obtained. Because this projection results in slightly different dimensions, the clinician should be cautious about making assessments of cardiac size with this technique. One should assess the quality of penetration, with an ideal film just barely revealing the thoracic vertebrae in the lower chest.

One approach to the chest radiograph proceeds from “outside in,” beginning with the soft tissues and bones, followed by examination of the pleural reflections, assessing for pleural effusions or pneumothoraces. Attention should be paid to the lung parenchyma, comparing right to left, upper lung zones to lower lung zones, and the periphery to more central areas of lung. Opacities are described as reticular, reticulonodular, fluffy, or confluent. Rounded abnormalities are termed *nodules* or *masses* based on size, with the former being  $<3$  cm in diameter. The mediastinum should be reviewed, focusing on the tracheal position and contour, the paratracheal stripe, the hila, and the aortic shadow. Finally, assess heart size, with attention to all four chambers. Although pattern recognition is important when examining chest radiographs, a systematic approach will result in the most comprehensive assessment of a film and yield the greatest diagnostic value. As with all studies, a collaborative approach between the radiologist and the internal medicine physician often results in the most clinically helpful interpretation.

### Pulmonary Function Testing

Pulmonary function tests (PFTs) are a useful first step in the evaluation of patients with dyspnea and other respiratory complaints. PFTs can establish obstructive or restrictive pathophysiology as well as gas-exchange abnormalities. They may be diagnostic for some respiratory disorders (e.g., COPD) and can be used to track progression of disease, assess for side effects of medications, or provide an objective assessment of disability related to lung disease.

Spirometry, in which a patient forcefully exhales from total lung capacity (TLC) down to residual volume (RV), provides information on both lung volumes and flows. The parameters of greatest utility are the forced vital capacity (FVC) and the forced expiratory volume in 1 second ( $FEV_1$ ). A decreased ratio of these two values ( $FEV_1/FVC$ ) defines obstructive pathophysiology, seen in diseases such as asthma and COPD. The cutoff often used for obstruction is an  $FEV_1/FVC < 70\%$ . Asthma is likely if the  $FEV_1$  and FVC normalize after the administration of a quick-acting bronchodilator (e.g., albuterol). An improvement in  $FEV_1$  and FVC can also be seen in COPD, but the ratio will remain low, indicating irreversible obstruction. A symmetric decrease in  $FEV_1$  and FVC, with a normal or increased ratio between  $FEV_1$  and FVC, suggests restrictive pathophysiology, requiring further testing.

Decreased TLC defines restrictive pathophysiology. This measurement is determined by the assessment of lung volumes either through helium dilution or plethysmography. In addition to TLC, lung volume measurement also provides the RV, which is elevated in obstructive lung disease because of air trapping. When assessing restrictive pathophysiology, an impaired diffusion capacity for carbon monoxide (DLCO) suggests parenchymal lung disease (see DPLD later). There are a variety of other studies available in the PFT laboratory, including measurement of maximal inspiratory and expiratory pressures, bronchoprovocation testing with exercise or methacholine, ABG sampling, and cardiopulmonary exercise testing. These tests are used alone or in combination to further evaluate dyspnea and gas exchange abnormalities.

## Respiratory Disorders

### Asthma

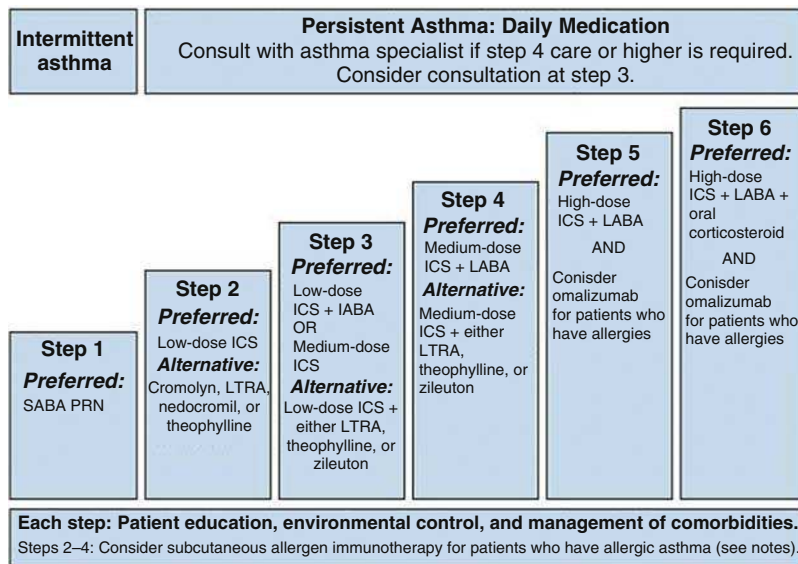

Asthma is characterized by reversible airflow obstruction as a result of airway inflammation and smooth muscle constriction. These events usually occur as a response to one of many triggers including exercise, allergens (e.g., cat dander or pollen), and irritants such as tobacco smoke or perfumes. Patients often describe a history of intermittent dyspnea and wheezing related to specific triggers. Physical examination in poorly controlled disease may reveal diffuse, polyphonic wheezes. It should be noted that “all that wheezes is not asthma,” and the differential diagnosis of wheezing includes heart failure and an obstructing mass in the case of a focal wheeze. PFTs may be normal when asthma is well controlled, and sometimes a methacholine challenge is used to diagnose asthma when baseline spirometry is normal. In this test, increasing doses of the respiratory irritant methacholine are given, with a decline in  $FEV_1$  noted at low concentrations in patients with the bronchial hyperreactivity characteristic of asthma.

The focus of the treatment of asthma is control of symptoms. The first step in this process is to eliminate triggers as much as feasible. This may include avoidance of allergens, for which radioallergosorbent or skin prick testing may help

identify specific stimuli. Use of high-efficiency particulate air filters, smoking cessation, and avoidance of secondary smoke exposure may all help. If symptoms persist despite efforts to decrease exposures to triggers of asthma, patients need to be treated with a combination of a controlled medication and quick-relief medication, usually an inhaled beta-agonist. The Guidelines for the Diagnosis and Management of Asthma released by the Expert Panel of the National Asthma Education and Prevention Program in 2007 recommends assessment of symptom control, lung function, and risk of future asthma exacerbations to guide adjustment of medications. These guidelines recommend that treatment be escalated along a six-step sequence until good asthma control is achieved (Fig. 46.1). Briefly, the six steps include:

1. Intermittent asthma, which is defined as symptoms necessitating a quick-relief bronchodilator no more than 2 days per week; nocturnal awakenings caused by asthma no more than 2 days per month; lung function within the normal range; and no more than one attack of asthma within the past year requiring a course of oral steroids, should be treated with an as-needed short-acting bronchodilator, usually a beta-agonist.
2. Mild persistent asthma that is not controlled with a quick-relief medication alone requires the addition of a controller medication, which could either be a low-dose inhaled steroid or a leukotriene modifier.
3. Recommendations for patients with moderate persistent asthma are in evolution, but clinicians generally increase the dose of inhaled steroid, add a long-acting beta-agonist (LABA) to a low-dose inhaled steroid, or supplement with a leukotriene modifier. Studies suggest an increased risk of death in asthma patients treated with LABAs alone and that LABAs should be used in conjunction with inhaled corticosteroids in patients with asthma.
4. If symptoms persist despite an additional agent or an increased dose of steroid, the recommendations are for use of a moderate-dose inhaled steroid plus LABA.
5. Severe persistent asthma is treated with a high-dose inhaled steroid combined with LABA, often in conjunction with a leukotriene modifier. Monoclonal antibody to IgE (omalizumab) is also considered in this step for patients with atopic asthma.
6. Refractory asthma is treated with biologic agents (as previously described) and/or oral glucocorticoids. Recently anti-IL-5 therapy was approved for severe persistent eosinophilic asthma with multiple exacerbations.

As control of symptoms is achieved, patients are “stepped down” in therapy as appropriate, with the goal of minimizing symptoms and maintaining lung function with the least medication necessary. Once control has been achieved, clinicians should work with patients to develop an action plan based on symptoms and peak flow measurement. Each plan is individually tailored and can allow a reliable patient to treat an exacerbation early, before severe symptoms and a true asthmatic attack ensue. Patients benefit from inhaler teaching, and inhaler technique should be routinely reviewed at follow-up visits.

- **Fig. 46.1** National Asthma Education and Prevention Program stepwise approach to asthma therapy. IABA, Immediate-acting beta-agonist; ICS, inhaled corticosteroids; LTRA, leukotriene receptor antagonist; PRN, as required; SABA, short-acting beta-agonist. (From the National Asthma Education and Prevention Program: Expert Panel Report 3: Guidelines for the diagnosis and management of asthma: National Institutes of Health Publication No. 08-4051. Bethesda, MD, 2007.)

## Chronic Obstructive Pulmonary Disease

The Global Initiative for Chronic Obstructive Lung Disease characterizes COPD as a disease of “airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases.” Most commonly, the noxious particles and gases are from cigarette smoke. This disease, in its myriad of presentations, conservatively affects more than 20 million Americans and is the third leading cause of death in the United States. With this in mind, it is important for all clinicians to be familiar with the diagnosis and treatment of COPD.

Patients with intermittent dyspnea and cough who have long-term exposure to cigarette smoke should be assessed for evidence of airflow obstruction by spirometry. As is the case with asthma, obstruction is generally defined as a ratio of  $FEV_1/FVC < 70\%$ . The diagnosis of COPD is made by the demonstration of obstruction that is not fully reversible with a short-acting bronchodilator. The severity of COPD is based on the measured  $FEV_1$  (Table 46.1). Additional testing including lung volumes, DLCO, blood gas sampling, exercise oximetry, and CT do not need to be routinely obtained but should be considered on an individual basis, particularly in those patients who have severe symptoms, resting hypoxemia, or severely impaired lung function.

The most important step in the treatment of COPD is inarguably smoking cessation. Patients with established COPD will slow the rate of decline in lung function when they quit smoking. Smoking cessation also has cardiovascular benefits. Therapies for smoking cessation include both

**TABLE 46.1 Gold Classification System of Chronic Obstructive Pulmonary Disease**

Stage 1	Mild	$FEV_1/FVC < 0.70$ $FEV_1 \geq 80\%$ predicted
Stage 2	Moderate	$FEV_1/FVC < 0.70$ $50\%$ predicted $\leq FEV_1 < 80\%$ predicted
Stage 3	Severe	$FEV_1/FVC < 0.70$ $30\%$ predicted $\leq FEV_1 < 50\%$ predicted
Stage 4	Very severe	$FEV_1/FVC < 0.70$ $FEV_1 < 30\%$ predicted or $FEV_1 < 50\%$ predicted plus chronic respiratory failure

$FEV_1$ , Forced expiratory volume in 1 second;  $FVC$ , forced vital capacity.

nonpharmacologic approaches (e.g., support groups) and medications (Table 46.2). Physicians should inquire about smoking cessation on each patient visit.

Pharmacologic therapy for stable, chronic COPD includes both short-acting and long-acting inhaled bronchodilators including beta-agonists and anticholinergics as well as inhaled steroids. In contrast with asthma treatment, multiple studies support the use of LABAs alone in the treatment of COPD without evidence of increased mortality. Most patients are initially treated with either a long-acting

**TABLE 46.2 Smoking Cessation Medications**

Drug	Side Effects	Advantages	Precautions
Nicotine patch	Skin irritation, insomnia	Easy to use	
Varenicline	Rash, nausea, bad dreams	Relieves withdrawal and blocks reward from smoking	Avoid if history of suicidal ideation or severe depression; lower dose in severe renal insufficiency
Bupropion	Insomnia, headache	Blunts post-cessation weight gain	Avoid in seizure disorder

antimuscarinic (LAMA) or LABA. Inhaled steroids are reserved for patients with moderate to severe COPD (based on FEV<sub>1</sub>) and recurrent exacerbations. Recent data suggest that a combination of LABA-LAMA may also decrease exacerbation rates. For patients who continue to have exacerbations despite optimal therapy, additional considerations include daily low-dose azithromycin and the phosphodiesterase-4 inhibitor roflumilast, both of which have been shown to decrease exacerbation rates in select populations. All patients should also receive pneumococcal and influenza vaccines.

Patients with severe COPD may develop resting hypoxemia. When oxygen saturation is <88% at rest or with exertion, supplemental oxygen should be initiated because there is a clear mortality benefit to oxygen therapy. Patients with more severe disease also benefit from pulmonary rehabilitation. The clinician should consider referral of such patients to a specialist because certain subsets of COPD patients may benefit from lung volume reduction surgery, lung transplantation, or other novel therapies.

### Diffuse Parenchymal Lung Diseases

There are a variety of uncommon diseases that diffusely affect the lung parenchyma. In the past, these conditions were referred to as the interstitial lung diseases (ILD). Because these processes often affect more than the interstitium, the grouping is now commonly called DPLD. The classic DPLD is idiopathic pulmonary fibrosis (IPF), but there are a myriad of other poorly understood diseases including sarcoidosis, cryptogenic organizing pneumonia (COP), and hypersensitivity pneumonitis included in the DPLDs. IPF is an insidious disease that results in progressive scarring of the lungs with impaired gas exchange and restrictive pathophysiology. The cause of IPF, as the name implies, is unknown.

Patients present with progressive dyspnea on exertion and nonproductive cough and are often initially misdiagnosed with asthma or pneumonia. On examination, basilar crackles and clubbing are common, and most patients progress to resting hypoxemia. Diagnosis can be made by a classic CT scan appearance with basilar, subpleural honeycombing, and a lack of ground-glass opacities; however, patients with less typical CT findings may require a lung biopsy for definitive diagnosis. On biopsy, subpleural changes including fibroblastic foci within heterogeneous areas of injury and fibrosis are pathognomonic for IPF.

Two new drugs have recently been shown to slow lung function decline in IPF. Nintedanib is a tyrosine kinase inhibitor that blocks elaboration of multiple fibrogenic growth factors. Pirfenidone is an antifibrotic agent, which inhibits transforming growth factor beta-mediated collagen synthesis and fibroblast proliferation. These drugs both appear to slow lung function decline and have not been compared head to head. Of note, patients with moderate-to-severe disease should still be referred early in their course for evaluation for lung transplantation.

Other DPLDs can be grouped into those with known causes and those of unknown etiology with many more diseases in the latter category. Changes in the lung related to inorganic inhalational exposures are termed *pneumoconiosis*. The best-described pneumoconiosis is asbestosis. This disease is quite similar pathologically to IPF but is secondary to chronic asbestos exposure. There is no proven therapy for asbestosis, although it is rarely as rapidly progressive as IPF. In contrast, inhalation of organic substances can lead to a granulomatous inflammation along the bronchovascular bundles called *hypersensitivity pneumonitis* (HP). A variety of materials can result in HP, and well-described exposures include actinomycetes, pigeon droppings, atypical mycobacteria (commonly from hot tubs), and *Aspergillus*. The initial therapy is removal of the offending agent. In the acute phase, these reactions are generally responsive to glucocorticoids; however, with chronic exposure, the parenchymal changes can become irreversible.

There are several poorly understood DPLDs related to cigarette smoking. These include desquamative interstitial pneumonitis, respiratory bronchiolitis interstitial lung disease, and pulmonary Langerhans-cell histiocytosis. These are much less common than COPD, which should be suspected first in patients with a history of tobacco exposure and new dyspnea or cough. They may variably improve with smoking cessation.

Sarcoidosis is a multiorgan disease of unknown etiology. The pathologic hallmark of sarcoidosis is noncaseating granulomatous inflammation. Lung involvement ranges from asymptomatic hilar lymphadenopathy to end-stage fibrosis. Most lung disease is at least initially responsive to glucocorticoids, although many patients with lymphadenopathy alone will require no therapy. Other organs commonly affected by sarcoidosis include the skin (e.g., erythema nodosum, lupus pernio), heart, liver, central nervous system, and eyes. Even in the absence of symptoms, all patients with sarcoidosis

should undergo yearly dilated eye examinations, liver function tests, 24-hour urine calcium, and electrocardiogram (EKG).

## Venous Thromboembolic Disease

Although the incidence increases after the age of 60 years, patients of all ages with a variety of risk factors and underlying diseases can develop venous thromboembolic disease (VTE), which encompasses both deep venous thrombosis (DVT) and pulmonary embolism (PE). The majority of patients who develop VTE have one or more risk factors including underlying malignancy, cigarette smoking, oral contraceptive use, recent surgery, trauma, or immobilization. Patients with a personal or family history of VTE are also at increased risk, which is sometimes secondary to a known genetic factor such as factor V Leiden or prothrombin gene mutation.

Patients with DVT usually present with symptoms related to lower extremity swelling and discomfort. Patients with PE classically present with dyspnea, pleuritic chest discomfort, and hypoxemia; however, PE can be clinically silent or result in hemodynamic collapse, refractory hypoxemia, and death. For this reason, clinicians need to always be alert to the possibility of PE, particularly in patients with multiple risk factors for VTE.

Diagnosis of VTE can be challenging. The gold standard for confirmation of DVT is contrast venography, but duplex venous ultrasound is the most common means of diagnosis. In the last 5 to 10 years, contrast CT scan has become the modality by which most pulmonary emboli are diagnosed. Ventilation-perfusion scans are useful when patients cannot receive contrast, but the results must be interpreted considering pretest clinical suspicion. MRI and pulmonary angiography are other options, but timeliness and invasiveness (respectively) are limitations with these studies. In many clinical situations, it is useful to rule out (exclude with a high degree of probability) PE, particularly when there is a low clinical probability. In these settings, the measurement of a serum D-dimer may be helpful because it has a strong negative predictive value in outpatient populations with low clinical likelihood of PE.

The mainstay of treatment of VTE is anticoagulation with heparin products, warfarin, or a novel oral anticoagulant. Choice of anticoagulation depends on severity of illness, bleeding risk, and patient comorbidities. Low-molecular-weight heparin may have a mortality benefit in patients with underlying malignancy and preserved renal function. Of the oral anticoagulants, rivaroxaban and apixaban have been approved as monotherapy (no heparin bridge) for hemodynamically stable patients with VTE. For patients who cannot be anticoagulated, placement of an inferior vena cava filter can acutely protect against a DVT resulting in a PE but may have significant long-term morbidity by increasing the risk of recurrent DVTs. Thrombolytic agents, catheter-based interventions, or surgical intervention are recommended for massive PE (associated with shock). Their use

in patients with submassive PE (no shock, but evidence of right heart strain by echo and cardiac biomarkers) remains controversial.

## Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is an underdiagnosed disease estimated to affect approximately 5% of the adult population. Because there are long-term health consequences of OSA, it is important for all clinicians to consider the possibility of this diagnosis in their patients. Patients with OSA have increased rates of hypertension, coronary artery disease, heart failure, diabetes, and stroke, as well as a significantly increased risk of motor vehicle accidents.

The hallmark of OSA is the obstructive apnea in which there is full collapse of the airway resulting in complete cessation of breathing for at least 10 seconds. The diagnosis of OSA, however, relies on the number of apneas and hypopneas (i.e., reduced airflow for at least 10 seconds due to partial airway collapse) per hour of sleep, often referred to as the *apnea-hypopnea index* (AHI). Most clinicians use a threshold of at least 15 episodes per hour to diagnose OSA in asymptomatic patients and between 5 and 15 events per hour in symptomatic patients. In some settings, the number of respiratory event–related arousals per hour is also tabulated because these events, related to increased work of breathing arising from partial airway collapse, also disrupt sleep.

Risk for OSA correlates with obesity and advanced age. There are a variety of other risk factors, some of which are modifiable, which should be assessed in any patient suspected of having OSA (Box 46.1). In addition, an individual patient's upper airway anatomy impacts the risk of OSA because smaller upper airway lumens are more likely to collapse. Airway caliber can be affected by large tonsils, large tongue, and increased adipose tissue.

Several symptoms should suggest a diagnosis of OSA. These include snoring (the most commonly reported symptom), daytime sleepiness, morning headaches, memory impairment, and depression. Patients are often formally evaluated with the Epworth Sleepiness Scale, a validated tool to assess for excessive daytime sleepiness. On examination, obesity and hypertension should raise a clinician's suspicion, but the airway examination is most helpful. Mallampati airway scores have been shown to predict risk for OSA.

Although the history and physical examination may raise the possibility of OSA, a polysomnogram is required for definitive diagnosis. This study records EKG, electroencephalogram, eye movements, chest wall movements, oxygen saturation, and muscle activity during sleep, allowing for the calculation of an AHI as well as measurement of a variety of other parameters. Many centers offer a split-night sleep study, which allows a patient to be diagnosed in the first half of the night and then to begin therapy with continuous positive airway pressure (CPAP) in the latter half of the night's sleep.

### • BOX 46.1 Risk Factors for Obstructive Sleep Apnea

Excess body weight  
 Advancing age  
 Male sex  
 Family/genetic predisposition  
 Tobacco use  
 Alcohol consumption  
 Medical conditions (e.g., polycystic ovarian syndrome, hypothyroidism, stroke)  
 Pregnancy  
 Menopause  
 Abnormal craniofacial anatomy  
 Neck circumference (>17 inches in men, >16 inches in women)  
 Small, hypoplastic, and/or retroposed maxilla and mandible  
 Narrow posterior airway space  
 Inferiorly positioned hyoid bone  
 High and narrow hard palate  
 Abnormal dental overjet  
 Macroglossia  
 Tonsillar enlargement  
 Nasal obstruction

There are a variety of therapies for OSA. Weight loss may help many patients, but it is often difficult to achieve. Other modifiable risk factors, such as sedative use and excessive alcohol intake, should also be addressed. Patients may have relief of symptoms by positional therapy because OSA is worse in most patients in the supine position. Many patients, however, will require CPAP to maintain an open airway. CPAP has been shown to decrease the majority of symptoms associated with OSA. For patients who do not tolerate CPAP, dental appliances and surgery are additional options for therapy.

### Critical Care

As the population of the United States ages, more and more patients will spend time in an intensive care unit (ICU). Although most clinicians will not directly deliver care to patients in an ICU, a familiarity with ventilator management and therapies for shock and sepsis are important for understanding a patient's post-ICU course and needs.

### Shock and Sepsis

One of the most common causes of admission to an ICU is a fall in blood pressure despite adequate volume resuscitation, resulting in impaired end-organ perfusion. This state, termed *shock*, results in significant morbidity and mortality. Shock can be categorized broadly into hypovolemic, cardiogenic, obstructive, or distributive.

Hypovolemic shock is usually the result of profound dehydration or severe bleeding associated with gastrointestinal disease or major trauma. The cornerstone of therapy for hypovolemic shock is rapid volume replacement with either crystalloid or colloid (e.g., packed red blood cells) and

resolution of the underlying disorder. Cardiogenic shock results from impairment of cardiac output from a variety of causes including cardiomyopathy, ischemia, valvular dysfunction, or arrhythmias. Obstructive shock can be considered a subset of cardiogenic shock because it results from blockage of forward flow from the heart. The most common cause of obstructive shock is massive PE, but cardiac tamponade and tension pneumothorax can result in the same pathophysiology by impairing right ventricular filling.

Distributive shock is the result of vasodilatation. Although anaphylaxis and spinal cord injury can result in distributive shock, the most common cause is sepsis. Sepsis can be defined as the systemic inflammatory response (SIRS) with a probable source of infection. SIRS is manifested by a combination of tachycardia, tachypnea, fever, and elevated white blood cell count. Common causes of sepsis include pneumonia, pyelonephritis, and biliary tract obstruction. Prompt administration of antibiotics and source control are the keys to treatment of sepsis, but patients will often require vasopressor agents to support their blood pressure before the infection resolves.

After rapid and aggressive volume resuscitation, vasoactive agents are initiated to maintain an adequate mean arterial pressure (MAP). Guidelines recommend the use of the catecholamines (alpha- and beta-agonists), norepinephrine, or epinephrine as an initial agent. Some intensivists augment one of these agents with intravenous vasopressin, which may decrease the required dose of norepinephrine. Vasopressors are titrated to an MAP that results in adequate tissue perfusion as demonstrated by clinical features such as decrease in lactate, improved mental status, and urine output.

### Mechanical Ventilation

Patients require mechanical ventilation because of problems with oxygenation, ventilation, or excessive work of breathing. Sometimes a patient has an endotracheal tube placed not because of a respiratory problem but instead for airway protection in the setting of altered mental status.

The degree of oxygenation support provided by the ventilator is determined by the fraction of inspired oxygen ( $F_{iO_2}$ ) and the positive end-expiratory pressure (PEEP). PEEP helps to hold alveoli open to increase surface area for gas exchange and thus improves oxygenation. In contrast, ventilation (or clearance of carbon dioxide [ $CO_2$ ]) is determined by a patient's minute ventilation ( $V_E$ ).  $V_E$  is calculated as the product of the respiratory rate and the tidal volume ( $V_E = RR \times V_T$ ). Different ventilator modes are used to support a patient's  $V_E$ . Some modes fully support a patient's breathing (e.g., assist control), whereas others allow a patient to initiate breaths (e.g., pressure support). In general, a ventilator is set to deliver either a given volume or a given pressure with each breath. If the mode is set to deliver a specific volume each breath, the resulting pressures will reflect the patient's respiratory system compliance and airway resistance. The converse is also true because pressure-delivered breaths

will vary in size based on the patient's physiology. Clinicians monitor these measurements as well as gas exchange (usually via pulse oximetry and ABG sampling) to assess a patient's condition.

### Arterial Blood Gas Interpretation

An ABG provides information both about a patient's oxygenation and acid-base status. Both aspects should be interpreted on any ABG obtained.

The partial pressure of arterial oxygen ( $P_{aO_2}$ ) reflects the amount of dissolved oxygen in plasma, and the oxygen saturation ( $S_{aO_2}$ ) is a measure of the amount of oxygen bound to hemoglobin. Although  $S_{aO_2}$  can be obtained noninvasively with a pulse oximeter, an ABG is required for the measurement of  $P_{aO_2}$ . In many circumstances, the  $S_{aO_2}$  is more useful to the clinician because it is the major determinant of blood oxygen content ( $CaO_2$ ). The following equation reflects this relationship:

$$CaO_2 = (SaO_2 \times \text{hemoglobin [Hb]} \times 1.34) + (PaO_2 \times 0.003)$$

The value of the  $P_{aO_2}$  is that it allows calculation of the alveolar-arterial oxygen difference ( $AaDO_2$ ).

$$AaDO_2 = PAO_2 - PaO_2$$

$$PAO_2 = (FiO_2 \times 713) - (PaCO_2/0.8).$$

The  $AaDO_2$  is used to determine the pathophysiologic cause of hypoxemia. Hypoventilation and low  $FiO_2$  result in a normal  $AaDO_2$ , whereas shunt and ventilation-perfusion mismatch cause a widened  $AaDO_2$ . Normal values for  $AaDO_2$  vary with age, but in general  $AaDO_2$  in the range of 8 to 14 is considered normal.

Acid-base status, including pH,  $P_{aCO_2}$ , and calculated bicarbonate ( $HCO_3$ ) can also be assessed with an ABG. Normal pH ranges from 7.38 to 7.42. A pH lower than

7.38 is called *acidemia*, whereas an elevated pH is termed *alkalemia*. The processes that result in these changes in pH are acidoses and alkaloses, respectively. An acidosis or an alkalosis can either be respiratory or metabolic in origin.

A respiratory acidosis, as indicated by an elevated  $P_{aCO_2}$ , is a result of inadequate  $V_E$  for the amount of  $CO_2$  produced. This can result from low  $V_T$ , low respiratory rate, or inefficient ventilation in the setting of structural lung disease. Common causes of a respiratory acidosis include severe airway obstruction (e.g., COPD exacerbation), neuromuscular weakness, or depressed mental status. In contrast, a respiratory alkalosis results from increased  $V_E$ , most commonly because of pain, sepsis, or anxiety.

Metabolic acidosis is most commonly the result of the production of increased acid, loss of  $HCO_3$ , or a decline in renal acid excretion, all of which cause a subsequent fall in the measured  $HCO_3$  level. Metabolic acidoses are categorized as anion-gap (AG) or non-AG processes. The AG is calculated as the difference between the serum Na and the serum Cl +  $HCO_3$ . This difference is usually 8 to 12. If there is an increased AG, it is an indication of unmeasured anions (acids). Common AG acidoses include diabetic ketoacidosis and lactic acidosis associated with poor tissue perfusion. A decrease in  $HCO_3$  not associated with an increased AG is a non-AG metabolic acidosis. Examples include renal tubular acidosis and acidosis from severe diarrhea. In the setting of an AG metabolic acidosis, one should calculate the delta-delta gap to evaluate if there is an additional acid-base disorder. This can be evaluated by calculating a corrected  $HCO_3$  as the difference between the patient's AG and the expected AG added to the patient's  $HCO_3$ . If the calculated value is above 28, an additional metabolic alkalosis is present, whereas if the calculated  $HCO_3$  value is less than 22, an additional nongap metabolic acidosis is present. Finally, loss of acid can result in a metabolic alkalosis. This is most commonly caused by dehydration or profound vomiting.

## Pituitary Disorders

FLORENCIA HALPERIN AND URSULA B. KAISER

Given its role in the regulation of multiple other endocrine glands, the pituitary gland is often referred to as the master gland. In this chapter, we will review basic pituitary physiology, which is essential for understanding pituitary disorders. We will then explore pituitary pathology that contributes to human disease, including pituitary lesions and disorders of hypofunction and hyperfunction.

### Pituitary Anatomy and Physiology

The pituitary gland sits in a depression in the base of the skull, the sella turcica, directly below the optic chiasm and is connected to the hypothalamus by the pituitary stalk. On each side, the pituitary is bordered by the cavernous sinus, through which run cranial nerves III, IV, VI, and the first and second branches of cranial nerve V (Fig. 47.1).

The pituitary gland is divided into an anterior and a posterior portion. The anterior pituitary, also known as the adenohypophysis, is composed of five distinct cell types, each of which secretes a distinct hormone. The anterior pituitary forms part of a tightly coordinated system of hypothalamic-pituitary-target organ axes, in which hormonal signals from the hypothalamus stimulate or inhibit secretion of anterior pituitary hormones, which in turn act on specific organs.

Hypothalamic neurons produce gonadotropin-releasing hormone (GnRH), which stimulates pituitary production of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and these signal the ovaries to secrete estrogen and progesterone or the testes to secrete testosterone. Hypothalamic corticotropin-releasing hormone (CRH) induces pituitary adrenocorticotropic hormone (ACTH) production, which regulates adrenal cortisol synthesis. Thyrotropin-releasing hormone (TRH) stimulates thyroid-stimulating hormone (TSH), which in turn regulates thyroid hormone production. Hypothalamic growth hormone–releasing hormone (GHRH) is responsible for pituitary growth hormone (GH) production, which leads to insulin-like growth factor-1 (IGF-1) production in the liver. Although most hypothalamic hormones have a stimulatory effect on the anterior

pituitary, somatostatin plays an inhibitory role; it inhibits the secretion of GH and TSH. Finally, prolactin secretion is tonically inhibited by hypothalamic dopamine (Fig. 47.2).

The hypothalamic-pituitary-target gland axes tend to function as negative-feedback systems in which hormones secreted by target organs suppress hypothalamic and/or pituitary activity. A hormone deficiency can be primary, caused by target gland failure, or secondary, caused by failure of the pituitary, or tertiary, caused by failure of the hypothalamus to stimulate the target gland.

The posterior pituitary, also known as the neurohypophysis, is the site of storage and secretion of vasopressin (AVP) and oxytocin, which are both synthesized in neurons in the hypothalamus.

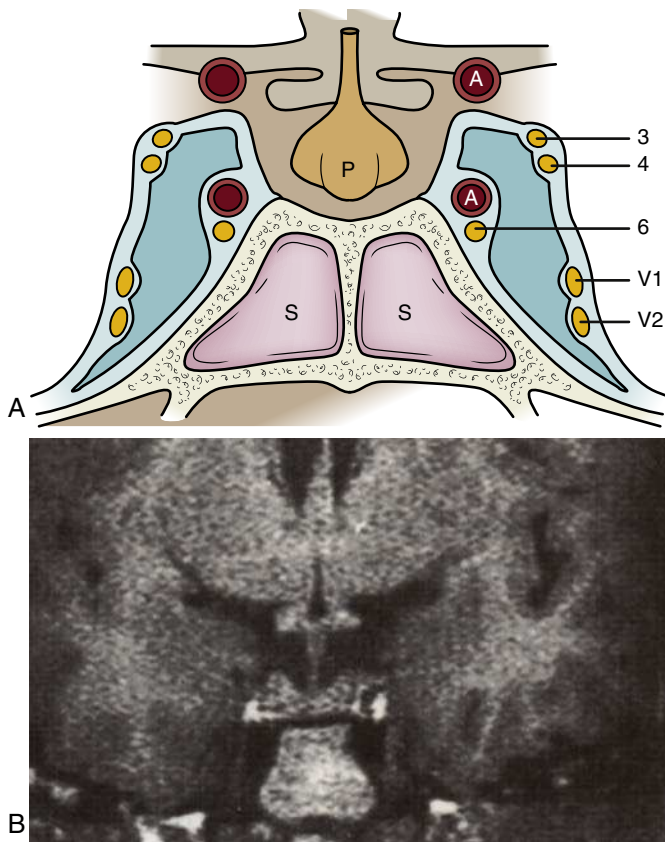

### Pituitary Lesions

Pituitary lesions can be of multiple etiologies and thus have a broad differential diagnosis. Tumors of several types can involve the pituitary gland. Benign tumors of anterior pituitary cell origin are known as adenomas. Very rarely, these can become carcinomas. Other tumors that can affect the pituitary gland include craniopharyngiomas, Rathke's cleft cysts, and germinomas. Malignancies from multiple primary sites, including hematologic malignancies, can metastasize to the pituitary. Also, granulomatous, infectious, infiltrative, and inflammatory processes such as sarcoidosis, eosinophilic granulomatosis, tuberculosis, mycosis, abscesses, hemochromatosis, and lymphocytic hypophysitis can all cause pituitary lesions (Box 47.1).

### Pituitary Adenomas

By far the most common pituitary lesion is the pituitary adenoma, with a prevalence of approximately 1 in 1000 to 1 in 10,000 individuals. In formulating a clinical approach to the diagnosis and management of a patient with a pituitary adenoma, two major factors need to be considered: mass effects and effects on pituitary function.

Mass effects are neurologic and hormonal abnormalities that develop secondary to the intracranial space occupied by

the lesion or to its proximity to important anatomic structures. Patients who develop mass effects from a pituitary lesion may complain of headaches. Temporal visual field deficits may develop as a result of compression of the optic chiasm.

Ocular nerve palsies and diplopia can occur if cranial nerves III, IV, or VI, which travel in the cavernous sinus, are compressed; facial numbness and pain can result if cranial nerve V is affected (see Fig. 47.1). In addition, the presence of a pituitary mass can distort regional anatomy sufficiently to decrease hormone production by adjacent cells. This can lead to various degrees of hypopituitarism. Hyperprolactinemia can result from compression of the pituitary stalk because this interrupts inhibitory dopamine signaling.

The second important consideration when evaluating a patient with a pituitary lesion is its effect on pituitary function. Adenomas can be nonfunctioning (15% of all adenomas), or they can secrete one or more pituitary hormones in excess. The most common type of hyperfunctioning lesions (60%) are lactotroph adenomas, which produce prolactin. GH-secreting adenomas (15%) result in the disease known as acromegaly, and 6% of adenomas secrete ACTH, resulting in Cushing disease. Adenomas that secrete bioactive LH, FSH, or TSH are rare.

At the same time, as mentioned earlier, whether an adenoma is hyperfunctioning or nonfunctioning, it can cause

pituitary hypofunction by compression of nearby normal anterior pituitary cells. Indeed, a pituitary tumor could cause impaired secretion of all hormones except for the one that it secretes in excess. The clinical manifestations and differential diagnosis of hypopituitarism are addressed in detail later.

## Prolactinomas

### Clinical Presentation

The most common symptoms of high prolactin levels, or hyperprolactinemia, in premenopausal women are menstrual abnormalities (oligomenorrhea or amenorrhea) and anovulation. Galactorrhea occurs in about 50% to 80% of women. In men, hyperprolactinemia can cause decreased libido, impotence, and infertility; galactorrhea is less common. The reproductive abnormalities seen in both sexes are thought to be secondary to a suppressive effect of prolactin on hypothalamic GnRH secretion, which inhibits gonadotropin (LH and FSH) release, and consequently impairs gametogenesis and gonadal steroidogenesis. Prolonged estrogen and androgen deficiency also leads to decreased bone density. The clinical presentation of a prolactinoma may also include symptoms from mass effect, including headache and visual field cuts, especially in men, who generally present with larger tumors.

### Differential Diagnosis of Hyperprolactinemia

Prolactinomas are not the only cause of hyperprolactinemia (Box 47.2). As previously stated, prolactin secretion is under tonic inhibitory control by dopamine, and any process that interferes with hypothalamic dopamine secretion or its delivery to the pituitary gland can result in hyperprolactinemia. Stimulation of prolactin release can occur in response to stress, exercise, sleep, chest wall stimulation (via afferent neural pathways), TRH, serotonin, estrogen, and other causes.

There are physiologic states of hyperprolactinemia, such as pregnancy and lactation. During pregnancy, rising estrogen levels stimulate prolactin, which can increase 10- to 20-fold. The stimulus of suckling maintains high prolactin levels during lactation. There are also multiple pharmacologic agents that elevate prolactin. The majority of these are dopamine antagonists, such as antipsychotic agents (risperidone, haloperidol) and metoclopramide. In addition, there are pathophysiologic states that result in hyperprolactinemia. Pituitary stalk compression secondary to tumors or infiltrative diseases interferes with dopamine inhibition of prolactin. Primary hypothyroidism results in elevation of TRH, which stimulates both TSH and prolactin (and in such cases, treatment of hypothyroidism should normalize prolactin). Chronic renal failure can cause hyperprolactinemia secondary to decreased clearance of the hormone. Finally, prolactinomas are a major cause of prolactin elevation; occasionally, adenomas cosecrete prolactin with other anterior pituitary hormones.

## • BOX 47.2 Causes of Hyperprolactinemia

### Physiologic

- Pregnancy
- Lactation
- Nipple or chest wall stimulation
- Stress

### Pharmacologic

- Dopamine antagonists
  - Phenothiazines
  - Haloperidol
  - Risperidone
  - Metoclopramide
  - Domperidone
- Amitriptyline
- Selective serotonin reuptake inhibitors
- Antihypertensives
  - Methyldopa
  - Reserpine
  - Verapamil
- Cimetidine
- Estrogens

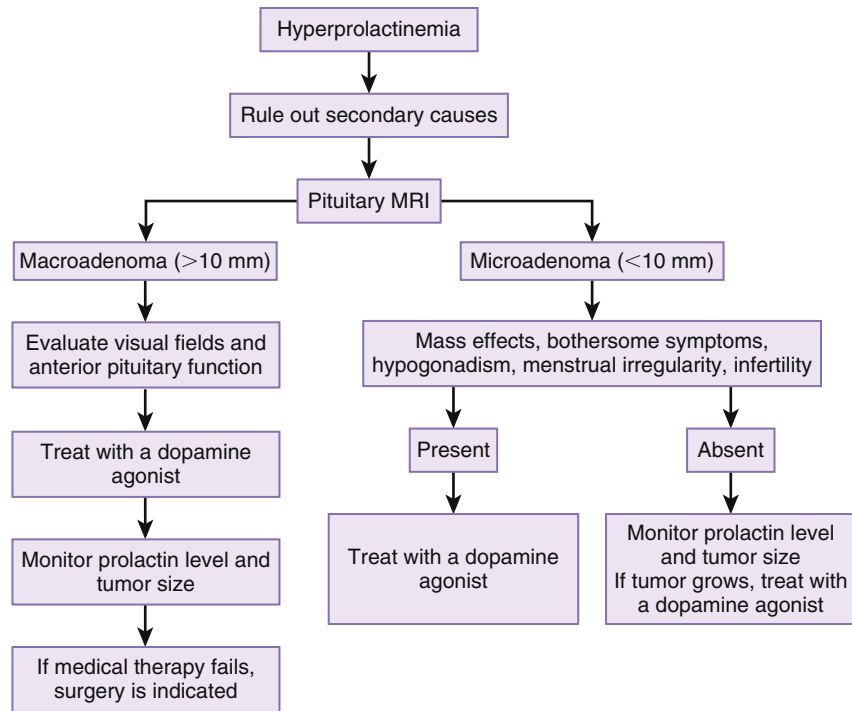

### Pathophysiologic

- Primary hypothyroidism
- Chronic renal failure
- Chest wall lesions
- Hypothalamic or pituitary lesions that cause pituitary stalk compression
- Prolactinoma
- Cosecretion of prolactin and other hormones from a pituitary adenoma
- Idiopathic

### Diagnosis

A patient who presents with symptoms of hyperprolactinemia can be evaluated with a random measurement of serum prolactin. If the prolactin level is mildly elevated the measurement should be repeated, given the various physiologic factors (listed earlier) that can transiently elevate prolactin. If the level remains high, further evaluation should include a detailed history of recent medication use, a pregnancy test (if the patient is female), and thyroid and renal function tests. If no secondary cause of hyperprolactinemia is identified, the patient should be evaluated for the presence of a pituitary mass by gadolinium-enhanced MRI.

Pituitary adenomas are classified as a microadenoma if they are <10 mm in size and as macroadenomas if they ≥10 mm in size. In general, in the case of prolactinomas, the magnitude of prolactin elevation correlates well with radiographic estimates of tumor size. Macroadenomas are generally associated with prolactin levels >200 to 250 μg/L. Therefore a mild prolactin elevation in the presence of a macroadenoma should raise suspicion that the tumor is not in fact prolactin secreting but is causing hyperprolactinemia secondary to compression of the pituitary stalk. In such cases, treatment with dopamine agonists will lower prolactin levels but will not cause a decrease in tumor size (see later).

• Fig. 47.3 Treatment algorithm for hyperprolactinemia.

## Management

The indications for treatment of a prolactin-secreting adenoma depend on the size of the tumor, the presence of hypogonadism, menstrual irregularities, bothersome symptoms such as galactorrhea, and the patient's desire for fertility.

The presence of a macroadenoma is an absolute indication for therapy because there is significant potential for tumor expansion (Fig. 47.3). Patients with macroadenomas extending beyond the sella turcica should undergo visual field testing and evaluation of anterior pituitary function. The goals of treatment are to normalize prolactin levels and achieve remission of symptoms, reduce tumor size, and prevent disease progression.

On the other hand, most microadenomas do not increase in size over time. Therefore these patients require treatment only if they desire fertility, have amenorrhea, hypogonadism, or troublesome galactorrhea, or if the adenoma enlarges. Patients with microadenomas without these indications for treatment can be followed with periodic prolactin measurements and MRI if their clinical symptoms progress (see Fig. 47.3). Women can also safely be treated with oral contraceptives or estrogen/progesterone replacement to prevent bone loss.

The first line of treatment for prolactin-secreting tumors is a dopamine agonist, of which two are approved for this indication in the United States: bromocriptine and cabergoline. Both medications effectively lower serum prolactin levels, restore gonadal function, and reduce tumor size. Cabergoline is the preferred choice because it is more efficacious than bromocriptine, is usually better tolerated, and can be administered once or twice weekly rather than daily.

Both bromocriptine and cabergoline are usually started at low doses and titrated until prolactin levels normalize. Side effects include nausea, headache, and dizziness. In women attempting to conceive, the medication is typically discontinued when pregnancy is achieved.

Dopamine agonists may not be necessary indefinitely. After 2 years of therapy, if prolactin levels have normalized and there has been significant tumor volume reduction on imaging, it is reasonable to taper and discontinue dopamine agonist therapy while monitoring prolactin levels.

It is worth noting that the ergot-derived dopamine agonists, pergolide and cabergoline, have been associated with increased risk of cardiac valve regurgitation in patients treated with these medications for Parkinson disease. However, the doses used for the treatment of Parkinson disease are much higher than those used for hyperprolactinemia, and there is no evidence that valvulopathy occurs at the lower cumulative doses used for this indication. A possible mechanism for the valvular disease associated with these drugs is the activation of cardiac serotonin receptor subtype 5-HT<sub>2B</sub>; valvulopathies associated with carcinoid syndrome and fen-fluramine also occur through this mechanism.

In addition to dopamine agonists, treatment options for prolactinomas include surgery and external radiation. Transsphenoidal removal of a prolactinoma is indicated when a macroadenoma does not respond to medical therapy or when there is tumor growth despite medical treatment. If a substantial amount of tumor remains after surgical excision, external radiation may occasionally be necessary.

## Acromegaly

### Clinical Presentation

Acromegaly is rare, with an incidence of approximately three cases per 1 million persons per year. The vast majority of cases are caused by pituitary GH-secreting adenomas. The clinical manifestations of acromegaly are varied. Accelerated growth and gigantism occur only if the disease develops in adolescence before epiphyseal plates are closed. In adults, the most common clinical features are coarsening of facial features, such as frontal bone bossing and jaw prognathism, and soft-tissue swelling that can lead to increases in ring, shoe, or hat size. Patients also frequently complain of increased sweating, and premenopausal women may note menstrual irregularities. Arthralgias and osteoarthritis are a source of significant functional disability. Metabolic complications include hyperglycemia and hyperlipidemia. Cardiac abnormalities such as arrhythmias, hypertension, valvular disease, and heart failure, as well as sleep apnea secondary to airway soft tissue swelling, may develop (Box 47.3). In addition, acromegaly is associated with an increased risk of certain tumors, such as colonic polyps.

More than 75% of patients with acromegaly have a macroadenoma at diagnosis, and if that is the case they may additionally present with symptoms of mass effect, such as headaches, visual field defects, and pituitary hormone deficiencies. About 25% of GH adenomas cosecrete prolactin, and in these instances galactorrhea may be present.

### Diagnosis

Under normal physiologic conditions, GH is released in a pulsatile fashion, which results in considerable variation in circulating levels. A random serum GH level is therefore not an accurate indicator of GH excess. GH induces the synthesis of IGF-1 from tissues such as the liver. Circulating IGF-1 concentrations reflect peripheral GH levels, but unlike GH, IGF-1 has a long half-life and can be reliably measured at any time of day. As a result, measurement of serum IGF-1 is the best screening test for acromegaly. IGF-1 levels should be compared against age- and gender-matched normative data.

If IGF-1 levels are elevated, the diagnosis of acromegaly can then be confirmed by documenting failure of suppression of GH secretion. This is best accomplished by performing a 75-g oral glucose tolerance test, during which GH levels are obtained. The most widely used diagnostic criterion is a GH level 2 hours after glucose ingestion of  $>1 \mu\text{g/L}$ . Conventionally, both an elevated IGF-1 level and failure of GH suppression are required for a diagnosis of acromegaly (Table 47.1). In clinical practice, however, GH suppression testing is not always necessary if the clinical picture is highly suggestive, IGF-1 levels are elevated, and a pituitary mass is present.

Indeed, the evaluation of a patient with suspected acromegaly should also include a gadolinium-enhanced pituitary MRI to establish the presence and dimensions of a pituitary tumor, as well as its proximity to the optic chiasm.

### • BOX 47.3 Clinical Features of Acromegaly in Adults

- Coarsening of facial features (frontal bone bossing; jaw prognathism)
- Soft tissue swelling (acral enlargement: increased ring, shoe, hat size)
- Arthralgias
- Osteoarthritis
- Excessive sweating
- Menstrual irregularities
- Hyperglycemia
- Hyperlipidemia
- Cardiac abnormalities (hypertension, heart failure, arrhythmias, valvular disease)
- Sleep apnea

In addition, given the significant number of patients who present with macroadenomas, these patients should undergo evaluation of other pituitary hormones to rule out hypopituitarism. This should include measurement of morning serum cortisol, TSH and free thyroxine ( $T_4$ ), testosterone levels in men, and a menstrual history in premenopausal women. Because many adenomas cosecrete growth hormone and prolactin, the latter should also be measured.

### Management

The goals of treatment for acromegaly are to control GH and IGF-1 levels (GH  $<1 \mu\text{g/L}$  after oral glucose suppression and IGF-1 levels in the normal range for age and gender) as well as to reduce tumor size and mass effects and improve comorbid conditions, including restoration or preservation of pituitary function. Patients with acromegaly have increased risk of premature mortality, and epidemiologic studies suggest that normalizing GH and IGF-1 levels helps to reduce complications and normalize mortality rates. During treatment for acromegaly, it is important to continue monitoring for associated morbidities including pituitary insufficiency, cardiovascular dysfunction, sleep apnea, hyperglycemia, musculoskeletal diseases, and colonic polyps.

Transsphenoidal surgery is the treatment of choice for acromegaly in most patients. This is the only treatment with potential for definitive cure. Surgery reduces tumor size and relieves complications from mass effects. Surgical outcomes depend on several factors. Certain tumor characteristics such as size, presence of extrasellar growth, and dural invasion are associated with lower rates of cure. Individual surgical expertise is another major determinant of outcome. Postoperatively, IGF-1 and random or nadir glucose-suppressed GH levels should be measured to determine the success of the procedure. In one series, after 12 months of postoperative follow-up, about 70% of patients had normal IGF-1 levels, and about 60% had nadir glucose-suppressed GH levels  $<1 \mu\text{g/L}$ .

When surgery fails to normalize the biochemical parameters, or when patients refuse or have a contraindication to surgery, medical therapy should be initiated. Several

**TABLE 47.1** Summary of Selected Endocrine Derangements and Diagnostic Strategies

Endocrine Derangement	Screening Test	Confirmatory Test	Confirmatory Result
Acromegaly (GH overproduction)	IGF-1	Oral glucose tolerance with measurement of GH	Elevated IGF-1 and glucose-suppressed GH >1 µg/L
ACTH deficiency	Morning cortisol (µg/dL) <3: deficient >18: normal 3–18: confirmatory test	Corticotropin stimulation ACTH	Stimulated cortisol <18 µg/dL ACTH low or normal
TSH deficiency	TSH and free T <sub>4</sub>		Low free T <sub>4</sub> and low or normal TSH
LH and FSH deficiency	Men: testosterone  Women: Premenopausal: menstrual history  Postmenopausal: LH and FSH	LH and FSH  LH and FSH	Low testosterone, low or normal LH and FSH  Low or premenopausal range LH and FSH
GH deficiency	IGF-1	Glucagon stimulation test	Failure to stimulate GH
Diabetes insipidus	Serum Na and osmolality Urinalysis and urine osmolality	Water deprivation test	Urine osmolality <600 when plasma osmolality >300 mOsm/kg H <sub>2</sub> O

*ACTH*, Adrenocorticotropic hormone; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *IGF-1*, insulin-like growth factor-1; *LH*, luteinizing hormone; *T<sub>4</sub>*, thyroxine; *TSH*, thyroid-stimulating hormone.

medical therapies are available, including somatostatin receptor ligands (octreotide, lanreotide, and pasireotide), a GH-receptor antagonist (pegvisomant), and dopamine agonists (especially cabergoline). Somatostatin receptor ligands suppress pituitary GH secretion and block the synthesis of IGF-1 in the liver. They are administered deep subcutaneously or intramuscularly, have long-acting forms that can be injected monthly, and are generally well tolerated, although gastrointestinal side effects such as nausea, vomiting, and diarrhea are common, and risk of gallstone formation and hyperglycemia is increased. When used as adjunctive therapy postoperatively, somatostatin receptor ligands normalize IGF-1 levels in about 60% of patients and result in symptomatic improvement and decreased soft tissue swelling in about 80%, but tumor size is reduced in only about 30% of cases. GH and IGF-1 assessment should be performed a few months after initiation of treatment to establish dose adequacy.

Another available drug is pegvisomant, a GH-receptor antagonist. Importantly, because the drug acts peripherally but does not affect the pituitary secretion of GH, it does not lower GH or reduce tumor size; therefore patients on pegvisomant should be monitored biochemically with IGF-1 levels and radiographically for tumor growth. Pegvisomant is administered subcutaneously on a daily basis and normalizes IGF-1 levels in 63% to 95% of cases.

Somatotroph adenomas express dopamine receptors, and dopamine agonists, particularly cabergoline, have been used in the management of acromegaly, but they are not

as effective as other agents. Cabergoline is most effective in patients with just modest elevations of GH secretion and IGF-1 and in those with prolactin cosecretion.

Radiation therapy is generally reserved as a last resort for patients who have undergone surgery and subsequently were resistant to or intolerant of medical treatment. Radiotherapy slows tumor growth and can effectively normalize biochemical parameters, but its effects are delayed, and hypopituitarism is a common adverse effect.

### Cushing Disease

Pituitary adenomas of corticotroph origin secrete ACTH, which in turn causes excess adrenal production of cortisol and results in Cushing disease. Note that Cushing disease refers specifically to an ACTH-producing pituitary adenoma, whereas Cushing syndrome refers to the clinical manifestations of cortisol excess of any etiology. Clinical features of Cushing syndrome include fatigue, weight gain, hirsutism, proximal muscle weakness, hypertension, hyperglycemia, and hypokalemia, as well as loss of bone mineral density. Patients with Cushing syndrome have a characteristic physical appearance with facial plethora, moon-shaped facies, and supraclavicular and dorsocervical fat pads, and they may have wide purple striae or ecchymoses. The etiologies of endogenous Cushing syndrome include adrenal cortisol-secreting tumors and ectopic ACTH production, for example from small cell lung cancer, in addition to ACTH-producing pituitary adenomas, which are the most common cause.

Screening for Cushing syndrome can be done by 24-hour urinary free cortisol measurement, overnight dexamethasone suppression testing (1 mg given overnight followed by morning serum cortisol measurement), or late-night salivary cortisol (two independent measurements). If the result of one of these tests is abnormal, it should be confirmed by performing another test. If values are elevated on both tests, further evaluation is required to determine the etiology of the disease. ACTH levels can be used to establish if the cause of excess cortisol is ACTH dependent, in which ACTH levels are elevated or inappropriately normal as is seen in pituitary or ectopic ACTH production, versus ACTH independent in which ACTH levels are low as seen in adrenal cortical tumors. If ACTH levels are elevated or normal, follow-up testing with high-dose (8 mg) dexamethasone suppression can be used to distinguish between a pituitary source, in which case cortisol should suppress, or an ectopic source, which will typically not respond to dexamethasone. If the results suggest a pituitary source, the pituitary gland should be imaged. Most clinicians favor proceeding at this point with catheterization and sampling of the inferior petrosal sinus veins to establish a central-to-peripheral gradient, as well as trying to lateralize the source of ACTH hypersecretion.

If sampling results are consistent with Cushing disease, transsphenoidal surgery is the treatment of choice. To improve the medical status of critically ill patients, often in preparation for surgery, or if the ACTH source is undetermined or the culprit tumor cannot be fully resected, medical therapies may help to control hypercortisolism in Cushing syndrome. Medications that inhibit adrenal steroidogenesis (and the diagnosis and management of Cushing syndrome) are reviewed in [Chapter 50](#) on adrenal gland disorders. Medications that suppress ACTH secretion, including a dopamine agonist (cabergoline) and a somatostatin receptor agonist (pasireotide), are also used. A selective glucocorticoid receptor antagonist, mifepristone, is approved for the treatment of hyperglycemia in Cushing syndrome in those who have failed surgery or who are not surgical candidates.

### Thyroid-Stimulating Hormone and Gonadotropin-Producing Pituitary Adenomas

Pituitary tumors that secrete biologically active LH or FSH are rare. Tumors of gonadotropic origin may also secrete gonadotropin subunits or proteins without functional activity. In fact, many adenomas considered nonfunctional are actually gonadotropic in origin. The diagnosis of gonadotroph adenoma can be difficult to make, because tumors that secrete gonadotropins or gonadotropin subunits usually do not result in a specific clinical syndrome. When they become sufficiently large, similar to all other pituitary tumors, gonadotroph adenomas can cause mass effects. Patients suspected of having gonadotropin-secreting adenomas should undergo pituitary MRI as well as testing of pituitary function. Transsphenoidal surgery is the treatment of choice.

Adenomas that secrete TSH are exceedingly rare. Clinically, these tumors present with hyperthyroidism. They are usually large at the time of diagnosis and as a result are usually also associated with mass effects. This diagnosis should be suspected in patients with elevated serum  $T_4$  and triiodothyronine ( $T_3$ ) levels but with an inappropriately normal or elevated TSH concentration (rather than suppressed TSH values, as would be expected in primary hyperthyroidism). The primary treatment for TSH-producing adenomas is transsphenoidal excision. In cases of residual tumor or contraindications to surgery, somatostatin analogues are an alternative therapeutic option.

### Genetic Syndromes Associated With Pituitary Tumors

Some genetic syndromes are associated with the formation of pituitary tumors. The familial isolated pituitary adenomas (FIPA) syndrome is an autosomal dominant disorder characterized clinically by presentation at an early age, most commonly with GH or prolactin-producing tumors, which are often large and invasive. A subset of FIPA families have germline mutations in the aryl hydrocarbon receptor interacting protein gene; in others the genetic basis remains unknown. More recently, a microduplication of a small portion of the X chromosome has been recognized in association with X-linked acro gigantism, with onset early in life, thought to be caused by a suppletion of a G protein-coupled receptor, GPR101. In contrast to these syndromes associated with pituitary defects exclusively, multiple endocrine neoplasia type 1 (MEN 1) is characterized by tumors in multiple endocrine glands, including pituitary adenomas but also parathyroid adenomas or hyperplasia, pancreatic and gastrointestinal neuroendocrine tumors, and, less frequently, other endocrine tumors. MEN 1 is an autosomal dominant disorder that results from a mutation in the gene that encodes menin, a tumor suppressor protein. Anterior pituitary tumors develop in approximately 65% of patients with MEN 1.

The MEN 2 syndromes (MEN 2A, MEN 2B, and familial medullary thyroid cancer) are autosomal dominant and caused by germline mutations in the *RET* protooncogene. In contrast to the MEN 1 syndrome, the MEN 2 syndromes do not involve the pituitary gland. The MEN 2 syndromes are all characterized by medullary thyroid cancer (MTC), which is fully penetrant in all affected individuals. MEN 2B is also associated with pheochromocytoma, mucosal and intestinal neuromas, and marfanoid habitus; MEN 2A is associated with MTC, pheochromocytoma, and parathyroid tumors.

Other syndromes associated with pituitary tumors include Carney complex (mutations in *PRKARIA*), neurofibromatosis (*NF1*), and McCune-Albright syndrome (*GNAS*). Somatic mutations in the pituitary tumor itself have been identified in acromegaly (*GNAS*) and in Cushing disease (*USP8*).

## Hypopituitarism

Hypopituitarism is characterized by decreased secretion of one or more anterior pituitary hormones, which include GH, ACTH, TSH, FSH, LH, and prolactin. Deficiencies may be partial or complete. Panhypopituitarism refers to a deficiency of all pituitary hormones.

### Differential Diagnosis

A pituitary hormone deficiency may result from intrinsic pituitary disease or from a derangement in the pituitary stalk or hypothalamus resulting in a deficiency in the production or delivery of hypothalamic neuropeptides that stimulate pituitary function. The causes of acquired hypopituitarism are myriad (Box 47.4), and the most common are described subsequently.

Mass lesions in or near the hypothalamus or pituitary gland can cause partial or complete hypopituitarism. By far the most common such lesions are pituitary adenomas, which may be functioning or nonfunctioning. As has been previously reviewed, a mass lesion causes hormone insufficiencies either by mechanical compression, by impairment of blood flow to adjacent pituitary tissue, or by interference with the delivery of hypothalamic regulating factors through the hypothalamic-hypophyseal portal system (Fig. 47.4). Excision or shrinkage of the tumor may result in restoration of pituitary function, although if pituitary tissue has been destroyed, this is unlikely, and lifelong hormone replacement therapy will be required.

In addition to benign tumors affecting the pituitary gland, many types of cancer, most commonly breast and lung, can metastasize to the hypothalamus or the pituitary and cause hypopituitarism. Metastases tend to occur in the posterior pituitary initially, causing diabetes insipidus (DI).

Iatrogenic causes of pituitary deficiency may ensue after pituitary surgery or after radiation therapy. Postoperative patients should undergo biochemical evaluation to detect changes in pituitary function. Patients who undergo pituitary radiation, either for functioning adenomas after incomplete resections or for brain tumors, should be screened at regular intervals, as many will eventually develop some degree of hypopituitarism.

Pituitary apoplexy is the infarction of or hemorrhage into the pituitary gland, causing abrupt damage to the tissue. This usually occurs in the setting of an undiagnosed pituitary adenoma. It presents clinically with the sudden onset of severe headache, visual field loss, and sometimes cranial nerve palsies (III, IV, or VI). Evaluation should include an MRI scan and neurologic assessment with formal visual field testing. Sheehan syndrome, which is pituitary necrosis after postpartum hemorrhage, is characterized by hypopituitarism and inability to breastfeed and can present immediately or several years after childbirth.

Less common causes of hypopituitarism include empty sella syndrome, which results from either a congenital or an acquired sellar diaphragmatic defect through which arachnoid herniates and enlarges the pituitary fossa.

## • BOX 47.4 Causes of Acquired Hypopituitarism

### Destruction of the Pituitary Gland

- Mass lesions
  - Pituitary tumors
  - Metastatic tumors
- Iatrogenic
  - Surgical destruction
  - Radiation
- Infarction or ischemia
  - Pituitary apoplexy
  - Sheehan syndrome (postpartum)
- Empty sella syndrome
- Traumatic brain injury
- Granulomatous disease
  - Sarcoidosis
  - Giant cell granuloma
  - Eosinophilic granuloma
  - Wegener granulomatosis
- Infiltrative disorders
  - Hemochromatosis
  - Hypophysitis
- Infections
  - Meningitis
  - Abscess
- Genetic
- Idiopathic

### Destruction of the Pituitary Stalk

- Trauma
- Compression by masses
- Surgical damage

### Hypothalamic Causes

- Trauma
- Masses
  - Craniopharyngioma
  - Meningioma
  - Other tumors
  - Tumor metastases
- Radiation
- Functional
  - Starvation/anorexia nervosa
  - Stress/critical illness

Most patients with a congenital empty sella have normal pituitary function; approximately 15% have mild hyperprolactinemia. Traumatic brain injuries can lead to hypothalamic or pituitary damage either immediately or years afterward, and patients should be monitored for hypopituitarism.

Granulomatous diseases, including sarcoidosis, giant cell granuloma, eosinophilic granuloma, and Wegener granulomatosis can affect the hypothalamus or pituitary and thus lead to hypopituitarism. Lymphocytic hypophysitis, a diffuse infiltration of the anterior pituitary, occurs predominantly in women and is often first evident during pregnancy or after delivery. Recently, hypophysitis has been identified to occur as the result of treatment with ipilimumab, an immune checkpoint inhibitor used to treat malignant melanoma and other cancers. In hemochromatosis, iron infiltrates the pituitary

• **Fig. 47.4** Pituitary mass (arrow). Note compression of nearby structures.

and results in one or more hormonal deficiencies. In addition, several types of infections, such as meningitis or an abscess, can involve the hypothalamus or pituitary and cause pituitary insufficiency. Certain genetic mutations, for example in *PROP-1* and *PIT-1*, cause combined pituitary hormone deficiencies. Finally, there can be functional hypopituitarism: reversible suppression of hypothalamic function from severe stress such as starvation or critical illness.

#### Clinical Presentation, Diagnosis, and Management of Pituitary Hormone Deficiencies

The clinical presentation of hypopituitarism depends on the rapidity of its onset and on which pituitary hormones are deficient and the degree of deficiency. The clinical manifestations of the endocrine abnormalities result from dysfunction of the target organs regulated by the deficient pituitary hormones, and the symptoms are similar to those of primary target organ failure; for example, in the case of TSH deficiency the clinical presentation is similar to that of primary hypothyroidism caused by intrinsic thyroid disease. Depending on the etiology of the hypopituitarism, patients may additionally present with symptoms of mass effects including headaches and visual field deficits or other neurologic abnormalities.

Pituitary adenomas and other tumors that affect this region are typically slow growing, so endocrine deficiencies and mass effects tend to develop slowly. However, when symptoms are acute in onset or abruptly exacerbated, an event such as pituitary apoplexy associated with rapid expansion in size and infarction of the gland should be considered.

In general, the diagnosis of hypopituitarism cannot be made by measurement of pituitary hormone levels in serum

because there are substantial overlaps between normal and deficient ranges. Instead, in most cases, serum levels of the hormones made by target organs (in response to stimulation from the pituitary) are used to assess the status of pituitary function. For example,  $T_4$  is measured to assess adequacy of TSH production. If the concentrations of target organ hormones are equivocal, subsequent stimulation tests can be performed to determine pituitary function. The dynamic studies that are appropriate for testing each hypothalamic-pituitary-target organ axis are described later.

After the clinical and biochemical diagnosis of hypopituitarism has been established, a radiographic study is indicated to determine whether a mass or other abnormality is present. The most informative imaging study of the pituitary gland is a gadolinium-enhanced MRI.

Patients with panhypopituitarism on standard replacement therapies have increased prevalence of obesity as well as osteopenia and fractures. They report decreased quality of life on neuropsychiatric evaluation. In addition, for reasons that remain poorly understood, cardiovascular mortality is increased in these patients. Deficiency of each pituitary hormone has a unique presentation, diagnostic strategy, and management, and these are addressed subsequently.

#### Adrenocorticotrophic Hormone (Corticotropin) Deficiency

The symptoms of ACTH deficiency include fatigue, weakness, headache, anorexia, weight loss, nausea, vomiting, and abdominal pain; hypoglycemia can also occur. If left untreated, particularly in the context of physiologic stressors such as illness, secondary adrenal insufficiency can lead to vascular collapse and death. On physical examination, orthostatic hypotension may be present and should be assessed. Cortisol deficiency leads to inadequate vascular tone, increased vasopressin, and water retention, and hyponatremia may ensue.

There are two important clinical distinctions between primary and secondary adrenal insufficiency. In patients with secondary adrenal insufficiency, ACTH is not elevated, and therefore hyperpigmentation is not present. In addition, in secondary adrenal insufficiency, adrenal aldosterone production is preserved, so serum potassium concentration should be normal; in primary disease, aldosterone deficiency may result in both hyponatremia and hyperkalemia.

A serum cortisol level is the best screening test for ACTH deficiency (see [Table 47.1](#)); because of diurnal variation, cortisol should be measured in the early morning. Measurement of ACTH is not useful for the diagnosis of secondary adrenal insufficiency. However, ACTH measurement is helpful to distinguish between etiologies of adrenal insufficiency: in primary (adrenal) disease, the ACTH level will be high, whereas in secondary (pituitary) adrenal insufficiency, the ACTH level will be low or inappropriately normal in the context of a low serum cortisol.

In general, a morning serum cortisol value of  $<3 \mu\text{g/dL}$  indicates adrenal insufficiency. The level of morning serum cortisol that accurately predicts normal hypothalamic-pituitary-adrenal (HPA) function remains less clear: some studies suggest that levels  $>11$  to  $14 \mu\text{g/dL}$  accurately predict normal adrenal function on dynamic testing. However, it is well accepted that patients with morning cortisol levels  $>18 \mu\text{g/dL}$  can be considered to have normal HPA function and do not need further testing. Therefore conventionally, if the morning serum cortisol concentration is between 3 and  $18 \mu\text{g/dL}$ , dynamic testing of hypothalamic-pituitary-adrenal function is indicated (see [Table 47.1](#)). The easiest and most widely used dynamic test is the corticotropin stimulation test, which consists of measuring serum cortisol concentrations before and 30 and 60 minutes after an intravenous injection of  $250 \mu\text{g}$  of cosyntropin. An increase in the serum cortisol concentration to 18 to  $20 \mu\text{g/dL}$  or more is considered a normal response. In patients with severe corticotropin deficiency the adrenal glands atrophy, and therefore the serum cortisol response to stimulation will be diminished (abnormal). Of note, this test is not useful in the acute setting: test results will be normal before adrenal atrophy has occurred, and this can take weeks to months to develop.

Other dynamic tests are available including the insulin tolerance test, in which insulin-induced hypoglycemia normally leads to an increase in CRH, ACTH, and subsequently cortisol. Although this test is considered the gold standard for diagnosis of secondary adrenal insufficiency, reflected by an insufficient rise in serum cortisol, it is rarely conducted because of the safety concerns of inducing hypoglycemia.

When the diagnosis of adrenal insufficiency is made, or when clinical suspicion is high, glucocorticoid therapy should be initiated immediately. Patients can be treated with hydrocortisone 15 to 30 mg daily, administered in divided doses in the morning and afternoon. Overtreatment should be avoided to decrease risks of iatrogenic hypercortisolism such as bone loss. Patients should be instructed to double or triple their steroid doses for periods of stress such as febrile illnesses. Mineralocorticoid replacement is not necessary in patients with secondary adrenal insufficiency, as aldosterone production is intact. All patients with adrenal insufficiency should wear medical alert bracelets.

### Thyroid-Stimulating Hormone (Thyrotropin) Deficiency

Symptoms and signs of TSH deficiency are similar to those of primary hypothyroidism and include fatigue, weight gain, constipation, cold intolerance, bradycardia, periorbital puffiness, and delayed relaxation of tendon reflexes. Laboratory findings may include mild hyponatremia and anemia.

To make a diagnosis of TSH deficiency, serum TSH and free  $T_4$  concentrations should be measured simultaneously (see [Table 47.1](#)). Patients with secondary hypothyroidism most commonly have low free  $T_4$  with normal

or low serum TSH concentrations, and therefore TSH should never be used alone as a screening test for central hypothyroidism. A normal or low TSH value is inappropriate in the context of a low serum  $T_4$  concentration and indicates TSH insufficiency. Occasionally, patients with central hypothyroidism may have an elevated serum TSH because of the formation of an abnormal TSH molecule that has reduced biological activity but is recognized by the immunoassay.

The treatment for secondary hypothyroidism is thyroid hormone replacement with levothyroxine. In patients with multiple pituitary hormone deficiencies, it is important to treat adrenal insufficiency before starting thyroid hormone replacement. This is because levothyroxine will increase the metabolism of cortisol, and an adrenal crisis can be precipitated. Laboratory studies should be repeated 4 to 6 weeks after initiation of therapy to evaluate appropriateness of dose. In patients with secondary hypothyroidism, free  $T_4$  (not TSH) should be used to monitor treatment, and the goal of therapy is a free  $T_4$  concentration in the normal range.

### Luteinizing Hormone and Follicle-Stimulating Hormone (Gonadotropin) Deficiency

In general, LH and FSH deficiency result in decreased production of gonadal steroids and present differently in men and in women. Gonadotropin deficiency before puberty results in failure to progress through sexual maturation. In adult premenopausal women, estrogen deficiency manifests as infertility, anovulatory cycles, and oligomenorrhea or amenorrhea. Other symptoms include hot flashes, decreased libido, and vaginal dryness. Because estrogen levels are low at baseline in postmenopausal women, if they develop hypopituitarism they usually present with symptoms of other hormonal deficiencies or of mass effects. Men with hypogonadism experience decreased libido and erectile dysfunction. Long-standing testosterone deficiency results in sparse facial and body hair and testicular atrophy. Both men and women can develop bone loss from chronic gonadal steroid deficiency.

Gonadotropin deficiency can occur secondary to all of the causes of hypopituitarism listed in [Box 47.4](#), and in addition there are various syndromes of isolated gonadotropin deficiency. A congenital condition known as congenital hypogonadotropic hypogonadism (HH) presents with failure to undergo puberty and persistently low gonadotropin levels. Kallmann syndrome is characterized by HH plus anosmia. An acquired form of HH has been described in men who develop isolated hypogonadism in adulthood without any identifiable cause. Physiologic stress can also cause acquired derangements in the hypothalamic-pituitary-gonadal axis. Women who suffer from anorexia nervosa or who exercise excessively can develop what has been termed *hypothalamic amenorrhea*: abnormal secretion of GnRH and gonadotropins resulting in menstrual dysfunction and other complications such as bone loss.

Appropriate evaluation for gonadotropin deficiency depends on age and gender. In women, serum LH, FSH, and estradiol concentrations may be low or normal. In premenopausal women, the best assessment of gonadotropin status is the menstrual history; regular menses indicate at least some gonadotroph function, and measurement of gonadotropins or estradiol provides little additional information. In contrast, in postmenopausal women, measurement of LH and FSH concentrations is useful (see [Table 47.1](#)). In these patients, gonadotropin levels are normally high, so low or normal levels are inappropriate and confirm gonadotropin deficiency and anterior pituitary dysfunction. In men, central hypogonadism results in low-serum testosterone and low or normal LH and FSH levels; in the setting of low testosterone, even normal values of gonadotropins are inappropriate and indicate deficiency. A serum testosterone concentration should always be measured as part of the diagnostic workup (see [Table 47.1](#)). Measurement of gonadotropins is helpful if the etiology is uncertain, to distinguish between primary (testicular disease, high LH and FSH) and secondary hypogonadism (hypothalamic or pituitary disease, low or normal LH and FSH).

Treatment for hypogonadism consists of gonadal steroid replacement unless fertility is desired. In women of reproductive age, estrogen and progesterone therapy are recommended to restore the normal hormonal milieu and prevent bone loss. If fertility is desired, it can be achieved with exogenous gonadotropin therapy. For men with hypogonadism, testosterone replacement can be provided by intramuscular injection or with testosterone patches and gels. Serum testosterone levels should be monitored during treatment, and supraphysiologic doses should be avoided because of risks of prostate stimulation and elevated hematocrit.

### Growth Hormone (Somatotropin) Deficiency

Symptoms and signs attributed to GH deficiency in adults include a diminished sense of well-being, decreased muscle strength and exercise tolerance, and changes in body composition including decreased lean body mass, increased central adiposity, and decreased bone density. GH deficiency also leads to increased total and low-density lipoprotein (LDL) cholesterol and increased risk of cardiovascular disease. In children, before epiphyseal plate closing, GH deficiency results in short stature.

For the diagnosis of GH deficiency, a single random measurement is not useful because even under physiologic conditions, GH is secreted in pulses and remains low during most of the day. A low serum IGF-1 level is suggestive of GH deficiency, but normal levels do not exclude the diagnosis. Therefore to formally establish the diagnosis, provocative testing is required, and multiple options exist. One widely used option is a glucagon stimulation test, in which glucagon, a stimulant of GH secretion, is infused, and GH is subsequently measured (see [Table 47.1](#)). Other options include a GHRH and arginine test or the insulin tolerance test. The insulin tolerance test, in which insulin-induced

hypoglycemia is the stimulus for GH secretion, has traditionally been considered the gold standard, although because of the risks associated with inducing hypoglycemia this test is used less frequently. A diminished response to these stimuli is considered diagnostic of GH deficiency.

Treatment for GH deficiency is available with recombinant human GH, injected subcutaneously on a daily basis. Therapy is indicated in GH-deficient children and should be given before epiphyses are closed, to promote growth. In GH-deficient adults there is evidence that GH therapy increases lean body mass and bone density, improves certain cardiac indices and LDL cholesterol, and improves quality of life. Long-acting GH preparations are currently in development to reduce the frequency of administration.

### Prolactin Deficiency

The serum prolactin concentration is rarely low in hypopituitarism. If prolactin deficiency exists, it manifests as an inability to lactate and typically reflects complete or near complete destruction of the anterior pituitary. As previously described, prolactin may in fact be elevated in patients with hypothalamic-pituitary disease of any cause if there is interference with the transport of dopamine to the pituitary. Serum prolactin should always be measured as part of the evaluation of hypopituitarism because it may provide valuable information about the cause of hypogonadism and the location of a mass.

### Posterior Pituitary Deficiency

Deficiency of AVP, which is secreted from the posterior pituitary, is known as central DI; it can be partial or complete.

#### Etiology

In 30% to 50% of cases, DI is idiopathic and may be autoimmune in nature. Trauma (commonly pituitary surgery) as well as tumors, tumor metastases, and infiltrative disorders of the hypothalamus or pituitary can all cause central DI. The differential diagnosis of DI includes nephrogenic DI (which is caused by resistance to the effects of AVP at the level of the kidneys), primary polydipsia, or osmoreceptor dysfunction.

#### Clinical Presentation

DI presents with polyuria (which is defined as urine output  $\geq 50$  mL/kg per 24 hours, usually including nocturia) as well as polydipsia. If there are alterations in serum sodium concentration and serum osmolality, patients may also have neurologic symptoms such as confusion and lethargy.

#### Diagnosis

Evaluation of a patient with polyuria and polydipsia should include serum osmolality, sodium, potassium, glucose, calcium, blood urea nitrogen, and creatinine, plus urinalysis including measurement of urine osmolality and glucose. The diagnosis is unlikely if the urine

osmolality is  $>600$  mOsm/kg  $H_2O$ ; a serum osmolality  $>300$  mOsm/kg  $H_2O$  with a urine osmolality  $<300$  mOsm/kg  $H_2O$  is suggestive of the diagnosis. However, the diagnosis is best confirmed by a water deprivation test (see Table 47.1). This consists of depriving the patient of oral intake while monitoring his or her weight, vital signs, serum sodium, osmolality, and serum AVP as well as urine sodium, osmolality, and volume on an hourly basis. If at any time during the test, the urine osmolality  $>600$  mOsm/kg  $H_2O$  this indicates normal ability to concentrate urine, and the patient does not have DI. If the serum osmolality rises  $>300$  mOsm/kg  $H_2O$  and the urine osmolality remains  $<600$  mOsm/kg  $H_2O$ , the test is diagnostic of DI. If a diagnosis of DI is made, desmopressin (DDAVP) is given to differentiate between

central and nephrogenic DI (in the latter there will be little response to DDAVP).

### Management

Water is the mainstay of therapy for DI. Thirst is an excellent defense mechanism against hypertonicity, and if free water losses can be adequately replaced, patients with DI will not develop hypernatremia. DDAVP, a synthetic vasopressin receptor agonist, is also available for symptomatic management. Because of significant variations in the duration of action of the drug, it is recommended that dose and dosing intervals be individualized; patients are advised to wait for symptoms of polyuria and polydipsia to restart before administering the next dose of medication. Typically, the drug is taken once or twice daily and can be taken orally or intranasally.

## Chapter Review

### Questions

- A 35-year-old woman presents for initial evaluation and complains of amenorrhea. Previously, her menstrual periods had been regular until about 2 years ago when they became less frequent, and they stopped altogether 1 year ago. She also mentions that she occasionally has milky discharge from her breasts, although she is nulliparous. She is taking no medications. A prolactin level is found to be 55 ng/mL on two separate occasions. All other blood tests are normal.

What should be the next step in her evaluation?

  - She should be started on cabergoline, a dopamine agonist.
  - She should be started on cabergoline, a dopamine antagonist.
  - A gadolinium-enhanced pituitary MRI should be obtained.
  - She should be started on oral contraceptive pills.
- A 27-year-old woman presents with fatigue, constipation, and weight gain. Her menstrual periods have been irregular over the last year but previously had been normal. On physical examination, her thyroid is mildly enlarged. She has mild expressible galactorrhea. Her deep tendon reflexes exhibit delayed relaxation phase. She is taking no medications. Laboratory studies reveal a prolactin level of 35 ng/mL and a TSH level of 24 mIU/L.

What should be the next step in the management of this patient?

  - She should be started on bromocriptine for treatment of hyperprolactinemia.
  - A gadolinium-enhanced pituitary MRI should be obtained.
  - She should be started on levothyroxine for treatment of hypothyroidism.
  - She should be referred to a neurologist for full neurologic evaluation.
- A 60-year-old woman with a long-term history of smoking presents for evaluation of an unsteady gait. She describes loss of balance and frequent falls at home. On review of systems, she has a chronic cough, which has been worsening, and has lost 15 lb. Furthermore, she has been feeling extremely thirsty for many weeks and gets up several times per night to drink and urinate, which is when many of her falls occur. Laboratory studies show a serum sodium of 142 mEq/L. A chest x-ray shows a mass in the right hilum, and a head CT scan shows several masses in her brain. The patient is referred to oncology. DI is suspected. Which one of the following is most likely to be associated with the diagnosis of DI?

  - A urine osmolality of 700 mOsm/kg  $H_2O$
  - A urine osmolality of 700 mOsm/kg  $H_2O$  with fluid restriction
  - A urine specific gravity of 1.020
  - A urine osmolality of 180 mOsm/kg  $H_2O$
- A 37-year-old construction worker falls from a roof and sustains a basilar skull fracture. One year later he is found to have testosterone deficiency, adrenal insufficiency, and hypothyroidism. Replacement therapy with testosterone injection, hydrocortisone, and levothyroxine is initiated. A few months later he returns for evaluation to a new primary care physician and complains of profound fatigue, constipation, and weight gain. His doctor suspects inadequate thyroid hormone replacement and checks a TSH level, which is 1 mIU/L.

What is the best next step in this man's management?

  - Reassure the patient that his symptoms will take some time to resolve.
  - Decrease his hydrocortisone dose to help him lose weight.
  - Check a morning cortisol level.
  - Check a serum free  $T_4$  level.
- A 44-year-old woman presents to the emergency department with a severe headache, which has been present constantly for 2 days and is not alleviated by analgesics at home. She has had dizziness and nausea but no vomiting. She takes oral contraceptive pills. Her blood pressure is 80/60 mm Hg and heart rate is 95 beats per minute. A contrast-enhanced MRI is ordered and reveals a 3-cm sellar mass with suprasellar extension and a large area of hemorrhage within the mass. Laboratory testing and a neurosurgical consult are

ordered. Of the following physical examination findings, which is the least likely to be present?

- A. Bitemporal hemianopsia
- B. Diplopia
- C. Tall stature
- D. Galactorrhea

### Answers

- 1. C
- 2. C
- 3. D
- 4. D
- 5. C

## Thyroid Disease

MATTHEW KIM

The principal function of the thyroid gland is to assist with the regulation of metabolism through the production and secretion of thyroid hormone. Two forms of thyroid hormone are produced by the thyroid: thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ). All the circulating  $T_4$  is produced within the thyroid, while 80% of circulating  $T_3$  is derived from conversion of  $T_4$  in the peripheral tissues.  $T_3$  mediates the physiologic function of almost all bodily tissues by binding to a specific nuclear receptor that regulates the transcription of dependent genes. The peripheral conversion of  $T_4$  to  $T_3$  is decreased by various medications including propranolol, glucocorticoids, propylthiouracil, and amiodarone. Peripheral conversion is also downregulated during the course of acute physiologic stress or illness.

The synthesis and release of thyroid hormone is controlled by pituitary-derived thyroid stimulating hormone (TSH) under the influence of thyrotropin releasing hormone secreted by the hypothalamus. TSH regulates the uptake and organification of iodine and the synthesis and secretion of thyroid hormone. Both  $T_3$  and  $T_4$  are bound to proteins in the circulation, preventing excessive tissue uptake while maintaining a readily accessible reserve of hormone. Several common medications (e.g., estrogen) affect levels of  $T_4$  binding globulin without generally affecting free thyroid hormone levels. Free  $T_4$  levels provide the most accurate reflection of the amount of active hormone present.

Although the thyroid is a relatively small organ in the body, thyroid disorders such as hyperthyroidism and hypothyroidism can cause profound systemic effects. Hyperthyroidism can be either transient or permanent depending on the etiology. Its incidence in adults appears to be independent of patient age. By contrast, the epidemiology of hypothyroidism is notable for an increasing incidence with advancing patient age. Nearly all thyroid illnesses (with only a few exceptions) demonstrate a substantial female predominance, although the underlying basis for this is unclear. Nodular thyroid disease is also quite common and often unrelated to gland function. Although most thyroid nodules are benign and inconsequential, some will prove to be malignant. The incidence of thyroid cancer has increased over the last two decades, although disease-related mortality remains very low.

A broader discussion ensues regarding screening for thyroid disease followed by a more in-depth discussion of the evaluation, treatment, and management of hyperthyroidism, hypothyroidism, and thyroid nodules.

### Screening for Thyroid Disease

Screening for hypothyroidism and hyperthyroidism is not recommended for the general population but may be considered for certain higher-risk individuals. It is reasonable to screen women aged >50 years with a sensitive TSH level given the increased prevalence of hypothyroidism in this population. Screening other high-risk populations may also be appropriate (Box 48.1). In particular, screening based on TSH measurement may be appropriate for the following cases: patients with evidence of Hashimoto disease or Graves disease in a first-degree relative; patients with other autoimmune diseases such as type 1 diabetes; patients with a history of any prior thyroid dysfunction, even if self-limited; patients living in an iodine-deficient region of the world; patients who are pregnant or attempting to conceive; and patients with conditions that may be explained or aggravated by hyperthyroidism including cardiac arrhythmias, weight loss, osteoporosis, and anxiety.

Particular attention should be paid to young women with hypothyroidism treated with levothyroxine replacement therapy who have either confirmed pregnancy or are attempting to conceive. During normal pregnancy, daily thyroid hormone requirements increase by approximately 30% to 40% above baseline beginning very early in gestation. In patients with hypothyroidism, doses of levothyroxine must be increased proportionately to provide adequate replacement. Failure to do so may result in maternal (and possibly fetal) hypothyroidism that may be associated with substantial morbidity to the mother and the fetus. For this reason, prepregnancy or pregnancy screening of women for underlying hypothyroidism is important. Women treated with levothyroxine should be counseled to contact their physician as soon as pregnancy is confirmed so that levothyroxine doses can be adjusted to maintain a euthyroid state throughout gestation. Finally, measurement of an annual TSH level is recommended in patients treated with levothyroxine because studies have shown that up to 30%

of these patients may be unintentionally undertreated or overreplaced.

Screening for thyroid nodules and thyroid cancer is not recommended. However, because most thyroid nodules are asymptomatic and unlikely to be noted by patients until very large, routine examination of the anterior neck is recommended during annual patient physicals. The anterior region of the neck should be palpated just below the cricoid cartilage. The patient should be asked to swallow during examination because this maneuver raises the thyroid and improves the sensitivity of detection of nodules. In general,

#### • BOX 48.1 Screening for Thyroid Dysfunction

- Examination of the thyroid is encouraged as part of an annual evaluation. Enlargement, asymmetry, or the presence of a palpable nodule should prompt further investigation.
- Population-wide screening for abnormal thyroid function is not recommended.
- Screening selective individuals is recommended given high rates of thyroid dysfunction as well as the greater potential for harmful effects. These populations include:
  - Women aged >50 years
  - Patients with first-degree relatives diagnosed with Hashimoto disease or Graves disease
  - Patients with autoimmune disorders such as type 1 diabetes mellitus or multiple sclerosis
  - Patients who have a history of prior thyroid dysfunction or are currently living in an iodine-deficient part of the world
  - Women who are currently pregnant or attempting to conceive
  - Patients in whom thyroid dysfunction may substantially aggravate or explain concurrent illness (such as atrial fibrillation or unexplained osteoporosis)

the left lobe, the right lobe, and isthmus should all be examined separately for overall size, symmetry, and the presence of palpable nodules.

## Hyperthyroidism

A diagnosis of hyperthyroidism should be considered in patients with signs or symptoms of thyrotoxicosis (Table 48.1) or in patients with diseases known to be caused or aggravated by thyrotoxicosis (such as atrial fibrillation). In hyperthyroidism, the TSH level is low or undetectable and the free  $T_4$  level is elevated. If the TSH level is suppressed and the free  $T_4$  level is normal, measure a  $T_3$  level.  $T_3$  thyrotoxicosis (suppressed TSH level, normal  $T_4$  level, and elevated  $T_3$  level) may be seen with increased frequency in patients with toxic multinodular goiters and autonomously functioning thyroid nodules. Physicians should look for apathetic thyrotoxicosis in elderly patients. This profile is characterized by a lower frequency of goiter (found in 50%), fewer hyperadrenergic symptoms, and a predominance of cardiac findings including heart failure and atrial fibrillation. Patients with a low or undetectable TSH level and a normal free  $T_4$  level have mild or subclinical hyperthyroidism. Typically, the TSH level is only mildly suppressed in this situation with a value between 0.1 and 0.5 mIU/L. This distinction is important as subclinical hyperthyroidism can be followed with periodic thyroid function tests in otherwise healthy patients <60 years old.

Most thyrotoxicosis is caused by Graves disease or thyroiditis. Rarely a toxic adenoma, toxic multinodular goiter, factitious thyrotoxicosis attributed to thyroid hormone consumption, or secretion of thyroid hormone from struma ovarii may be causative. Pregnant women are often found to have mild to moderately suppressed TSH levels during the

**TABLE 48.1** Common Signs and Symptoms of Hyperthyroidism and Hypothyroidism

Hyperthyroidism	Hypothyroidism
<p><b>Common Symptoms</b></p> <ul style="list-style-type: none"> <li>• Nervousness or emotional lability</li> <li>• Insomnia</li> <li>• Increased sweating</li> <li>• Heat intolerance</li> <li>• Palpitations</li> <li>• Fatigue</li> <li>• Weight loss</li> <li>• Hyperdefecation</li> <li>• Menstrual irregularity</li> </ul> <p><b>Common Signs</b></p> <ul style="list-style-type: none"> <li>• Tremors</li> <li>• Tachycardia or evidence of atrial fibrillation</li> <li>• Proptosis of the eyes or extraocular muscle palsy</li> <li>• Stare, lid lag, or signs of Graves orbitopathy</li> <li>• Goiter</li> <li>• Pretibial myxedema</li> </ul>	<p><b>Common Symptoms</b></p> <ul style="list-style-type: none"> <li>• Fatigue and excessive sleep</li> <li>• Weight gain</li> <li>• Alopecia</li> <li>• Cold intolerance</li> <li>• Sluggish affect or depression</li> <li>• Fluid retention</li> <li>• Delayed deep tendon reflexes</li> <li>• Poor concentration</li> <li>• Constipation</li> </ul> <p><b>Common Signs</b></p> <ul style="list-style-type: none"> <li>• Dry coarse skin and hair</li> <li>• Periorbital swelling</li> <li>• Bradycardia</li> <li>• Slow movements and speech</li> <li>• Hoarseness</li> <li>• Goiter</li> <li>• Dementia or confusion</li> </ul>

first trimester as a result of physiologic stimulation of the thyroid by human chorionic gonadotropin (hCG). This is self-limited and not pathologic. Occasionally, however, differentiation between physiologic TSH suppression during pregnancy caused by hCG stimulation and true hyperthyroidism can be difficult. In such cases, endocrine consultation should be considered. A rare but important form of thyrotoxicosis may be triggered by a reaction to amiodarone administration. Thyrotoxicosis in this setting can be caused by different mechanisms, and endocrine consultation is required.

In almost all cases, a radioactive iodine uptake study is the best test to differentiate between thyrotoxicosis caused by excess thyroid hormone production (Graves disease, a toxic adenoma, or toxic multinodular goiter) and increased hormone release from a damaged thyroid (thyroiditis). An elevated uptake is consistent with excess thyroid hormone production (Fig. 48.1), whereas a suppressed uptake (usually <5% at 24 hours) is consistent with release of hormone from an inflamed thyroid gland. An uptake study should not be performed if a patient is suspected or confirmed to be pregnant. Patients with acute nonthyroidal illness may have TSH suppression that is part of the underlying euthyroid sick syndrome and not caused by underlying thyrotoxicosis. The free  $T_4$  level is most often normal or low in this setting. Additional testing over a period of days or weeks may be required to conclusively confirm a diagnosis of euthyroid sick syndrome.

Thyroid storm is defined as a life-threatening condition manifested by an exaggeration of the clinical signs and symptoms of thyrotoxicosis accompanied by systemic decompensation. It is usually caused by rapid release of thyroid hormone in the setting of extreme physiologic stress or illness. Most often a diagnosis of thyroid storm is made when hyperthyroidism also causes coexistent cardiovascular, neurologic, or gastroenterologic dysfunction. Early recognition, prompt hospitalization, and consultation with endocrinology are the keys to a successful outcome. Thyroid storm is a clinical diagnosis, and there is no degree of thyroid hormone elevation that is diagnostic of the illness.

The risks of hyperthyroidism are primarily related to arrhythmias, cardiomyopathy, bone loss, and the persistence of a hypermetabolic state. Graves ophthalmopathy (soft tissue swelling, proptosis, extraocular muscle dysfunction, and optic neuropathy) may be present in 10% to 25% of affected patients, although subclinical enlargement of extraocular muscles may be present in up to 50% to 70% of patients without overt eye findings. Pretibial myxedema (infiltrative dermatopathy characterized by nonpitting scaly thickening and induration of the skin) is a rare complication of Graves disease. Once it has been treated effectively, the overall risk associated with hyperthyroidism can be substantially diminished. Early in the treatment of thyrotoxicosis, restriction of exercise and avoidance of exposure to excessive amounts of iodine (including the contrast agents used in CT scans) may be recommended.

If thyroiditis is suspected, conservative follow-up with serial measurement of thyroid hormone profiles checked over a 3- to 4-month period may be indicated. Thyrotoxicosis caused by thyroiditis is usually managed conservatively because it is often self-limited. Beta-blockers can be used to treat sympathomimetic symptoms including tachycardia, tremor, and anxiety. Nonsteroidal antiinflammatory drugs or glucocorticoids can also be administered to reduce inflammation and discomfort. For patients with Graves disease and autonomously functioning thyroid nodules, antithyroid drugs or radioactive iodine treatment ( $^{131}\text{I}$ ) should be considered (Box 48.2). Patient preference, age, comorbidity, severity of thyrotoxicosis, and the presence of Graves ophthalmopathy must be considered when selecting a treatment modality. Antithyroid drugs are used as principal therapy for the treatment of hyperthyroidism to approximate a euthyroid state. They may also be administered in preparation for eventual radioactive iodine treatment, or as preparation for thyroid surgery in selected patients. Antithyroid drugs are preferred to radioactive iodine treatment in the presence of severe Graves ophthalmopathy and thyroid storm. Many patients in the United States ultimately select radioactive iodine treatment as therapy for hyperthyroidism caused by Graves disease, toxic multinodular goiter,

• **Fig. 48.1** Radioactive iodine uptake scans. Both images are of hyperthyroid patients with suppressed TSH levels. (A) Left toxic adenoma: a large left-sided toxic hot adenoma, with relative suppression of right-sided activity. (B) Graves disease: bilateral diffuse uptake consistent with Graves disease.

or an autonomously functioning thyroid nodule. Radioactive iodine treatment is also indicated in patients who fail to achieve remission after a course of treatment with antithyroid drugs. When administered, radioactive iodine is likely to cause permanent thyroid destruction requiring lifelong levothyroxine replacement therapy.

When treatment with antithyroid drugs is indicated, methimazole is effective in most cases. It is usually started at an oral dose of 10 to 40 mg daily. Alternatively, propylthiouracil may be preferred for pregnant patients or those with

### • BOX 48.2 Initial Treatment Regimens for Hyperthyroidism

#### Etiology: Unregulated Production of Excessive Thyroid Hormone

##### Possible Diagnosis

Graves disease  
Functional (hot) nodule or toxic adenoma  
Toxic multinodular goiter  
Pregnancy (late first trimester)

##### Biochemical and Laboratory Findings

Suppressed thyroid-stimulating hormone (TSH) level  
Elevated  $T_4$  (or  $T_3$ ) level  
Detectable (or elevated) iodine uptake on thyroid scintigraphy  
(Note: radionuclide imaging is contraindicated in any pregnant individual)

##### Treatment

If pregnant, involve endocrine and high-risk obstetric services.

In all other cases, consider:

- Methimazole (starting dose: 10–20 mg daily; 5–60 mg daily titrated to normalization of free  $T_4$  level) or propylthiouracil (starting dose: 50–150 mg twice or 3 times daily; 100–900 mg total daily dose titrated to normalization of free  $T_4$  levels)
- Beta-blocker (titrated to avoid hypotension, yet reduce heart rate modestly)
- Inorganic iodine (e.g., SSKI; starting dose: three drops in 8 oz. liquid twice daily for 7 d). This is rarely needed, only in severe cases.

#### Etiology: Release of Preformed (Stored) Thyroid Hormone

##### Possible Diagnosis

Silent thyroiditis  
Postpartum thyroiditis  
Painful (DeQuervain) thyroiditis

##### Biochemical and Laboratory Findings

Suppressed TSH level  
Elevated  $T_4$  (or  $T_3$ ) level  
Undetectable (or absent) iodine uptake on thyroid scintigraphy

##### Treatment

Conservative therapy usually indicated unless patient severely symptomatic. As needed, consider:

- Beta-blocker (titrated to avoid hypotension, yet reduce heart rate modestly)
- Glucocorticoid (rarely needed for severe pain and thyroid inflammation; starting dose prednisone 20–40 mg daily for 7 d)

SSKI, Saturated solution of potassium iodine;  $T_3$ , triiodothyronine;  $T_4$ , thyroxine.

an allergy to methimazole. Recent data suggest that propylthiouracil may be associated with an increased risk of fulminant hepatic failure. When administered, propylthiouracil is usually started at a dose of 50 to 150 mg two to three times daily, depending on the severity of the illness. With either drug, patients should be counseled about the risk of hepatitis and agranulocytosis, both rare but with potentially severe side effects. Propylthiouracil has also been associated with vasculitis and concomitant renal dysfunction. If immediate control of severe thyrotoxicosis is required, inorganic iodine in the form of Lugol's solution or saturated solution of potassium iodine can be administered. This therapy is self-limited in duration (usually ~3 weeks) and precludes further use of radioactive iodine for months thereafter. Subtotal thyroidectomy is a rarely considered but reasonable option to consider when managing hyperthyroid patients with concomitant malignant or suspicious thyroid nodules. Patients who cannot tolerate antithyroid drugs and refuse to be treated with radioactive iodine may also be candidates for thyroid surgery.

Managing Graves hyperthyroidism during pregnancy can be difficult given the differential effects of antithyroid drugs on the fetus in comparison to the mother. In general, the developing fetus is much more sensitive to both methimazole and propylthiouracil. A biochemical euthyroid state in the mother does not predict safe and normal development of the fetus. As a rule, endocrine consultation should be sought in these situations, and the lowest effective dose of antithyroid medication should be administered.

Graves ophthalmopathy is often treated conservatively in patients with mild to moderate disease. In more severe cases, a course of intravenous or oral glucocorticoids may be considered, although it should be administered by physicians with expertise and experience with this illness. Rarely, surgical decompression of the orbit may be required to preserve vision.

## Hypothyroidism

Hypothyroidism may present with a wide range of clinical symptoms and signs (see Table 48.1). The TSH level increases when the thyroid itself begins to fail (primary hypothyroidism) and is low or normal in conjunction with a low free  $T_4$  level in rare cases of hypothyroidism caused by pituitary or hypothalamic disease (secondary hypothyroidism). Patients with a mildly elevated TSH level (5–10 mIU/mL) and a normal free  $T_4$  level have mild or subclinical hypothyroidism. This distinction is important because patients with subclinical hypothyroidism may not require treatment if asymptomatic and not currently pregnant or desiring pregnancy.

The most common underlying causes of hypothyroidism are chronic lymphocytic thyroiditis (Hashimoto disease), prior thyroid surgery, treatment with head or neck radiation, or a history of radioactive iodine treatment. Hashimoto disease is an autoimmune disorder that may present at any age but increases in prevalence with aging. Its onset

is usually insidious and may be associated with a visible or palpable goiter. The presence of elevated concentrations of antithyroid peroxidase antibodies in the serum is highly correlated with the presence of Hashimoto disease and can be useful in confirming a suspected diagnosis or assessing the risk of developing hypothyroidism in the future. Subacute and painful thyroiditis are other illnesses that may lead to hypothyroidism, although most patients follow a triphasic thyroid hormone response characterized by mild thyrotoxicosis that gives way to mild hypothyroidism followed by normalization of TSH levels. This triphasic pattern occurs over a 2- to 4-month interval. If the final phase of TSH normalization is impaired, hypothyroidism may persist. This occurs most often in patients with positive antithyroid peroxidase antibodies.

Levothyroxine is the preferred agent selected for the treatment of hypothyroidism. It safely, effectively, and reliably relieves symptoms while normalizing thyroid hormone levels in hypothyroid patients. Levothyroxine is converted to  $T_3$  (the active hormone) in peripheral tissues at an appropriate rate to meet overall metabolic needs. Treatment with a combination of  $T_4$  and  $T_3$  is not usually recommended. Although all patients with overt hypothyroidism (TSH level  $>10$  mIU/L) should be treated, there is limited evidence that treatment of subclinical hypothyroidism is beneficial in nonpregnant asymptomatic patients. Most patients with subclinical hypothyroidism can be safely followed with TSH levels checked every 4 to 6 months to monitor for progression of disease. This recommendation excludes women who are currently pregnant or attempting to conceive who should be treated once a TSH level is above the normal range because of greater maternal and fetal risk.

During initial management, the degree of hypothyroidism should be assessed in affected individuals. Biochemical and clinical parameters often correlate, although at times they may be discordant. For patients with severe hypothyroidism (TSH level  $>100$  mIU/L), several important factors must be considered when thyroid hormone replacement is instituted. Importantly, morbidity and mortality in such patients are most often related to simultaneous (although often silent) infection, hypoventilation, or medication overdose. For these reasons sedatives and narcotics should be avoided or administered at significantly reduced doses to compensate for reduced drug clearance associated with hypothyroidism. For patients with mild-to-moderate hypothyroidism, these considerations usually do not apply.

A full daily replacement dose of levothyroxine can be approximated by multiplying  $0.8 \mu\text{g} \times$  the patient's weight (lbs). The severity of hypothyroidism should determine the urgency of thyroid hormone replacement. Whenever possible, a modest dose of levothyroxine ( $50\text{--}75 \mu\text{g}$  daily) is preferred during the first week of therapy in patients who are not in acute danger. Mild-to-moderate hypothyroidism can often be treated with 50 to  $100 \mu\text{g}$  of levothyroxine daily. An acute rise in thyroid hormone concentration can rarely increase cardiac demand to a level that precipitates ischemia. For this reason, caution should be exercised in patients who

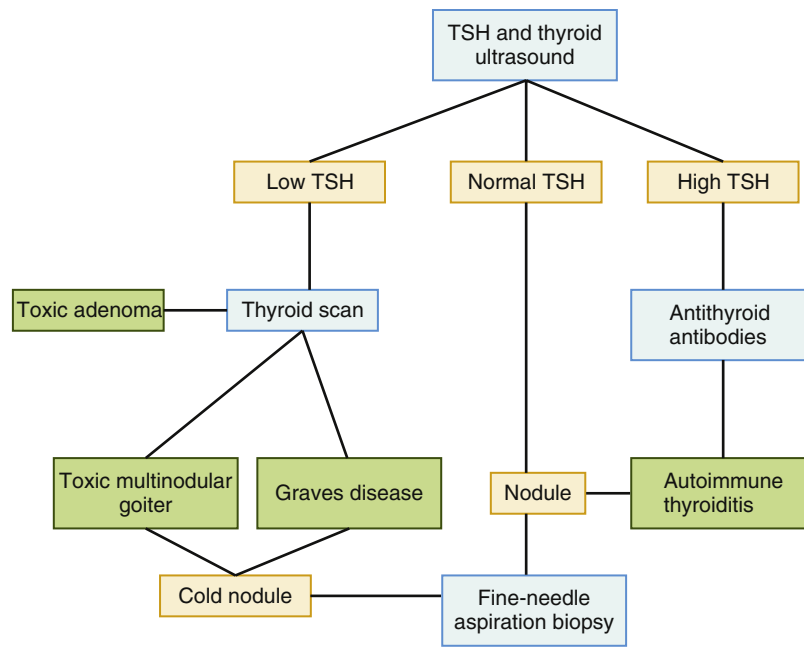

are over 80 years of age or have known or suspected coronary artery disease. Higher-risk patients can be started on treatment with 12.5 to  $25 \mu\text{g}$  of levothyroxine daily with provisions to gradually increase doses in smaller increments. Once initiated, levothyroxine treatment is usually lifelong. The target TSH level in patients on treatment should be within the normal range. Over the long term, most patients can be safely monitored with TSH levels checked every 6 to 12 months. Levothyroxine should be taken on an empty stomach at least 4 hours before or after ingestion of agents that may impair absorption including iron supplements, bile acid resins, and high doses of calcium supplements. In situations where patients cannot take oral medications, intravenous levothyroxine can be administered daily at a dose decreased to 75% of a patient's usual oral dose.

Myxedema coma is a rare and extreme form of hypothyroidism manifested by features such as delayed reflexes, sparse hair, dry skin, and puffy or edematous facies. It is considered to be a life-threatening manifestation of severe hypothyroidism. Frequently, hypothermia (core temperature  $<95^\circ\text{F}$ ) as well as impaired cardiovascular, neurologic, and gastroenterologic function may be documented. Similar to thyroid storm, myxedema coma is a clinical diagnosis, and no specific TSH level or thyroid hormone level defines this illness. Treatment is with thyroid hormone administration. Because this condition may be fatal, both  $T_4$  and  $T_3$  preparations are often used initially following consultation with an endocrinologist. Intravenous preparations are often preferred because hypothyroidism-associated bowel edema can impair the absorption and action of oral preparations. The possibility of unrecognized adrenal insufficiency should be considered. In severe cases, concomitant treatment with thyroid hormone and glucocorticoids may be warranted.

## Thyroid Nodules

Thyroid nodules are common, occurring more frequently in women and with increasing age. Most nodules are asymptomatic and come to attention as a mass palpated during a routine physical examination or as an incidental finding on an imaging procedure performed for another indication. Differentiating malignant nodules from benign nodules is the most important consideration. A secondary consideration for evaluation is nodule size because some large nodules (usually larger than 4 cm in diameter) can cause tracheal deviation or compressive symptoms prompting further intervention. However, most clinically relevant nodules measure between 1 and 3 cm in diameter, are nonmalignant, and cause no adverse symptoms. Such nodules are almost always followed conservatively without further intervention or surgery.

Approximately 10% to 15% of thyroid nodules  $>1$  cm prove to be malignant. This provides the rationale for investigating patients with nodular disease. Ironically, thyroid cancers  $<1$  cm in diameter (often termed *microcarcinomas*) are almost always indolent and pose little or no risk to the patient. Epidemiologic evidence suggests that

• **Fig. 48.2** Evaluation of a patient with a thyroid nodule larger than 1 cm in diameter. *TSH*, Thyroid stimulating hormone.

the properties of well-differentiated thyroid carcinomas appear to change once growth exceeds 1 cm in diameter. Tumors that grow to this size increasingly gain the potential to invade, spread, and ultimately metastasize. There are few exceptions to this dogma, most of which are primary well-differentiated thyroid cancers measuring 8 to 9 mm in size. Given these findings, combined with known interobserver variability associated with ultrasound and histopathologic measurement of tumors, consensus expert opinion has recommended that only thyroid nodules >1 cm in diameter undergo further evaluation in a typical patient without risk factors.

In patients with one or more thyroid nodules >1 cm in diameter, initial evaluation is assessment of thyroid function. This is most accurately measured by checking a TSH level. Patients with suppressed TSH levels (~5%–10%) may have one or more autonomously functioning nodules (see Fig. 48.1A). This is important because such nodules pose virtually no risk of being malignant and are often treated with radioactive iodine. Patients with normal or elevated TSH levels should be referred for fine-needle aspiration biopsy (FNAB; Fig. 48.2). Most experts recommend that FNAB be performed with ultrasound guidance because improved accuracy and decreased diagnostic error (false-negative results) have been demonstrated. Aspiration of a thyroid nodule is a safe and relatively painless procedure in most cases, especially when performed by an experienced clinician.

Findings from FNAB cytology determine further evaluation or intervention. Approximately 66% of aspirates will reveal no evidence of malignancy. This is a highly accurate diagnosis when the aspirate is performed with ultrasound guidance. Such nodules are considered benign, and 1- to 2-year follow-up with repeat imaging is generally recommended. It is currently believed that benign thyroid

nodules do not transform into malignant lesions. Rather, slow growth over time is often expected, often at the rate of 1 mm or less annually. Growth beyond this rate may prompt repeat evaluation, although data are insufficient to provide clear recommendations. Approximately 10% of aspirates will be insufficient for evaluation (nondiagnostic) on initial FNAB. In such cases repeat FNAB is recommended because a diagnostic sample is often obtained on the second attempt. The remaining aspirates (~25%) return results that are either positive or suspicious for malignancy. Often such cytology varies in terms of final terminology used to describe abnormal cellular features. Patients with suspicious or indeterminate nodules are usually told that malignancy cannot be excluded based on cytology findings. Additional FNAB samples can be submitted for mutation analysis or genetic expression classifier testing that can help to further stratify the risk of possible malignancy. Surgical hemithyroidectomy or near-total thyroidectomy is often required for diagnostic purposes. If pathology from a hemithyroidectomy confirms that an indeterminate nodule is benign, no additional surgery should be necessary.

Importantly, the risk of cancer is similar in patients with solitary nodules >1 cm when compared with those with multiple nodules each measuring >1 cm. Because of this, patients with multinodular goiters usually undergo aspiration of all nodules that are >1 cm. Thyroid hormone administration targeted to the goal of suppressing TSH levels should not be used in the evaluation and treatment of patients with nodular thyroid disease. Randomized controlled trials of this intervention have shown no effect on nodule size, and exposure to excessive levels of thyroid hormone can have adverse effects on the cardiovascular and skeletal systems.

## Summary

Thyroid disorders are common. Given the association of most thyroid illness with female sex and increasing patient age, it is likely that the number of patients diagnosed with such illness in the United States will greatly increase over the next 30 to 50 years. Understanding the common presentations of hyperthyroidism, hypothyroidism, and

nodular thyroid disease is critical for effective diagnosis and subsequent care of the patient. Although many types of thyroid illnesses can be effectively managed by primary care physicians, complex cases involving severe disease, unique situations, or thyroid illness during pregnancy should prompt consultation with an endocrinologist. Fortunately, most thyroid illnesses are readily treatable in experienced hands.

## Chapter Review

### Questions

1. A 29-year-old woman who works as a jewelry maker presents with restlessness, difficulty concentrating at work, and a tremor that has been apparent for the past 6 weeks. She also complains of feeling hot and has had difficulty sleeping. Although noting increased intake of food, she reports that her weight has decreased by 11 lbs over the past 2 months. On physical examination, the patient's temperature is 99.5°F, heart rate is 101 beats per minute, respiratory rate is 22 breaths per minute, and blood pressure is 145/85 mm Hg. Which finding is most likely to be present in this woman?
  - A. Decreased catecholamines
  - B. Decreased iodine uptake
  - C. Decreased plasma insulin
  - D. Decreased TSH
  - E. Increased adrenocorticotropic hormone
  - F. Increased calcitonin
2. A 62-year-old woman has noted painless enlargement of the lower anterior region of her neck over the past 6 months. On physical examination she has diffuse, symmetric thyroid enlargement without tenderness. FNAB of the thyroid yields cells suspicious for malignancy. She has normal thyroid function tests but an elevated serum calcitonin level of 42 pg/mL. A thyroidectomy is performed. Pathology reveals malignant cells with positive staining for calcitonin. In the stroma, green birefringence on Congo red staining is seen. The most likely diagnosis is:
  - A. Papillary thyroid carcinoma
  - B. Medullary thyroid carcinoma
  - C. Anaplastic thyroid carcinoma
  - D. Follicular thyroid carcinoma
  - E. Parathyroid carcinoma
3. A 49-year-old woman reports increasing cold intolerance, feelings of being tired and sluggish, and a weight gain of 8 lbs over the past 18 months. Physical examination reveals dry coarse skin and alopecia of the scalp. Her thyroid is not palpably enlarged. Her TSH level is 18.7 mIU/L with a total T<sub>4</sub> level of 3.1 µg/dL. On further workup, antithyroid peroxidase antibodies are detected at a high titer. Which of the following disorders is she most likely to have?
  - A. DeQuervain thyroiditis
  - B. Papillary carcinoma
  - C. Hashimoto disease
  - D. Nodular goiter
  - E. Graves disease
4. Which one of the following statements about propylthiouracil is true?
  - A. The US Food and Drug Administration has issued a notice of serious liver injury associated with propylthiouracil use.
  - B. Propylthiouracil is first-line therapy for Graves disease.
  - C. Methimazole should be used in place of propylthiouracil in the first trimester of pregnancy.
  - D. Propylthiouracil is recommended in pediatric patients unless the patient is allergic to it, in which case methimazole should be used.
  - E. Propylthiouracil administration is contraindicated in breastfeeding women.
5. Which one of the statements regarding the effect of amiodarone on the thyroid is false?
  - A. In the United States, amiodarone-associated thyrotoxicosis is much more commonly seen than amiodarone-associated hypothyroidism.
  - B. Each 200-mg tablet of amiodarone is estimated to contain about 75 mg of organic iodide.
  - C. Amiodarone and its metabolites may have a direct cytotoxic effect on the thyroid follicular cells, which causes a destructive thyroiditis.
  - D. TSH levels usually rise after the start of amiodarone therapy but return to normal in 2 to 3 months.
  - E. Amiodarone-induced hypothyroidism does not necessitate discontinuation of amiodarone administration, as levothyroxine can be administered simultaneously.

### Answers

1. D
2. B
3. C
4. A
5. A

## Reproductive and Androgenic Disorders

MARIA A. YIALAMAS

Abnormalities in female and male reproduction include disruption of the endocrine function of end organs, such as the ovaries and testes, but may also encompass abnormal function of the pituitary, adrenal, and thyroid glands. Causes may be genetic or congenital or acquired from tumors or infiltrative or infectious diseases. Understanding these disorders requires knowledge of some basic physiology. Here we consider common diseases that might come up on the board examination.

### Female Reproductive Endocrinology

Normal menstrual cycle function requires careful coordination between the hypothalamus, pituitary gland, and ovaries. The hypothalamus releases gonadotropin-releasing hormone (GnRH) in a pulsatile manner. The frequency of the GnRH pulses varies across the menstrual cycle to promote follicular development and ovulation. GnRH stimulates the pituitary gland to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH and LH stimulate the ovaries for follicular development with subsequent estrogen, progesterone, inhibin A, and inhibin B production.

A normal menstrual cycle length is 25 to 35 days. Menstrual cycles <25 days or >35 days are likely anovulatory. The follicular phase can vary in length from cycle to cycle; the luteal phase is typically constant at 12 to 14 days. Menstrual disorders can occur as a result of a defect in the hypothalamus, pituitary gland, or ovary.

Here we review the evaluation and etiologies of amenorrhea with a special emphasis on hypothalamic amenorrhea (HA) and polycystic ovary syndrome (PCOS).

### Amenorrhea

Primary amenorrhea is defined as the absence of menses by age 16, and secondary amenorrhea is defined as the absence of menses for a period of 3 months. The pathophysiologic considerations are the same for both primary and secondary amenorrhea, but uterine and outflow tract abnormalities are much more common in patients with primary amenorrhea.

The most common cause of amenorrhea is pregnancy, and this diagnosis must always be excluded. The other two main categories to consider are ovulatory disorders and structural disorders of the uterus or outflow tract. Ovulatory disorders are caused by impaired hormone production at the hypothalamus and/or pituitary gland or ovary.

### Hypothalamic and Pituitary Gland Disorders

In menstrual cycle disorders caused by hypothalamic and/or pituitary gland defects, estradiol is low, and FSH and LH are low or normal (hypogonadotropic hypogonadism). There are many etiologies for hypogonadotropic hypogonadism, the most common of which is functional HA. HA occurs because of a stress to the system, whether physical or psychological, or from an energy imbalance in which energy output exceeds energy input. This energy imbalance can be observed in women with eating disorders, weight loss, or those undertaking excessive exercise. Leptin appears to be the hormone that signals to the brain that there are adequate fat stores and proper energy balance for reproduction. This important role of leptin was delineated in a study in which physiologic doses of leptin were administered to women with HA with follicle growth and to those who were ovulating. Recovery of menstrual function in women with HA depends on the etiology, with stress and weight loss having the best prognoses.

Other common etiologies for hypogonadotropic hypogonadism include hyperprolactinemia and thyroid disease (hypothyroidism or hyperthyroidism). Other less-common etiologies include Sheehan syndrome, lymphocytic hypophysitis, hypothalamic or pituitary tumors, infiltrative diseases (i.e., hemochromatosis, sarcoidosis, tuberculosis), and genetic disorders such as idiopathic hypogonadotropic hypogonadism/Kallmann syndrome.

### Ovarian Dysfunction (Spontaneous Primary Ovarian Insufficiency/Premature Ovarian Failure)

In menstrual cycle disorders caused by ovarian dysfunction (hypergonadotropic hypogonadism) estradiol is low, and FSH and LH are elevated. Primary ovarian insufficiency

**TABLE 49.1 1990 NIH Criteria and Rotterdam Criteria for the Diagnosis of Polycystic Ovary Syndrome**

NIH Criteria	Rotterdam Criteria
Oligo/anovulation and hyperandrogenism	Two of the following: <ul style="list-style-type: none"> <li>• Oligo/anovulation</li> <li>• Hyperandrogenism</li> <li>• Polycystic ovary morphology</li> </ul>

*NIH*, National Institutes of Health.

(POI) is defined as a woman <40 years of age with amenorrhea and an elevated FSH. The FSH should always be repeated in the follicular phase to confirm the diagnosis. Etiologies of POI include Turner syndrome, X chromosome deletions/translocations, fragile X premutations, autoimmune disease, chemotherapy, or radiation therapy to the pelvic area. In patients with POI, diagnostic testing should include a karyotype, especially in women <35 years of age. Many women with Turner syndrome demonstrate mosaicism and may not have the full features of Turner syndrome on physical examination, and therefore they can only be diagnosed on karyotype testing. Fragile X premutation carriers have increased risk of POI; therefore screening is important because women with POI may intermittently ovulate and conceive. Antiovarian antibodies have no utility because of their low specificity, and ovarian biopsy is not helpful in most cases.

### Polycystic Ovary Syndrome

PCOS is a common cause of amenorrhea as well as irregular menses. It is a complicated disorder characterized by increased ovarian androgen production, disordered GnRH pulsatility, and insulin resistance. In 1990 a National Institutes of Health (NIH) conference defined PCOS as a disorder characterized by oligomenorrhea and either biochemical or clinical evidence of hyperandrogenism in the absence of other known disorders such as thyroid disease, hyperprolactinemia, and congenital adrenal hyperplasia. Using these criteria, studies have shown a prevalence of PCOS of 4% to 7% in reproductive-aged women. In fact, PCOS may be the most common endocrinopathy in young women and is the most common cause of female infertility. In 2003 the definition for PCOS was revisited by the American Society for Reproductive Medicine and European Society for Human Reproduction and Embryology (Table 49.1). The new Rotterdam criteria stated that PCOS was present if two of the following three criteria were present in the absence of other known disorders: (1) oligoovulation or anovulation; (2) clinical and/or biochemical evidence of hyperandrogenism; and (3) polycystic ovary morphology (PCOM). PCOM was defined when at least one ovary is at least 10 cm<sup>3</sup> in volume or has 12 or more follicles, 2 to 9 mm in diameter.

The main clinical manifestations of PCOS are oligoovulation or anovulation, hyperandrogenism, infertility, and insulin resistance. The oligoovulation and anovulation can lead to infertility as well as endometrial hyperplasia and

increased risk of endometrial cancer. Hyperandrogenism can present as hirsutism, acne, and/or alopecia. One of the clinically most worrisome features of PCOS is the insulin resistance that can be present. The prevalence is not trivial, with as many as 31% to 35% with impaired glucose tolerance and 7.5% to 10% with type 2 diabetes as defined by the oral glucose tolerance test. Because insulin resistance has been demonstrated in lean women as well as obese women with PCOS, there appears to be an intrinsic insulin resistance that is present in this disorder. Therapeutic studies in PCOS women have shown that reductions in insulin resistance with weight loss, metformin, and thiazolidinediones result in a decrease in serum androgen levels and/or serum LH levels. In fact, patients treated with metformin or thiazolidinediones have not only improved insulin sensitivity, androgen levels, and LH levels but also improved ovulatory rates. These data strongly suggest that the underlying insulin resistance of PCOS is responsible for the oligomenorrhea and hyperandrogenism seen in this disorder.

More recent studies have suggested that the insulin resistance observed in women with PCOS confers an increased risk of fatty liver disease, metabolic syndrome, and sleep apnea.

### Uterine/Outflow Tract Disorders

Uterine/outflow tract disorders are characterized by normal estradiol, FSH, and LH levels. Many of these disorders present as primary amenorrhea in adolescence. Etiologies include absent cervix, imperforate hymen, and Mayer-Rokitansky-Küster-Hauser syndrome (absent vagina and/or uterus). Androgen insensitivity syndrome can also present with amenorrhea; this syndrome is diagnosed with a karyotype. In adults, amenorrhea caused by Asherman syndrome can occur after instrumentation or infections of the uterus.

### Evaluation of the Patient with Amenorrhea

#### History

Because of the many possible etiologies described previously, a detailed history must be obtained from patients who present with amenorrhea. Important historical points include unprotected sexual intercourse to assess for the possibility of pregnancy. A history of headaches or neurologic symptoms, galactorrhea, or excessive exercising or dieting may point to a hypothalamic or pituitary etiology. Because thyroid disease is so common in women, a careful review of signs and symptoms of hypothyroidism and hyperthyroidism should be discussed with the patient. Hot flushes, night sweats, and insomnia may make POI a likely diagnosis. Classic symptoms for outflow tract obstruction or uterine abnormalities include cyclic menstrual pain or premenstrual symptoms without menses.

#### Physical Examination

Important physical examination findings begin with the general appearance of the patient, especially young women with primary amenorrhea. Assess these patients for any evidence of Turner syndrome, and note the amount of breast development. The skin examination is also extremely

### • BOX 49.1 Laboratory Evaluation of Amenorrhea

- $\beta$ -human chorionic gonadotropin (rule out pregnancy)
- Follicle-stimulating hormone (best test for ovarian function)
- Prolactin
- Thyroid-stimulating hormone

If all laboratory data normal: progesterone challenge

The initial laboratory evaluation for amenorrhea assesses for pregnancy, premature ovarian failure, hyperprolactinemia, and thyroid disease.

important. For example, hirsutism, acne, and male pattern balding may indicate that PCOS is the etiology of the menstrual abnormality. Vitiligo may indicate autoimmune disease and increase the probability of POI. Other aspects of the examination that should be carefully assessed include the thyroid examination, the presence of galactorrhea, the neurologic examination with a special focus on the visual field examination, and the pelvic examination to assess the external genitalia as well as the uterus and ovaries.

#### Laboratory Evaluation and Diagnostic Tests

Every patient with amenorrhea should have human chorionic gonadotropin (hCG), prolactin, thyroid-stimulating hormone (TSH), and FSH tests to exclude pregnancy, hyperprolactinemia, thyroid disease, and POI, respectively. FSH is the single best marker of ovarian reserve; LH and estradiol are not needed in the initial evaluation (Box 49.1). If any signs or symptoms of hyperandrogenism are present and PCOS is suspected, a total testosterone and dehydroepiandrosterone (DHEAS) should be drawn to exclude an ovarian or adrenal neoplasm. Levels that increase suspicion of a malignancy include a testosterone >200 ng/dL and a DHEAS >800  $\mu$ g/dL.

Often all the laboratory test results return normal, and the underlying etiology of the amenorrhea is unclear. In these cases, a progesterone challenge test is helpful. If there is no withdrawal bleed, this indicates a low-estrogen state and possibly a hypothalamic or pituitary etiology for the amenorrhea. If there is a withdrawal bleed, this indicates adequate estrogen production and PCOS as the possible diagnosis.

The question of whether a woman with HA needs pituitary MRI often arises. Most women diagnosed with HA do not require brain imaging. Exceptions include patients with an elevated prolactin (even if it is a mild elevation), headaches or neurologic symptoms, or primary amenorrhea that is caused by hypogonadotropic hypogonadism or if an underlying etiology for the HA cannot be elicited.

For patients with amenorrhea caused by a low-estrogen state (hypothalamic and pituitary sources as well as POI), bone mineral density testing to assess for bone loss caused by estrogen deficiency may be considered if the amenorrhea has been present longer than 6 months.

#### Treatment

##### Hypothalamic Amenorrhea

Treatment includes changing the energy imbalance by increasing weight or decreasing exercise. Oral contraceptive

pills (OCPs) and calcium and vitamin D supplements are also important to preserve bone health. If fertility is desired, gonadotropins are administered.

##### Primary Ovarian Insufficiency

A major concern for women with POI is the preservation of bone health, and therefore OCPs or hormone replacement therapy is prescribed.

##### Polycystic Ovary Syndrome

Treatment options for PCOS target the symptom most problematic for the patient. If the most concerning symptom is the hyperandrogenism, the most commonly prescribed treatment is an OCP, sometimes with the antiandrogen spironolactone. OCPs are also useful for providing endometrial protection for women with anovulation. For those women with anovulation who do not wish to be on OCPs, treatment with cyclic progesterone is another option to promote endometrial protection. Other possible treatment options for the hyperandrogenism and oligomenorrhea include weight loss and metformin. For infertility, clomiphene is the most commonly prescribed treatment, often in conjunction with metformin and weight loss.

## Male Reproductive Endocrinology

The hypothalamic-pituitary-testicular axis tightly regulates testosterone production in men. GnRH is released in a pulsatile fashion approximately every 2 hours and stimulates the pituitary gland to produce LH and FSH, which in turn stimulate testosterone production and spermatogenesis in the testes. Testosterone plays a number of important physiologic roles in men. It is necessary for virilization, normal sexual function, and normal bone and muscle mass.

The following section reviews the diagnosis and evaluation of male hypogonadism.

### Male Hypogonadism Symptoms

Symptoms of hypogonadism include low libido, erectile dysfunction, infertility, fatigue, low mood, decreased strength, and gynecomastia. Many of these symptoms are nonspecific; therefore the diagnosis of hypogonadism is difficult to obtain on history alone in many cases.

#### Physical Examination

The physical examination is extremely important when evaluating a patient for hypogonadism. Important signs include the presence of eunuchoidal proportions, the distribution of body hair, the presence of gynecomastia, and, most importantly, the testicular size.

#### Laboratory Assessment

Because the symptoms of hypogonadism are nonspecific, testosterone measurements are extremely important in confirming the diagnosis. When assessing the reproductive axis in men, the single best test is the total testosterone level.

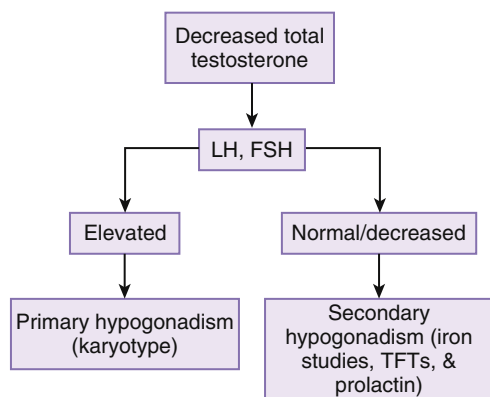

Except for the free testosterone by equilibrium dialysis assay, most free testosterone assays are inaccurate. The timing of the blood draw is also important. Testosterone secretion is diurnal, with the highest levels in the morning and lowest in the afternoon. Therefore early morning total testosterone levels are the most diagnostic in assessing whether a patient has hypogonadism. Testosterone measurements should always be checked on two separate occasions when assessing for hypogonadism, because there can be variability from day to day.

If hypogonadism is confirmed, then LH and FSH should be obtained to determine whether primary or secondary hypogonadism is present (Fig. 49.1). Primary hypogonadism is defined as hypogonadism because of a testicular defect and is characterized by a low testosterone and elevated LH and FSH levels. Secondary hypogonadism is defined as hypogonadism because of a hypothalamic or pituitary defect and is characterized by a low testosterone and low or inappropriately normal LH and FSH.

In addition to assessing the etiology of the hypogonadism, it is also important to assess the end-organ effects of the patient's hypogonadism. These assessments may include a semen analysis to assess sperm counts, hematocrit to assess for anemia, and bone mass density scan to assess for osteopenia/osteoporosis.

### Primary Hypogonadism

Primary hypogonadism may be congenital or acquired (Table 49.2). The most common congenital etiology is Klinefelter syndrome, which has been described to occur in 1 in 800 live births. In patients with Klinefelter mosaicism, the hypogonadism may not be recognized until later in life. Therefore all patients with primary hypogonadism should have a karyotype.

• **Fig. 49.1** Evaluation of male hypogonadism. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone; *TFTs*, thyroid function tests.

Acquired etiologies for primary hypogonadism include infectious etiologies such as mumps, chemotherapy, or radiation therapy to the pelvic area.

### Secondary Hypogonadism

Secondary hypogonadism may also be congenital or acquired. Congenital etiologies include idiopathic hypogonadotropic hypogonadism, with or without anosmia. Acquired etiologies include hemochromatosis, hyperprolactinemia, opiate use, and pituitary or hypothalamic tumors.

All patients with secondary hypogonadism require a transferrin saturation to assess for hemochromatosis and a prolactin level to assess for hyperprolactinemia. Patients under the age of 60 years with secondary hypogonadism require imaging of their pituitary gland to exclude a pituitary neoplasm.

### Treatment

Treatment depends on the patient's goals. Testosterone replacement therapy is prescribed in men without immediate desire for fertility. Various formulations are available including intramuscular injections, transdermal patches, transdermal gels, buccal tablets, and axillary solution. Older oral formulations are no longer available in the United States because of the significant hepatotoxicity associated with them.

If a patient desires fertility and has secondary hypogonadism, then testosterone is not recommended because it can impair spermatogenesis. Instead, these men are treated with gonadotropins.

Potential dangers of testosterone overreplacement include exacerbation of sleep apnea, increase in hematocrit exceeding the normal range, and possibly an increase in prostate cancer.

**TABLE 49.2** Etiologies of Primary and Secondary Hypogonadism

Primary Hypogonadism	Secondary Hypogonadism
Klinefelter syndrome	Hyperprolactinemia
Orchitis (i.e., mumps)	Hemochromatosis
Trauma	Opiates
Chemotherapy	Chronic illness
Radiation therapy	Pituitary adenoma
Alcohol	Hypothalamic tumor
	Cushing syndrome
	Head trauma
	Head irradiation
	IHH/Kallmann syndrome
	Alcohol

*IHH*, Idiopathic hypogonadotropic hypogonadism.

## Chapter Review

### Questions

1. A 24-year-old woman with a 6-month history of amenorrhea comes in for evaluation. Her thyroid review of systems is negative. She does not have hot flushes, night sweats, or galactorrhea. She is on no medications. Physical examination is unremarkable. hCG is negative. FSH and TSH are normal. Prolactin is slightly elevated at 30 ng/mL (normal <18 ng/mL) and confirmed on repeat evaluation. What is the best next step?
  - A. Treat with bromocriptine/cabergoline.
  - B. Treat with an oral contraceptive pill.
  - C. Give a progesterone challenge.
  - D. Obtain a pituitary MRI.
  - E. Repeat the prolactin in 3 months; no treatment for now.
2. A 34-year-old woman with a 4-month history of amenorrhea comes to see you for evaluation. Her menses had occurred every 2 months before they stopped. Her exercise routine is unchanged; she runs about 25 miles per week. She has had no hot flushes or night sweats. Her thyroid review of systems is negative. Physical examination reveals some terminal hair growth of her face. TSH, FSH, prolactin, total testosterone, and DHEAS are normal; hCG is negative. What would you do next?
  - A. Provera challenge
  - B. Treat with OCPs
  - C. Treat with metformin
  - D. MRI of the pituitary gland
  - E. Pelvic ultrasound
3. An 18-year-old woman presents for evaluation of primary amenorrhea. Her review of systems is remarkable for normal breast development and increasing headaches over the last few months. Physical examination is unremarkable with normal visual field, thyroid, and pelvic examinations and no galactorrhea. Her hCG, TSH, and prolactin are all normal. FSH is 50 IU/L (normal 3–12 IU/L). Which of the following is not appropriate at this time?
  - A. Karyotype
  - B. Fragile X premutation carrier testing
  - C. Pituitary MRI
  - D. Bone mineral density scan
  - E. Antiadrenal antibody testing
4. A 22-year-old woman presents with a 6-month history of amenorrhea. She had normal menarche until 6 months ago. Over the last year, she has had a 30-lb weight gain. During this time, she also noted worsening acne and some upper-lip terminal hair growth. Her hCG, prolactin, TSH, and FSH are all normal. What would be your next step?
  - A. Pelvic ultrasound
  - B. Total testosterone and DHEAS levels
  - C. LH and estradiol levels
  - D. Pituitary MRI
  - E. Adrenal CT scan
5. A 30-year-old man presents with symptoms of low libido and erectile dysfunction. He had normal pubertal development, and his symptoms started about 4 months ago. His total testosterone level is decreased at 150 ng/dL (normal 300–1000 ng/dL). This is confirmed on a repeat early morning blood draw. His LH and FSH are in the normal range. Which of the following laboratory tests are appropriate in the next phase of your evaluation?
  - A. Iron studies
  - B. Prolactin level
  - C. Karyotype
  - D. A and B
  - E. A and C

### Answers

1. D
2. A
3. C
4. B
5. D

## Adrenal Disorders

ANAND VAIDYA AND ROBERT G. DLUHY

The adrenal gland consists of the cortex and medulla. The adrenal cortex secretes three classes of steroid hormones: glucocorticoids, mineralocorticoids, and androgens. The outer zona glomerulosa secretes the mineralocorticoid aldosterone, which performs a key role in the maintenance of intravascular volume and potassium homeostasis. The central zona fasciculata produces cortisol, a glucocorticoid and mineralocorticoid, which is a crucial player in the stress response and an important factor in metabolism and immune functions. The inner layer, the zona reticularis, produces androgens, which serve as precursors of testosterone and androstenedione; they play a role in the development of secondary sexual characteristics in females.

### Glucocorticoids

The adrenal cortex, upon stimulation by adrenocorticotropic hormone (ACTH) through a steroidogenic acute regulatory protein (StAR), takes up cholesterol, the primary substrate for steroidogenesis. The specific hormones for the three zones of the adrenal cortex are then produced through a series of coordinated steps of cytochrome P450 enzymes. Cortisol circulates in the plasma as free and protein-bound cortisol and cortisol metabolites. Cortisol is the main physiologic endogenous glucocorticoid that acts by binding to intranuclear glucocorticoid receptors that are expressed in many tissues. Cortisol is also a potent mineralocorticoid receptor agonist capable of inducing effects similar to aldosterone; however, the coexpression of the 11 $\beta$ -hydroxysteroid dehydrogenase (11 $\beta$ -HSD II) enzyme with the mineralocorticoid receptor in the kidney ensures inactivation of most cortisol to cortisone and thereby prevents a mineralocorticoid excess state. Free or unbound cortisol, which is approximately 5% of the total cortisol, is the physiologically active hormone acting at tissue sites.

### Regulation of the Hypothalamic-Pituitary-Adrenal Axis

ACTH secreted by the anterior pituitary gland regulates adrenal cortisol synthesis. ACTH is processed from a large precursor

molecule, proopiomelanocortin (POMC), along with a number of other peptides including beta lipotropin, endorphins, and melanocyte-stimulating hormone. Corticotropin-releasing hormone (CRH), produced in the hypothalamus, stimulates the release of ACTH and its related peptides (Fig. 50.1).

Several factors influence ACTH release: CRH, arginine vasopressin (AVP), circadian rhythm, stress, and free cortisol levels. ACTH has a pulsatile secretion pattern and follows a circadian rhythm, with the peak levels before waking and nadir values in the late evening. The sleep-wake pattern, which is disturbed by long-distance travel across time zones or by night-shift working, takes about 2 weeks to reset. Stress such as fever, surgery, hypoglycemia, exercise, and acute emotions triggers the release of CRH, AVP, and subsequently ACTH; the sympathetic nervous system is also activated. Immune-endocrine interaction occurs when proinflammatory cytokines (particularly interleukin-1, interleukin-6, and tumor necrosis factor- $\alpha$ ) augment the effects of CRH and AVP on ACTH secretion. Finally, negative feedback control of ACTH secretion is exerted by free plasma cortisol, whereby cortisol inhibits *POMC* gene transcription in the anterior pituitary gland and CRH and AVP secretion in the hypothalamus. Cortisol also stimulates the higher brain centers (such as the hippocampus and reticular system) and inhibits the locus coeruleus/sympathetic system. Chronic administration of corticosteroids suppresses the hypothalamic-pituitary-adrenal (HPA) axis, which persists for months after cessation of treatment.

### Physiologic and Pathophysiologic Actions of Glucocorticoids

Glucocorticoids play a pivotal role in the intermediary metabolism of carbohydrate, protein, and fat. Glucocorticoids increase the blood glucose concentration by increasing hepatic glycogen synthesis and stimulating gluconeogenesis. Glucocorticoids also exert an antiinsulin action in the peripheral tissues by reducing glucose uptake. Consequently, increased glucocorticoid actions result in insulin resistance and an increase in blood glucose concentrations in the setting of increased protein and lipid catabolism.

• **Fig. 50.1** Feedback regulation of the hypothalamic-pituitary-adrenal (HPA) system. The HPA axis. The main sites for feedback control for plasma cortisol are the pituitary gland, hypothalamus, and higher centers of the brain. There is a short feedback loop involving the inhibition of corticotropin-releasing hormone (CRH) by adrenocorticotropic hormone (ACTH). There is a negative feedback control of cortisol over the pituitary and hypothalamus. Inflammatory cytokines in response to stress lead to increased cortisol via the hypothalamus, and the cortisol produced in turn suppresses the proinflammatory cytokines. (–) Suppression; (+) stimulation; DHEA, dehydroepiandrosterone; IL, interleukin; POMC, proopiomelanocortin; TNF, tumor necrosis factor. (From Trikudanathan S, Dluhy RG. Adrenal cortical dysfunction. In: Blake MA, Boland G, eds. *Adrenal Imaging*. New York: Humana Press; 2009:35–56.)

Excess cortisol leads to increased deposition of adipose tissue centrally in the viscera as opposed to the periphery. Excess glucocorticoids cause sarcopenia by catabolic actions as well as by reducing the protein synthesis in muscle. In the skeleton, osteoblastic activity is inhibited leading to osteoporosis in glucocorticoid excess. Glucocorticoids suppress the inflammatory cytokines and impair cell-mediated immunity. Glucocorticoids increase neutrophil counts by demargination of neutrophils with depletion of the eosinophils. Changes in cortisol levels affect mood and sleep, implicating the brain as an important target of this hormone. Hypercortisolism is strongly associated with depressed mood, depression, and insomnia.

## Cushing Syndrome

Cushing syndrome results from prolonged and inappropriate exposure to elevated levels of glucocorticoids. Endogenous hypercortisolism can be caused by excessive secretion of ACTH from either the pituitary (Cushing disease 70%) or from ectopic nonpituitary neuroendocrine tumors (15%)

### • BOX 50.1 Causes of Cushing Syndrome

#### ACTH-Dependent

ACTH-producing pituitary adenoma  
Ectopic ACTH/CRH-producing neuroendocrine tumors<sup>a</sup>

#### ACTH-Independent

Adrenocortical carcinoma  
Primary pigmented nodular adrenocortical disease (PPNAD)<sup>b</sup>  
Adrenal macronodular hyperplasia  
Exogenous use of glucocorticoids

ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

<sup>a</sup>Neuroendocrine tumors: bronchogenic carcinoma, carcinoid tumors, pancreatic tumors.

<sup>b</sup>PPNAD: sporadic or part of familial Carney syndrome.

or from excessive cortisol secretion by adrenal tumors (15%). However, the most common cause of Cushing syndrome is iatrogenic from medical prescription of glucocorticoids. **Box 50.1** enumerates the causes of Cushing syndrome. Rare causes of ACTH-independent Cushing syndrome include macronodular hyperplasia and primary pigmented nodular adrenocortical disease (PPNAD, micronodular hyperplasia). PPNAD can be sporadic or, most often, a part of Carney complex. Carney complex is an autosomal dominant disorder characterized by skin pigmentation, endocrine tumors (most prominently PPNAD) and nonendocrine tumors such as cutaneous myxomas, cardiac myxoma, and schwannomas.

#### Clinical Features of Cushing Syndrome

The prominent features of Cushing syndrome include central or truncal obesity with increased fat depots in distinctive sites such as the dorsocervical area (buffalo hump), supraclavicular fat pads, and the mesenteric bed. The extremities are depleted of fat and appear thin. Patients may develop moon face, hirsutism, and facial plethora. Signs of protein wasting are characteristically seen with thin skin, easy bruisability, broad violaceous cutaneous striae, and proximal myopathy. Osteoporosis may occur with vertebral fractures. Glucose intolerance occurs owing to insulin resistance, with overt diabetes mellitus in about 20% of the patients. Imaging studies show hepatic steatosis and increased visceral fat. Cortisol excess predisposes to hypertension and thereby increases the cardiovascular risk. In women, increased levels of adrenal androgens (when the Cushing syndrome is ACTH mediated) can lead to acne, hirsutism, and menstrual abnormalities such as oligomenorrhea and amenorrhea. Emotional dysfunction ranging from irritability to depression or even frank psychosis may occur. Wound infections are common and contribute to poor wound healing. The spectrum of clinical presentation is broad and overlaps with many common conditions such as simple obesity, and hence the diagnosis can be challenging. The morbidity and mortality from Cushing syndrome occur mostly from

cardiovascular complications including thrombosis, followed by infectious causes.

### Screening for Cushing Syndrome

Initial testing for Cushing syndrome should be done in patients with clinical features suggestive of Cushing syndrome or in patients with incidentally discovered adrenal tumors. It is reasonable to screen patients with unusual features for their age that could reflect hypercortisolism such as osteoporosis, hypertension, or easy bruising. Studies have shown that Cushing syndrome is prevalent in 2% to 5% of poorly controlled diabetic patients.

Initial screening for Cushing syndrome should demonstrate increased cortisol production and/or failure to suppress cortisol secretion when exogenous glucocorticoid (dexamethasone) is administered. Once the diagnosis of hypercortisolism is ascertained, the etiology should be sought. The following tests are useful and complementary as initial diagnostic studies for Cushing syndrome: measurement of urinary free cortisol (UFC) levels, late-night salivary cortisol, and overnight low-dose dexamethasone suppression test (DST).

Measurement of 24-hour UFC (along with urinary creatinine to ascertain the completeness of collection) is useful to diagnose hypercortisolism. It measures the cortisol that is not bound to corticosteroid-binding globulin, which is filtered by the kidney unchanged and not reabsorbed. UFC should not be measured in patients with moderate-to-severe renal impairment. UFC can also be normal if a patient has cyclic disease or mild Cushing syndrome. False-positive results are seen in any physiologic state that increases cortisol production; hence two measurements done on separate occasions may be needed.

Cortisol secretion follows a diurnal pattern with peak levels in the morning that nadir at night. Cortisol typically reaches a nadir at night; however, this normal circadian rhythm is lost in Cushing syndrome. Therefore detection of an elevated late-night or midnight cortisol is another sensitive method to detect hypercortisolism. A midnight salivary cortisol, obtained via oral mucosal swabs, is the most used test for this indication.

A simple outpatient screening test is the overnight DST (1 mg of dexamethasone between 10 PM and midnight followed by assessment of a morning cortisol at 8–9 AM). A morning postdexamethasone cortisol level  $>5$   $\mu\text{g/dL}$  is considered abnormal, and a level  $>1.8$   $\mu\text{g/dL}$  is considered suggestive for endogenous hypercortisolism.

### Investigations to Identify the Cause of Cushing Syndrome

Once a diagnosis of hypercortisolism is confirmed, the next step is to determine whether the etiology is ACTH dependent or ACTH independent. A low or undetectable ACTH level ( $<9$   $\text{pg/mL}$ ) confirms the diagnosis of primary adrenal disorders. There is also suppression in plasma dehydroepiandrosterone sulfate (DHEAS) because adrenal androgen production is reduced as a result of ACTH suppression. In

adrenal carcinomas, hypercortisolism is often accompanied by increased androgen secretion. The steroid production in adrenal carcinoma is usually resistant to ACTH stimulation and dexamethasone suppression. Patients with primary adrenal disorders should undergo high-resolution CT scanning of the abdomen. In pituitary ACTH-secreting microadenomas (Cushing disease), the ACTH levels are inappropriately normal or modestly elevated (27–136  $\text{pg/mL}$ ), whereas in pituitary macroadenomas and ectopic ACTH syndrome, ACTH values can be 2- or 3-fold elevated.

To distinguish the etiologies of ACTH-dependent Cushing syndrome, high-dose dexamethasone suppression testing (8 mg overnight test or 2 mg every 6 hours for 2 days) may be used. Pituitary macroadenoma and ectopic ACTH production often show no suppression, whereas there is usually some suppression of ACTH and cortisol in ACTH-secreting pituitary microadenomas. This functional method of localizing the source of ACTH excess is not highly reliable, and therefore the use of imaging in combination with inferior petrosal sinus sampling (IPSS) may be needed.

MRI to assess for a pituitary mass is the initial imaging study when suspecting ACTH-dependent Cushing syndrome; however, it may not always demonstrate a pituitary lesion in patients with Cushing disease. Some ACTH-secreting adenomas are too small to be reliably seen on MRI. Keep in mind that 10% to 20% of normal patients have nonfunctioning pituitary “incidentalomas.” In most circumstances, IPSS is needed to prove pituitary hypersecretion of ACTH. Blood from each half of the pituitary drains into the cavernous sinus and then into ipsilateral inferior petrosal sinus. Catheterization and venous sampling for measurement of ACTH from both the sinuses simultaneously compared with a peripheral sample would differentiate a pituitary source from an ectopic source. In pituitary ACTH-secreting tumor, the ratio of ACTH concentrations from the inferior petrosal sinus to simultaneously drawn peripheral blood would be greater than 2-fold basally and greater than 3-fold after CRH injection. Thus IPSS is a highly sensitive and specific test to distinguish between pituitary and nonpituitary sources of ACTH excess. However, IPSS is technically demanding, and complications such as thrombosis can occur; therefore this test should be performed in an experienced center.

To locate sources of ectopic ACTH production, it is reasonable to start with imaging of the chest and abdomen to search for a lung or pancreatic source of ACTH. Octreotide scanning can also be useful to image ACTH-producing neuroendocrine tumors such as carcinoids.

### Differential Diagnosis

#### Pseudo-Cushing Syndrome

Obesity, chronic alcoholism, and depression can mimic the biochemical abnormalities of hypercortisolism. For example, chronic and excessive alcohol intake and depression may cause mild elevations in UFC, blunted circadian rhythmicity, and resistance to suppression with dexamethasone.

However, these patients usually do not have the more reliable clinical signs and symptoms of Cushing syndrome such as proximal myopathy and easy bruisability. Following discontinuation of alcohol or with relief of depression, steroid testing returns to normal. When available (typically in selected academic medical centers), a CRH-stimulated DST can be performed to differentiate pseudo-Cushing syndrome from true endogenous and autonomous hypercortisolism.

### Management

Surgical resection of the pituitary adenoma using the transphenoidal approach is the first line of therapy for Cushing disease (ACTH-secreting pituitary tumor). Remission in the hands of an experienced surgeon is in the range of 65% to 90% for microadenomas and 50% for macroadenomas. After removal of the ACTH-producing pituitary adenoma, the normal corticotropes are suppressed; hence patients usually need glucocorticoid treatment postoperatively until the HPA axis recovers. A postoperative morning serum cortisol level of  $<2 \mu\text{g/dL}$  the day after surgery is suggestive of remission and possible surgical cure. In the past, bilateral adrenalectomy was considered as an option for Cushing disease; however, removal of the adrenal glands can lead to the development of Nelson syndrome in 10% to 20% of patients (an aggressive ACTH-secreting pituitary macroadenoma). Nelson syndrome is thought to be the consequence of eliminating the source of negative feedback on ACTH, resulting in marked growth and function of the ACTH-secreting adenoma. Pituitary irradiation may be used for patients with postoperative recurrence and in Nelson syndrome. In other centers, gamma knife and stereotactic techniques have been used to treat pituitary adenomas.

In ectopic ACTH syndrome, tumor-directed therapy involving resection of the primary tumor (e.g., bronchial carcinoid) can lead to cure. However, the prognosis remains poor for small cell lung tumors, and medical therapy inhibiting steroidogenesis is indicated for symptoms of cortisol excess.

Laparoscopic, or retroperitoneoscopic, adrenalectomy is preferred for adrenal adenomas. Adrenal carcinomas carry a poor prognosis with dismal 5-year survival rates. Adrenal carcinomas are generally not radiosensitive and respond poorly to systemic chemotherapies, although mitotane has been shown to improve disease-free survival if administered adjunctively following surgical resection of the neoplasm. The best predictor of outcome is the ability to achieve a complete surgical resection.

### Medical Therapies for Cushing Syndrome

Drugs can be used to treat hypercortisolism by inhibiting steroidogenesis: metyrapone, ketoconazole, and mitotane. Metyrapone inhibits  $11\beta$ -hydroxylase whereas ketoconazole blocks multiple adrenal steroidogenic cytochrome P450-dependent enzymes. These drugs can be used preoperatively or as adjunctive treatment following surgery or radiotherapy. Mitotane inhibits steroidogenesis but in some patients is also cytotoxic to the adrenal gland. Its use is primarily for adrenal carcinoma because of its cytotoxicity.

Pasireotide, a novel somatostatin analogue with high affinity to somatostatin-receptor subtype 5 has been recently approved by the US Food and Drug Administration for Cushing disease. Because ACTH-producing adenomas highly express somatostatin-receptor subtype 5, activation of this receptor inhibits the secretion of ACTH. In clinical trials, pasireotide reduced UFC and improved clinical features of hypercortisolism. Of note, a high frequency of hyperglycemia was observed.

### Adrenal Insufficiency

Primary adrenal insufficiency (Addison disease) results from the destruction of the adrenal cortex, resulting in a deficiency in aldosterone, cortisol, and adrenal androgen production. Secondary adrenal insufficiency is the consequence of decreased ACTH production leading to reduced cortisol and adrenal androgen secretion; aldosterone production is normal because the renin-angiotensin axis remains intact in such patients. Although Addison disease is uncommon, it carries significant morbidity and mortality if left untreated.

### Etiology

The most common cause of Addison disease is autoimmune adrenalitis, with the majority of the patients having autoantibodies directed toward  $21$ -hydroxylase and side-chain cleavage enzymes. Primary adrenal insufficiency can occur as a part of autoimmune polyendocrine syndromes (APS I and II).

In the developing world, primary adrenal insufficiency is often caused by infections, especially tuberculosis. However, any infiltrative process (infection, malignancy, hemorrhage) that affects both adrenal cortices can result in primary adrenal insufficiency. Because cancer therapies allow patients with metastatic malignancies to survive longer, and because patients with organ transplants on immune suppression fare better, the prevalence of primary adrenal insufficiency attributed to invasive malignancies and fungal infections is rising. Secondary adrenal insufficiency can be caused by any process that disrupts the hypothalamus and/or pituitary, including malignancy, infection, inflammation, or hemorrhage. The most common cause of secondary adrenal insufficiency is likely iatrogenic medication-induced by glucocorticoids. The use of exogenous glucocorticoids can suppress the central secretion of ACTH by binding to the hypothalamic and pituitary glucocorticoid receptor and therefore result in decreased adrenal secretion of cortisol and, if prolonged, adrenal cortical atrophy. Short-acting opioids may also transiently suppress ACTH secretion. Because endogenous opioids are secreted by the hypothalamus and pituitary (they are a product of the cleavage of POMC, as is ACTH), opioid receptors are expressed on the hypothalamus and pituitary. Although large cohort studies are lacking, a collection of anecdotal observations suggest that opioids, especially short-acting opioids that bind to the mu receptor, transiently reduce ACTH and cortisol.

Whether these can result in a clinical syndrome of adrenal insufficiency or not has not been well studied but should be considered when evaluating patients with features concerning for adrenal insufficiency that are also receiving opioid therapy. Other causes of adrenal insufficiency are listed in [Box 50.2](#).

## Clinical Features

Symptoms of chronic adrenal insufficiency are nonspecific and include fatigue, weakness, listlessness, anorexia, and weight loss. Gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal cramps can occasionally be the only presenting complaint. A specific sign of primary adrenal insufficiency is cutaneous and mucosal membrane hyperpigmentation, which occurs because of elevated melanocyte-stimulating hormone and ACTH from the absence of negative cortisol feedback on the hypothalamus and pituitary. Darkening of the skin is typically seen in the sun-exposed areas, recent scars, palmar creases, and buccal and vaginal mucosa. Orthostatic hypotension may be marked in primary adrenal insufficiency because of aldosterone deficiency; salt craving is a frequent complaint. Women may note loss of axillary and pubic hair, as a result of the adrenal androgen deficiency. Biochemical abnormalities include hyponatremia (frequent), hyperkalemia, hypoglycemia, elevation of blood urea, mild hypercalcemia, mild normocytic anemia, lymphocytosis, and eosinophilia. In

primary adrenal insufficiency, hyponatremia occurs because of aldosterone deficiency and sodium wasting, whereas in secondary hypoadrenalism, it is dilutional because of cortisol deficiency, which is associated with increased antidiuretic hormone levels and ineffective free water clearance.

Acute adrenal insufficiency, when caused by adrenal hemorrhage or precipitated by acute infection, presents as hypotension, acute circulatory failure, confusion, abdominal pain, and fever; prompt recognition is extremely important.

In secondary adrenal insufficiency, pallor, headache, scanty axillary and pubic hair, and visual symptoms may point toward hypothalamic-pituitary disease. Hyperkalemia is not seen because there is normal aldosterone secretion. Patients with secondary adrenal insufficiency usually do not present with hypotension and hemodynamic complications because aldosterone regulation is maintained, and therefore intravascular volume is generally normal. However, in situations of stress (such as infection or trauma), the relative cortisol deficiency may give rise to a progressively worsening syndrome that may mimic the hemodynamic pathophysiology seen in primary adrenal insufficiency.

## Diagnosis

A morning plasma cortisol level of  $\leq 3$   $\mu\text{g/dL}$  is diagnostic for overt adrenal insufficiency and precludes the need for further testing; levels  $\geq 18$   $\mu\text{g/dL}$  rule out the disorder. Morning cortisol levels that are  $>10$  to  $15$   $\mu\text{g/dL}$  are typically reflective of a normal HPA axis when the pretest probability for adrenal insufficiency is relatively low. There is no absolute cut-off value for a normal or abnormal morning cortisol when levels are  $>5$   $\mu\text{g/dL}$ ; rather, careful clinical judgment must be used to determine whether the peak morning cortisol being assessed is “appropriate” for the clinical scenario. This can make the diagnosis of subtle cases of adrenal insufficiency challenging.

The most commonly used diagnostic test for adrenal insufficiency is the ACTH stimulation test wherein 250  $\mu\text{g}$  of cosyntropin is given intramuscularly or intravenously, and the cortisol response is measured at 0, 30, and 60 minutes. The normal response is a basal or peak cortisol response  $>18$   $\mu\text{g/dL}$ . This test is useful in diagnosing primary destruction of tissue and long-standing secondary adrenal insufficiency. This test may be normal in patients with mild or recent-onset secondary adrenal insufficiency. In early morning plasma, ACTH level is useful to distinguish primary from secondary adrenal insufficiency if the cortisol levels are abnormal. The plasma ACTH values are usually elevated ( $>100$   $\text{pg/mL}$ ) in primary adrenal insufficiency as opposed to secondary hypoadrenalism, where the plasma ACTH values may be low or “inappropriately” normal. Other tests such as the insulin tolerance test, metyrapone test, and CRH test are uncommonly used to diagnose secondary adrenal insufficiency.

CT scan of the adrenal glands may show enlargement (e.g., hemorrhage) or calcification depending on the etiology of the adrenal failure. In secondary adrenal insufficiency,

### • BOX 50.2 Causes of Adrenal Insufficiency

#### Primary

Autoimmune-sporadic: APS I and APS II  
 Infections: tuberculosis, fungal infections, cytomegalovirus, HIV  
 Hemorrhage: anticoagulant therapy, CAPS, Waterhouse-Friderichsen syndrome  
 Invasion: metastatic disease  
 Infiltrative disorders: amyloid, hemochromatosis  
 Drugs: enzyme inhibitors of steroidogenesis, cytotoxic agents  
 Miscellaneous: congenital adrenal hyperplasia, adrenoleukodystrophy

#### Secondary

Pituitary tumors  
 Pituitary surgery  
 Pituitary apoplexy  
 Sheehan syndrome  
 Lymphocytic hypophysitis  
 Granulomatous disease: sarcoid, eosinophilic granuloma  
 Exogenous glucocorticoid therapy  
 Exogenous (short-acting) opioids

APS I, Autoimmune polyglandular syndrome type I (Addison disease, chronic mucocutaneous candidiasis, hypoparathyroidism, dental enamel hypoplasia, alopecia, primary gonadal failure); APS II, autoimmune polyglandular syndrome type II (Addison disease, primary hypothyroidism, primary hypogonadism, insulin-dependent diabetes, pernicious anemia, vitiligo); CAPS, catastrophic antiphospholipid syndrome; HIV, human immunodeficiency virus.

there is normal aldosterone secretion, and hyperkalemia is not seen. Pituitary MRI scans and assessment of anterior pituitary functions are usually needed in these patients for concomitant deficiencies of other pituitary hormones.

Individuals receiving long-term high-dose steroid therapy will develop prolonged HPA suppression leading to adrenal atrophy. Recovery may take months to years after glucocorticoid withdrawal. Early morning cortisol levels and ACTH stimulation testing should be used to assess adrenal recovery.

## Differential Diagnosis

Chronic nonspecific symptoms such as fatigue, weakness, and malaise should make the possibility of a diagnosis of adrenal insufficiency. When insidious in onset, adrenal insufficiency is frequently mistaken for chronic fatigue syndrome. Occasionally such patients have been misdiagnosed with anorexia nervosa or depression. However, hyperpigmentation, weight loss, and gastrointestinal symptoms should alert the clinician to consider adrenal insufficiency. It is also reasonable to look for other organ-specific autoimmune diseases in the context of polyglandular syndromes.

## Management

In the setting of adrenal crisis, parenteral treatment with high doses of hydrocortisone should be immediately initiated along with fluid resuscitation with normal saline. In nonacute situations, replacement doses of oral hydrocortisone at a dosage of 8 to 10 mg/m<sup>2</sup>/d should be started in divided doses. To mimic the diurnal pattern of steroid secretion, two-thirds of the total dose is given in the morning, and one-third is given in late afternoon with mealtime or snack. In secondary adrenal insufficiency, only glucocorticoid therapy is needed.

In primary adrenal insufficiency, mineralocorticoid insufficiency is replaced with fludrocortisone, administered at a daily dose of 0.05 to 0.1 mg orally. Plasma renin activity, blood pressure, and serum electrolytes are useful parameters to titrate the dose of fludrocortisone. In female patients, some studies have suggested the benefit of androgen treatment with 25 to 50 mg/d of DHEA orally to improve sexual function and general well-being; however, the clinical response to DHEA is variable.

Patient education and daily replacement therapy form a cornerstone in the management of primary adrenal insufficiency. Patients are advised to double the dose of hydrocortisone during periods of intercurrent illness or surgery. All patients should wear a medical alert bracelet and should be instructed in self-injection of steroids if they cannot take their dosing orally.

## Regulation of Renin-Angiotensin-Aldosterone Axis

Renin is formed in the juxtaglomerular cells (JG), located adjacent to the renal afferent arteriole of the glomerulus.

Renin is stimulated when renal perfusion is decreased, as sensed by decreased distal delivery of chloride ion. Renin acts on the substrate angiotensinogen (hepatic origin) to form angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has several crucial roles: It is a potent arterial vasoconstrictor, it directly increases sodium reabsorption from the proximal tubule, it stimulates vasopressin release (thus ensuring water reabsorption is coupled with sodium reabsorption), and it stimulates the zona glomerulosa of the adrenal cortex to increase aldosterone secretion (Fig. 50.2). The control of adrenal aldosterone secretion includes the renin-angiotensin system, potassium, and ACTH. Aldosterone serves two important functions: regulation of extracellular fluid volume and potassium homeostasis. Chronic exposure to aldosterone over 3 to 5 days leads to an “escape” from mineralocorticoid action; after an initial period of sodium retention and a gain of several kilograms, sodium balance is reestablished. Therefore edema does not develop. An increase in atrial natriuretic peptide and interplay of renal hemodynamic factors play a role in the “escape” from the sodium-retaining action of aldosterone. However, it is important to realize that there is no “escape” from the potassium-losing effects of chronic mineralocorticoid exposure.

Nonepithelial toxic action of aldosterone includes inflammation, necrosis, and subsequent fibrosis in a variety of tissues including the heart, kidney, and vasculature. These pathophysiologic situations occur when aldosterone levels are inappropriately elevated on a high-salt intake such as in primary aldosteronism (PA). Aldosterone has been implicated in the pathophysiology of heart failure. Mineralocorticoid receptors are overexpressed in failing cardiac tissue, leading to cardiac fibrosis. In the RALES (Randomized Aldactone Evaluation Study) study, spironolactone, a mineralocorticoid receptor antagonist, reduced mortality in patients with systolic heart failure by 30% and reduced frequent hospitalizations from heart failure by 35%. Eplerenone, a selective mineralocorticoid receptor blocker, was also shown to reduce cardiovascular mortality and morbidity in postmyocardial infarction patients with left ventricular failure (EPHESUS [Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study] trial).

## Primary Aldosteronism

PA is now recognized to be the most common form of secondary hypertension, prevalent in nearly 10% of all patients with hypertension. It is caused by autonomous secretion of aldosterone from a unilateral adrenal adenoma or from bilateral adrenal hyperplasia.

Hypokalemic patients with PA present with nonspecific symptoms such as muscle cramping, weakness, headaches, palpitations, polyuria, and nocturia. Normokalemic hypertension remains the more common form of presentation

• **Fig. 50.2** Renin-angiotensin-aldosterone system. This figure shows the interplay of various signals from the nephron in the kidney, liver, and adrenal gland that form the feedback loop to maintain circulating blood volume and aldosterone secretion. (–) Suppression; (+) stimulation; *ANP*, atrial natriuretic peptide; *DCT*, distal convoluted tubule; *JG*, juxtaglomerular; *K<sup>+</sup>*, potassium. (From Trikudanathan S, Dluhy RG. Adrenal cortical dysfunction. In: Blake MA, Boland G, eds. *Adrenal Imaging*. New York: Humana Press; 2009:35–56.)

of this disorder and likely reflects earlier detection of disease. A diagnosis of PA should be considered in hypertensive patients with refractory hypertension, which is poorly controlled blood pressure on three antihypertensive agents (including a diuretic), and in patients with spontaneous or diuretic-induced hypokalemia. Further, all patients with an adrenal tumor should be screened for PA, as should family members of patients with PA or hemorrhagic stroke before age 40 years and patients with early onset of PA before age 25 years. Several studies have also shown that patients with PA have a higher cardiovascular morbidity and mortality when compared with age-matched patients with essential hypertension.

## Diagnosis

The Endocrine Society recommends the use of plasma aldosterone:renin ratio (ARR) to screen for PA. Testing should ideally be performed in the morning in a seated ambulatory patient who has been on unrestricted dietary salt intake. Although certain medications can affect the ARR mainly by altering renin levels (for example spironolactone, eplerenone, amiloride, ACE inhibitors and angiotensin receptor blockers, and triamterene can

increase renin, whereas beta-blockers can lower renin), it is not routinely recommended that all of these medications be stopped before screening. The use of spironolactone, eplerenone, and amiloride are particularly potent stimulants of renin, and therefore testing for the ARR when these medications are being used should be considered uninterpretable unless the renin is fully suppressed or undetectable.

The rationale behind the ARR is to evaluate for renin-independent aldosteronism, where aldosterone is being secreted despite the relative absence of plasma renin activity (PRA). An ARR >30 (when the serum aldosterone is >15 ng/dL and PRA <1 ng/mL/h) is highly suggestive for PA (Fig. 50.3); however, lower concentrations of serum aldosterone in the patients with an abnormal ARR usually need a confirmatory test to diagnose PA. Any of the following four confirmatory procedures can be used: oral sodium loading, saline infusion, fludrocortisone suppression, and captopril challenge. The endpoint for testing in these tests is to demonstrate autonomy of aldosterone secretion. There is inadequate evidence to recommend one test over the others, and the choice of testing is often center-specific. For oral sodium-suppression testing, patients are instructed to take sodium

• **Fig. 50.3** Algorithm for diagnosis of primary aldosteronism. <sup>a</sup>Inadequate control of hypertension on three antihypertensives (including a diuretic). <sup>b</sup>Oral/intravenous salt loading: 2 g of sodium chloride tablets for 3 days or 2 L of isotonic saline over 4 hours intravenously. 24-hour urinary aldosterone collected on day 3. Dedicated adrenal protocol CT examination (see text). *APA*, Aldosterone-producing adenoma; *AVS*, adrenal venous sampling; *PA*, plasma aldosterone; *PRA*, plasma renin activity. (From Trikudanathan S, Dluhy RG. Adrenal cortical dysfunction. In: Blake MA, Boland G, eds. *Adrenal Imaging*. New York: Humana Press; 2009:35–56.)

chloride tablets (2 g) with each meal on a normal-salt diet for 4 days. On the fourth day, a 24-hour urinary aldosterone excretion  $>10$  to  $12 \mu\text{g}/24 \text{ h}$  in the presence of urinary sodium excretion  $>200 \text{ mmol/d}$  is diagnostic of autonomous aldosterone production. It should be noted that an oral sodium-loading test and intravenous saline infusion test should not be performed in patients with uncorrected hypokalemia, severe uncontrolled hypertension, or congestive heart failure.

After biochemical confirmation of PA, patients who are surgical candidates and willing to undergo a surgical procedure can proceed with a localization study using CT or MRI of the adrenals. Patients who are not surgical candidates or who are unwilling to undergo a potential adrenalectomy can be empirically treated with a mineralocorticoid receptor antagonist. Bilateral adrenal venous sampling (AVS) is often used, despite the imaging findings, to confirm the localization and laterality of the aldosterone excess. AVS should be performed in a center with experienced radiologists to ensure a successful catheterization

and to minimize the risk of adrenal hemorrhage and venous thrombosis.

### Treatment

Patients diagnosed with unilateral aldosterone-producing adenoma (APA) should be offered unilateral laparoscopic adrenalectomy. This can lead to dramatic improvements in both blood pressure and serum potassium concentrations in all patients. Hypertension is cured in about 50% of patients after unilateral adrenalectomy; persistent hypertension after adrenalectomy in APA patients is caused by coexistent essential hypertension, older age, renal insufficiency, and longer duration of the hypertension.

In patients with bilateral adrenal disease or when APA patients are not surgical candidates for adrenalectomy, they should be treated with a mineralocorticoid antagonist (spironolactone or eplerenone). In male patients who develop predictable dose-related side effects from spironolactone such as gynecomastia, decreased libido, and impotence,

eprenone, a selective mineralocorticoid receptor antagonist devoid of antiandrogen and progesterone actions, should be used. Other useful agents include the potassium-sparing diuretics amiloride and triamterene.

### Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA), inherited as an autosomal dominant disorder, results from a chimeric gene duplication, which is the result of an unequal crossover between the homologous  $11\beta$ -hydroxylase and aldosterone synthase genes. As a result, there is ectopic expression of the aldosterone synthase enzyme in the cortisol-producing zona fasciculata, under the regulation of ACTH. GRA is characterized by early-onset hypertension, hemorrhagic stroke, and suppressed plasma renin levels. Genetic testing using Southern blot technique should be considered for PA patients with a family history of PA or family history of hemorrhagic strokes at a young age (<30 years) or with early-onset hypertension. A 24-hour urine collection would reveal marked elevation in the levels of the “hybrid” steroids 18-oxocortisol and 18-OH-cortisol. Treatment with a long-acting glucocorticoid will suppress the ACTH-regulated aldosterone secretion. The smallest effective dose should be used to control blood pressure while minimizing the risk of Cushing syndrome. Alternative treatments include mineralocorticoid receptor and sodium-epithelial channel antagonists.

### Secondary Hyperaldosteronism

In secondary hyperaldosteronism, there is an appropriate increase in aldosterone production caused by elevated circulating levels of renin. The elevated renin production may occur in the setting of reduced effective circulating blood volume (e.g., cirrhosis, nephrotic syndrome, and congestive cardiac failure) or decreased renal perfusion. Atherosclerotic renal artery stenosis or fibromuscular hyperplasias are examples of renin overproduction caused by decreased renal perfusion. These patients may have hypokalemic alkalosis as a result of hyperaldosteronism and moderate to marked increases in plasma renin activity.

## Other Causes of Hypermineralocorticoidism

### Hypoaldosteronism With Suppressed Plasma Renin Activity

Apparent mineralocorticoid excess (AME) can occur in both heritable and acquired forms of impaired activity of the renal enzyme  $11\beta$ -HSD II. The enzyme deficiency results in the failure to degrade cortisol to the biologically inactive cortisone in renal tubules. As a result, cortisol binds to the MR exerting mineralocorticoid actions. The acquired form of this syndrome is caused by the ingestion of certain

licorices or chewing tobacco, which contains glycyrrhizic acid. These patients demonstrate hypertension and hypokalemia; PRA and aldosterone levels are suppressed. Cortisol levels are normal because the ACTH feedback loop is intact. Small doses of dexamethasone can be used to suppress the endogenous cortisol production.

Liddle syndrome is an autosomal dominant disorder caused by gain-of-function mutations in the subunits of the renal sodium epithelial channel that is normally regulated by aldosterone. Constitutive activation of the channel results in sodium retention, hypokalemia, and low renin/aldosterone levels.

### Hyperaldosteronism With Elevated Plasma Renin Activity

Bartter syndrome (BS) patients exhibit hypokalemic alkalosis, hypercalciuria, normal blood pressure, and absence of edema. In BS, loss-of-function mutation in the loop of Henle Na-K-2Cl cotransporter gene results in activation of the renin-angiotensin-aldosterone system and hence renal wasting of sodium. Patients with Gitelman syndrome (GS) have similar features to BS except that they are hypocalciuric. GS results from loss-of-function mutations in the thiazide-sensitive Na-Cl cotransporter in the distal convoluted tubule of the kidney.

### Hypoaldosteronism

Hyporeninemic hypoaldosteronism, usually occurring in diabetic adults with mild renal impairment, results in hyperkalemia and metabolic acidosis that are out of proportion to the level of renal failure (renal tubular acidosis type IV). Isolated aldosterone deficiency with low renin levels also occurs postoperatively following removal of an aldosterone-producing adenoma and following long-standing heparin treatment.

## The Sympathoadrenal System

The sympathoadrenal system is derived from the neural crest and consists of the ganglia of the sympathetic nervous system and the adrenal medulla. Epinephrine, synthesized in the adrenal medulla, and norepinephrine, at the peripheral nerve endings, are formed from the amino acid tyrosine. The rate-limiting enzyme in the biosynthetic pathway is tyrosine hydroxylase. Metabolism of epinephrine and norepinephrine to biologically inactive compounds by catecholamine-O-methyl transferase results in metanephrine and norepinephrine, respectively. Further oxidation results in vanillylmandelic acid.

### Pheochromocytoma and Paraganglioma

Pheochromocytomas are neuroectodermal tumors arising from the chromaffin cells. These catecholamine-secreting tumors mostly arise from the adrenal medulla; if these

chromaffin tumors arise in the parasympathetic or sympathetic ganglia, they are referred to as paragangliomas.

Pheochromocytomas may occur sporadically or may be a part of a larger inheritable tumor syndrome. These genetic syndromes are being increasingly recognized, and it is now estimated that 40% of all pheochromocytomas and paragangliomas can be attributed to a known germline mutation with implications for not only the patient but also the patient's family. The clinical presentation of catecholamine-producing tumors varies from essential hypertension to the classic paroxysmal hypertensive crises. Failure to diagnose and treat pheochromocytoma can lead to hypertensive crises and fatality.

## Clinical Features

Classically, patients present with paroxysms of severe hypertension and palpitations; however, sustained hypertension occurs in approximately 50% of the patients. Generalized sweating and headache are other frequent symptoms. Weakness, weight loss, pallor, nausea, and abdominal pain have also been associated with pheochromocytoma. Occasionally patients with adrenal incidentaloma or those undergoing periodic screening for a familial syndrome can be asymptomatic. **Box 50.3** summarizes indications for screening for pheochromocytoma.

## Diagnosis

Because catecholamines (dopamine, norepinephrine, and epinephrine) are typically secreted in an episodic fashion and have short half-lives, random levels may miss the diagnosis unless they are checked during a paroxysmal attack. Therefore measurement of blood levels of catecholamines is not recommended and may be misleading. Because the metabolism of catecholamines produced by pheochromocytoma is largely intratumoral, there is a continuous release of O-methylated metabolites, that is, metanephrine (metabolites of epinephrine) and normetanephrine (metabolites of norepinephrine). As a result, measurement of metanephrines (referring to the combination of metanephrine and normetanephrine) in blood or urine has become the preferred diagnostic test.

### • BOX 50.3 Screening for Pheochromocytoma

Hypertension with episodic features  
 Refractory hypertension  
 Prominent lability of blood pressure  
 Severe pressor response during anesthesia, surgery, or an angiography  
 Unexplained hypotension during anesthesia, surgery, or pregnancy  
 Family history of pheochromocytoma, MEN-2, VHL disease, neurofibromatosis  
 Adrenal incidentalomas  
 Idiopathic dilated cardiomyopathy

*MEN 2*, Multiple endocrine neoplasia type 2; *VHL*, von Hippel-Lindau syndrome.

The Endocrine Society recommends the use of either plasma-free metanephrines or 24-hour urinary-free metanephrines for the initial screening of pheochromocytomas and paragangliomas. Plasma-free metanephrines have the advantage of a simple peripheral venous and random blood test in the office. Plasma metanephrines have a high negative predictive value except in patients with early preclinical disease or dopamine-secreting tumors. On the other hand, a 24-hour urine collection for fractionated catecholamines and metanephrines is also a reliable test to diagnose pheochromocytoma. Blood or urinary metanephrine levels that are 2- or 3-fold elevated above the upper limit of normal are considered diagnostic of pheochromocytoma. Interfering medications, tricyclic antidepressants, levodopa, and other sympathomimetics may result in smaller false-positive elevations in metanephrines. If the testing is equivocal and the clinical suspicion for pheochromocytoma is high, clonidine suppression testing can be considered.

After biochemical confirmation of catecholamine excess, CT or MRI scanning of the abdomen usually diagnoses adrenal pheochromocytoma because most tumors are  $\geq 2$  to 3 cm in size. Functional imaging, such as  $^{123}\text{I}$ -metaiodobenzylguanidine (MIBG) scintigraphy, is done if adrenal imaging is negative to search for an extraadrenal paraganglioma. MIBG is taken up into adrenergic neurosecretory granules and hence images chromaffin tumors. Other imaging techniques to locate catecholamine-producing tumors include octreotide scan and  $^{18}\text{F}$ -fluorodeoxyglucose positron emission tomography (PET) scanning.

## Treatment

Surgical removal of the pheochromocytoma is the treatment of choice, but it is essential to preoperatively treat the patient with alpha-adrenergic blockade. Alpha-adrenergic blockers include phenoxybenzamine, a noncompetitive, nonselective drug, or selective alpha-blockers such as doxazosin or prazosin. Beta-blockers should not be initiated before adequate alpha-blockade because unopposed alpha-receptor stimulation can further raise blood pressure. After alpha-blockade has been established, beta-blockers may be used to control tachycardia or arrhythmias. Metyrosine, an inhibitor of catecholamine synthesis, may be used preoperatively in some situations. Preoperatively increased volume expansion with high sodium intake should be prescribed routinely because pheochromocytoma patients are known to be plasma volume contracted. Following resection of a pheochromocytoma, catecholamine levels should be periodically measured to rule out malignant disease.

## Pheochromocytoma and Genetic Syndromes

Pheochromocytoma and paraganglioma have now been attributed to over 15 germline mutations. Because approximately 40% of all of these tumors will be found

to harbor one of these mutations, it is now strongly recommended that all patients with pheochromocytoma or paraganglioma be considered for genetic testing. The genes and syndromes associated with pheochromocytoma and paraganglioma include von Hippel-Lindau (VHL) syndrome, multiple endocrine neoplasia 2A and 2B, neurofibromatosis type 1, the succinate dehydrogenase genes (A, B, C, D, and AF2), *TMEM127* gene, *MAX* gene, hypoxia inducible factor 2-alpha gene, and fumarate hydratase deficiency. Many of these tumor syndromes also increase the risk for developing other tumors and sequelae.

Paragangliomas are located in the head and neck and also in the thorax, abdomen, and pelvis. [Box 50.4](#) enumerates the frequent germline mutations in pheochromocytoma and paraganglioma.

## Adrenal Incidentaloma

An adrenal mass >1 cm serendipitously discovered on radiologic imaging is termed an *adrenal incidentaloma*. The prevalence of adrenal incidentalomas is higher with older age. Autopsy and imaging series have estimated the prevalence of incidentally discovered adrenal masses to be between 1% and 10%. Conversely, adrenal incidentalomas are uncommon in patients age <30 years. When an adrenal mass is identified, the approach requires evaluation of malignant potential (Is this a malignant or benign tumor or nontumoral entity?) and functional status (Does this mass hypersecrete adrenal hormones?).

The first step in evaluation should be a careful review of history and physical examination searching for clues of excessive hormonal secretion. It is generally recommended that all adrenal tumors be evaluated for hypersecretion of cortisol, usually via the 1-mg DST, which is most sensitive. Postdexamethasone cortisol values >5 µg/dL are considered to represent overt hypercortisolism: if signs or symptoms of Cushing syndrome are not apparent,

this is referred to as subclinical hypercortisolism or subclinical Cushing syndrome. Postdexamethasone cortisol values between 1.8 and 5 are also considered to represent subclinical hypercortisolism or an intermediate hypercortisolism and are associated with a higher risk of developing cardiovascular outcomes and death. Traditionally, postdexamethasone cortisol values of <1.8 µg/dL are considered to be “normal” or representative of a “nonfunctional” adrenal tumor; however, newer evidence suggests that even “nonfunctional” adrenal tumors increase the risk for incident diabetes. Although it is generally accepted that adrenal tumors with overt Cushing syndrome require urgent intervention, to date, there are no intervention studies or longitudinal prospective studies with evidence to support interventions to mitigate outcomes in subclinical hypercortisolism. In addition to assessment for hypercortisolism, screening for pheochromocytoma and PA should be considered, especially in patients with hypertension or other clinical signs that are suggestive of these disorders. If clinical features of androgen hypersecretion are observed in women, DHEAS levels should be measured.

The next concern is whether the mass is malignant. Radiologic features that predict malignancy include tumor size and imaging phenotype. Masses >6 cm are more likely to be malignant and should be resected. Benign adrenal adenomas are typically <4 cm (usually 1–2 cm), homogeneous with smooth margins, and characteristically lipid-rich by CT or MRI criteria. Benign adrenal adenomas are lipid-rich, typically <10 Hounsfield units on unenhanced CT scan. Benign adenomas also have a rapid washout of contrast medium on contrast-enhanced CT scanning. Lesions 4 to 6 cm lie in the gray area, and decision to surgically resect should be based on patient’s age, imaging phenotype, and coexisting conditions. To diagnose metastatic disease of an extraadrenal malignancy, fine-needle aspiration biopsy can be used in a patient with a history of malignancy. This should be performed only after ruling out pheochromocytoma.

In summary, for lesions that are hypersecretory or >6 cm in diameter, surgical resection should be performed. For lesions likely to be benign, repeated imaging should be done at 6, 12, and 24 months. An increase in size >1 cm per year should raise concern for possible malignancy, and resection should be considered ([Box 50.5](#) and [Fig. 50.4](#)).

## Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder resulting from loss-of-function mutations of enzymes involved in cortisol synthesis. The most frequent enzymatic deficiency is 21-hydroxylase deficiency. Patients with 21-hydroxylase deficiency have impaired synthesis of cortisol; as a result, compensatory ACTH secretion results in the shunting of precursors into the androgen pathway. The phenotype ranges from ambiguous genitalia in newborn girls to hirsutism in adulthood and to sexual precocity in males. Aldosterone

Rapidly of washout on contrast-enhanced CT scan

DHEAS, Dehydroepiandrosterone sulfate.

synthesis is also impaired, resulting in salt wasting, failure to thrive, and hypotension.

In late-onset CAH, there is a partial enzymatic 21-hydroxylase deficiency resulting in hirsutism and oligomenorrhea in adult women. This diagnosis is established by documenting elevated morning levels of 17-hydroxyprogesterone (17-OHP) or an abnormal increase in 17-OHP levels following ACTH stimulation. The therapeutic goal in adults with late-onset CAH is the minimal dose of long-acting steroids to suppress androgen production. Typically, 5 mg of prednisone or 0.25 to 0.5 mg of dexamethasone is given at bedtime to suppress adrenocortical androgen production.

## Chapter Review

### Questions

1. A 42-year-old female comes to see her primary care physician for fatigue and weakness over the last few months. Her medical history is unremarkable. She is not on any medications. During her last physical examination 2 years ago, her blood pressure was within normal limits, but during this visit it was elevated, 180/100 mm Hg. The remainder of her physical examination was unremarkable. Laboratory studies so far reveal a low PRA and serum potassium level of 3.2 mEq/L. What would be the most appropriate next step in evaluating this patient?
  - A. Plasma-free metanephrines
  - B. CT scan of adrenal gland
  - C. Salt suppression of aldosterone excretion
  - D. MR angiography of renal arteries
  - E. PA/PRA ratio
2. A 38-year-old female is admitted in the hospital for the management of acute myelogenous leukemia. During her hospitalization, she complains of bilateral upper quadrant pain. Subsequently she develops fever

• **Fig. 50.4** (A) 1.5-cm right adrenal mass (*arrow*) measuring  $-8$  Hounsfield units (HU) seen in this oral contrast-enhanced CT scan. (B) Oral and intravenous contrast-enhanced CT scan in a patient with adrenal carcinoma. In contrast to the tumor in (A), the right adrenal mass is large (12 cm; *arrowheads*) and heterogeneous. The mass is contiguous with the inferior vena cava and extends into the right lobe of the liver and the upper pole of the kidney. (From Trikudanathan S, Dluhy RG. Adrenal cortical dysfunction. In: Blake MA, Boland G, eds. *Adrenal Imaging*. New York: Humana Press; 2009:35–56.)

to 102°F and hypotension (80/50 mm Hg). Physical examination reveals no cutaneous or buccal pigmentation; abdominal examination shows mild tenderness in both her upper quadrants with no rigidity or guarding. Her laboratory values indicate sodium 131 mEq/L, potassium 5.0 mEq/L, blood urea nitrogen 24 mg/dL, creatinine 1.0 mg/dL. Her complete blood count also reveals hematocrit 31%, white blood cells 24,300/mm<sup>3</sup>, and platelets 20,000/mm<sup>3</sup>. What would be your next diagnostic approach?

- A. 8 AM ACTH levels
  - B. 8 AM cortisol level
  - C. CT scan abdomen/pelvis
  - D. Administer dexamethasone followed by a cosyntropin test.
  - E. Treat with intravenous fluids and recheck electrolytes.
3. A 60-year-old male smoker has a CT scan of chest performed for cough. His medical history is unremarkable, and he takes no medications. On physical examination, his blood pressure is 128/74 mm Hg. His CT scan/

- contrast-enhanced study that included the upper quadrants of the abdomen demonstrates a 1.3-cm mass in his left adrenal gland. What would be the next radiologic study?
- Unenhanced CT scan of the abdomen
  - I-MIBG scan
  - Unenhanced CT scan followed by contrast washout adrenal protocol
  - CT-guided fine-needle aspiration biopsy of the mass
  - PET scan
4. Which of the following biochemical evaluations should be performed on the patient of question 3?
- 24-hour urine for 17-ketosteroids
  - Plasma-free metanephrine and overnight DST
  - Overnight DST and ARR
  - ACTH stimulation test
  - Salt suppression of aldosterone excretion
5. A 25-year-old female presents with symptoms of paroxysmal hypertension, sweating, and tachycardia. Her father had died of metastatic extraadrenal paraganglioma. During episodes, her heart rate was 100 beats per minute and blood pressure 188/100 mm Hg. Which is the best diagnostic study?
- 24-hour urine for VMA
  - Plasma norepinephrine/epinephrine
  - Plasma-free metanephrines
  - MRI of the abdomen
  - MIBG scan
6. A 38-year-old female was seen in the hematology clinic for easy bruisability. Her physical examination showed mild facial plethora, acne on her back, increased facial hair, and supraclavicular and dorsocervical fat pads. Examination of the abdomen showed truncal obesity but no cutaneous striae. She has been on oral contraceptives for several years. Which of the following would be your next step?
- Low-dose 48-hour DST
  - MRI of pituitary gland
  - CT scan abdomen-adrenal protocol
  - 24-hour urinary cortisol or midnight salivary cortisol
  - Inferior petrosal sinus sampling for the measurement of ACTH

## Disorders of Calcium Metabolism

CAROLYN B. BECKER

Calcium is vital for the regulation of a vast array of human physiologic processes including cell division, cell adhesion, plasma membrane integrity, protein and hormone secretion, muscle contraction, neuronal excitability, glycogen metabolism, platelet aggregation, and blood coagulation. Given this list, it is not surprising that calcium levels are very tightly regulated.

The human body contains about 1000 g of calcium, of which >99% resides in the skeleton. This leaves <1% of total body calcium in the soluble phase, divided between intracellular and extracellular fluid compartments. The concentration of extracellular calcium is approximately 10,000-fold higher than the concentration of intracellular calcium, yet both are critical for the proper functioning of physiologic processes. Of the extracellular calcium, 50% is bound (40% to albumin; 10% to citrate, phosphate, and other ions), whereas the other 50% is unbound, or ionized. It is only the ionized calcium that is biologically active and only this fraction that is regulated hormonally. To adjust the calcium level for elevations in plasma proteins, total serum calcium should be reduced by 0.8 mg/dL for every 1 g/dL of albumin above the normal range.

The exquisite regulation of ionized calcium is truly remarkable, given the ever-changing supply of calcium from the diet versus the constant demands for calcium by various tissues throughout the body. Given the complexity of the system, it is not surprising that four different organs and at least two different hormones are needed to maintain calcium homeostasis around a desired set point. The four key organs are the parathyroids, intestine, kidneys, and skeleton, whereas the most critical regulatory hormones are parathyroid hormone (PTH) and vitamin D. Magnesium and phosphorus, as well as calcitonin and fibroblast growth factor 23, contribute to mineral homeostasis.

When serum calcium rises 2% to 3% above the genetically determined set point, homeostatic mechanisms are quickly activated to return the level to normal. First, at the parathyroid glands, excess calcium acts via innumerable calcium-sensing receptors (CaSRs) to immediately shut down PTH secretion. The CaSRs are G-protein-coupled transmembrane receptors that are exquisitely sensitive to changes in ionized calcium concentration (Fig. 51.1). Reduction in PTH decreases calcium resorption from bone, increases

renal excretion of calcium at the distal tubule, and reduces the renal synthesis of calcitriol (1,25-dihydroxyvitamin D), thus decreasing the intestinal absorption of calcium. Activation of the CaSR at the kidneys by excess ionized calcium also directly inhibits tubular reabsorption of calcium and inhibits urinary concentrating ability in the distal collecting duct. In most cases the reduced bone resorption, combined with reduced gastrointestinal calcium absorption and enhanced renal excretion of calcium, restores serum calcium to normal. Note that because the kidneys filter 10,000 mg of calcium per day, anything that impairs renal function will greatly impact the body's ability to regulate calcium loads. In the converse situation, when serum calcium falls by 2% to 3% below the desired set point, the opposite cascade occurs (Fig. 51.2): A drop in ionized calcium stimulates PTH release from the parathyroids; higher PTH increases calcium flux from bone, decreases renal excretion of calcium at the distal tubule, and stimulates the synthesis and secretion of calcitriol, enhancing absorption of calcium from the gut. Homeostasis is restored.

### The Parathyroid Glands and Parathyroid Hormone

The four parathyroid glands derive from the third and fourth branchial pouches and reside adjacent to the thyroid gland in the neck. They are very small, each weighing only about 40 mg. The predominant epithelial cell in the parathyroid glands is called the *chief cell*, which has a clear cytoplasm and is distinct from the larger oxyphil cell, which has an eosinophilic granular cytoplasm. Both cell types contain PTH.

The parathyroid cells “sense” the level of ionized calcium by way of the CaSRs that are expressed on the surface of the cells. The relationship between the extracellular ionized calcium concentration and PTH is a steep sigmoid curve in which small changes in ionized calcium produce marked changes in PTH (Fig. 51.3).

The initial effect of a decrease in extracellular ionized calcium is to stimulate the secretion of preformed PTH via exocytosis from storage granules in the parathyroid cells. Interestingly, most cells in the body require calcium to

• **Fig. 51.1** Calcium-sensing receptor. COOH, Carboxylic acid; MAPK, mitogen-activated protein kinase; NH<sub>2</sub>, amide; PLC, phospholipase C.

• **Fig. 51.2** Calcium homeostasis in setting of low serum calcium. PTH, Parathyroid hormone. (Redrawn from <http://lpi.oregonstate.edu/infocenter/minerals/phosphorus>.)

stimulate the process of exocytosis. How, then, can parathyroid cells release PTH via exocytosis in an environment of calcium deficiency? It appears that this critical role is played by intracellular magnesium in the parathyroid cells. This explains why severe prolonged magnesium deficiency essentially paralyzes PTH secretion, inducing reversible hypoparathyroidism. Interestingly, more moderate hypomagnesemia stimulates PTH secretion, whereas hypermagnesemia inhibits it, similar to the effects of hypocalcemia and hypercalcemia.

Changes in serum calcium regulate both the secretion of preformed PTH and the de novo synthesis of PTH at the level of gene transcription. Vitamin D also plays a role in PTH gene regulation in that high levels of calcitriol

(1,25[OH]<sub>2</sub>) inhibit PTH gene transcription. This allows calcitriol or vitamin D analogues to be used in the treatment of secondary hyperparathyroidism (HPT) in patients with renal failure.

## Hypercalcemia

The differential diagnosis for hypercalcemia is shown in [Box 51.1](#). The first question to ask in any case of hypercalcemia is: what is the PTH level? If PTH is frankly high or even inappropriately normal in the setting of hypercalcemia, the diagnosis is primary hyperparathyroidism (PHPT). There are a few other diagnoses that should be considered.

• **Fig. 51.3** Relationship between changes in serum calcium and intact parathyroid hormone. *PTH*, Parathyroid hormone.

These include tertiary HPT (from chronic renal failure) and use of lithium or thiazides, possibilities that are easily eliminated. A fourth possibility is the very rare autosomal dominant condition known as *familial benign hypercalcemia* or *familial hypocalciuric hypercalcemia* (FHH). Individuals with FHH have inactivating mutations of the CaSR, rendering the receptor less sensitive or resistant to the ambient serum calcium concentration at both the parathyroids and kidneys. In other words, these individuals require higher serum calcium levels to maintain normal calcium homeostasis. The hallmark of FHH is an inappropriately low urinary calcium excretion that can be easily calculated using a simple formula:

$$\text{CaCl/CrCl} = \frac{\text{Urinary calcium} \times \text{plasma creatinine}}{\text{Plasma calcium} \times \text{urinary creatinine}}$$

Urine CaCl/CrCl <0.01 is consistent with FHH. These patients should not be sent for parathyroid surgery. Genetic testing for mutations of the CaSR can be done if the diagnosis is uncertain.

### Primary Hyperparathyroidism

PHPT accounts for 80% to 90% of hypercalcemia in asymptomatic individuals and is by far the most common cause of hypercalcemia in healthy outpatients. It is the third most common endocrine disorder in the United States, occurring in 1 in 1000 people. Women comprise 75% of patients with PHPT, and the average age at diagnosis is 55 years. The vast majority (80%) of cases of PHPT are caused by solitary adenomas. Around 15% of patients will have four-gland hyperplasia, and 2% to 4% will have multiple adenomas. Parathyroid hyperplasia is most commonly found in three autosomal dominant inherited syndromes: multiple endocrine neoplasia (MEN) 1, MEN 2A, and isolated familial HPT. Parathyroid carcinoma represents <0.5% of cases. Genetic screening for MEN1

should be done in very young patients with PHPT (less than age 30–35 years), those with positive personal or family histories of other endocrine tumors (parathyroid, pancreatic, pituitary), or those with atypical or multiple parathyroid adenomas at any age.

The classic signs and symptoms of PHPT have been referred to as “stones, bones, abdominal groans, and psychic moans.” These are listed in [Box 51.2](#). Before the introduction of multiphasic chemistry screening, most patients with PHPT presented with renal manifestations (stones, nephrocalcinosis, renal failure) and/or the classic bone disease, osteitis fibrosa cystica. Now up to 85% of individuals with PHPT are asymptomatic. Kidney stones occur in fewer than 15% of patients with PHPT, whereas the most common bone disorder, osteoporosis, mainly affects skeletal sites rich in cortical bone (such as the distal one-third of the radius). Other manifestations of mild PHPT include dyspepsia, nausea, and constipation (“abdominal groans”) as well as fatigue, lethargy, depression, and difficulty concentrating (“psychic moans”). Myalgias, muscle weakness, chondrocalcinosis, polyuria/polydipsia, and nocturia can also occur. Nonclassical manifestations of PHPT such as cardiovascular and neurologic dysfunction are under active investigation at this time.

Laboratory findings in PHPT typically show elevated serum calcium (corrected for serum albumin) with a simultaneously elevated serum intact PTH. However, many patients with mild PHPT have serum calcium levels that fluctuate in and out of the normal range. Similarly, up to 50% of serum PTH levels may be in the middle or upper level of normal range, although such levels are still inappropriate within the context of hypercalcemia. Even low-normal PTH levels may be associated with PTH-secreting parathyroid adenomas. Serum phosphorus levels tend to be below 3.5 mg/dL because of the phosphaturic effect of PTH on the renal tubules. Note that concomitant vitamin D deficiency is very common in patients with PHPT and, in some cases, may mask the hypercalcemia. Recent guidelines recommend checking 25-hydroxyvitamin D levels in

### • BOX 51.1 Differential Diagnosis of Hypercalcemia

#### PTH-Mediated

- Sporadic primary hyperparathyroidism
- Familial syndromes
  - Associated with MEN 1 or MEN 2A
  - Isolated familial hyperparathyroidism/hyperparathyroidism–jaw tumor syndrome
  - Familial hypocalciuric hypercalcemia
- Parathyroid carcinoma
- Tertiary hyperparathyroidism (in end-stage renal disease or postrenal transplant)
- Drugs
  - Lithium
  - Thiazide diuretics

#### Non-PTH-Mediated

- Absorptive
  - Milk-alkali syndrome
- Resorptive (benign)
  - Hyperthyroidism
  - Immobilization
  - Vitamin A intoxication
  - Paget disease
- Resorptive (malignant)
  - Humoral (PTHrP-mediated) hypercalcemia of malignancy
  - Solid tumors, especially squamous and renal cell carcinomas
  - Adult T-cell leukemias
  - Vitamin D (1,25[OH]<sub>2</sub>D)-mediated lymphomas
- Local osteolytic hypercalcemia
  - Multiple myeloma
  - Leukemia
  - Lymphoma
  - Metastatic breast cancer
- Mixed (absorptive and resorptive)
  - Exogenous vitamin D intoxication
  - Endogenous vitamin D excess (1,25[OH]<sub>2</sub>D mediated)
  - Granulomatous diseases (sarcoidosis)
  - Lymphomas
- Miscellaneous
  - Adrenal insufficiency
  - Pheochromocytoma
  - VIPoma

*MEN*, Multiple endocrine neoplasia; *PTH*, parathyroid hormone; *PTHrP*, parathyroid hormone-related peptide.

all patients with PHPT and correcting any deficiencies to maintain levels above 20 ng/mL.

In recent years, a new category of HPT has been recognized, known as *normocalcemic HPT* (NPHPT). Patients with NPHPT have persistently normal total and ionized serum calcium levels but elevated intact PTH levels. The differential diagnosis includes vitamin D deficiency, malabsorption (e.g., occult celiac disease), chronic kidney disease, hypercalciuria, and the use of certain drugs. Once these have all been ruled out, the diagnosis of NPHPT is confirmed. Most of these patients are discovered during a workup for osteoporosis whereas some present with kidney stones or fractures. About 20% become hypercalcemic over time, and 20% to 30% will go on to need parathyroid surgery.

### • BOX 51.2 Signs and Symptoms of Primary Hyperparathyroidism

#### Stones

- Renal stones
- Nephrocalcinosis
- Polyuria
- Polydipsia

From Shoback D, Sellmeyer D, Bikle DD. Metabolic bone disease. In: Gardner DG. *Greenspan's Basic and Clinical Endocrinology*. 8th ed. New York: McGraw-Hill; 2007:241-245.

Parathyroidectomy remains the definitive treatment for PHPT. For individuals with mild, asymptomatic PHPT, a 2013 international workshop of experts developed guidelines for surgical intervention (Box 51.3). Patients who do not meet any of these criteria (up to 50% in some series) may be monitored with annual serum calcium, serum creatinine, estimated glomerular filtration rate (GFR) and bone mineral density (BMD) measurements every 1 to 2 years (Box 51.4). Longitudinal studies of patients with asymptomatic PHPT show remarkable biochemical stability over 10 to 15 years, although up to 25% ultimately require surgery. Following surgical cure of PHPT, there are dramatic improvements in BMD and a 90% to 95% reduction in renal stone formation in those with previous nephrolithiasis. Recent clinical trials randomizing subjects with PHPT to either parathyroidectomy or observation have found improvements in bone density in the surgical groups but variable effects on quality of life and symptoms.

For nonsurgical patients, medical management includes moderate calcium intake of 1000 mg/d (but lower in those

• **BOX 51.3** **Fourth International Workshop Guidelines for Surgery for Asymptomatic Primary Hyperparathyroidism**

Creatinine clearance (calculated) reduced to <60 mL/min  
 Serum calcium >1 mg/dL above normal  
 Bone mineral density T-score of -2.5 or lower at the spine, hip, or distal third of radius  
 Age <50 years  
 Situations in which long-term medical surveillance is neither desired nor possible  
 Vertebral fracture noted on any imaging modality  
 24-hour urine calcium >400 mg and increased stone risk by comprehensive stone risk analysis  
 Nephrolithiasis or nephrocalcinosis

• **BOX 51.4** **Guidelines for Follow-Up of Nonsurgically Treated Patients With Asymptomatic Primary Hyperparathyroidism**

Serum calcium: annually  
 Skeletal: every 1 to 2 years with DXA (3 sites), vertebral fracture assessment, or spinal radiograph if clinically indicated  
 Renal: serum creatinine and estimated GFR annually; if stones suspected, obtain urinary comprehensive stone analysis and/or renal imaging (KUB, ultrasound or CT)  
 Clinical: annually, checking for symptoms or complications developing over time

DXA, Dual-energy x-ray absorptiometry; GFR, glomerular filtration rate; KUB, kidneys, ureters, and bladder.  
 From Bilezikian JP, Brandi ML, Eastell R, et al. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the Fourth International Workshop. *J Clin Endocrinol Metab.* 2014;99:3561-3569.

with high calcitriol or high urinary calcium levels), correction of vitamin D deficiency, good hydration, and, in select cases, antiresorptive therapy with bisphosphonates or other antiresorptive agents. The calcimimetic cinacalcet is US Food and Drug Administration (FDA) approved for primary and secondary HPT and parathyroid cancer, but in recent trials it has successfully controlled hypercalcemia in patients with PHPT for up to 3 to 5 years. Unfortunately, cinacalcet did not improve bone density in patients with PHPT even though serum calcium was normalized and PTH levels were reduced.

### Non-Parathyroid Hormone-Mediated Hypercalcemia

Etiologies of non-PTH-mediated hypercalcemia can be divided into three broad categories: absorptive, resorptive,

or mixed. Absorptive hypercalcemia, from excess calcium, is characterized by increased absorption of calcium from the gut. The best example of this is ingestion of excessive calcium carbonate leading to the milk-alkali syndrome. Mixed disorders with both absorptive and resorptive hypercalcemia include vitamin D-mediated hypercalcemia such as exogenous vitamin D intoxication or excess 1,25-dihydroxyvitamin D production from activated macrophages in granulomatous diseases (e.g., sarcoidosis) or certain lymphomas.

Resorptive hypercalcemia occurs whenever excessive osteoclastic bone resorption is the primary mechanism underlying the hypercalcemia. Although a number of benign disorders may be associated with non-PTH-mediated resorptive hypercalcemia (including hyperthyroidism, immobilization, Paget disease, vitamin A intoxication), the majority of cases are caused by malignancies. Mechanisms of malignant hypercalcemia include local release of osteoclast-activating cytokines in bone (multiple myeloma), osteolytic destruction of bone from metastases (breast cancer), or parathyroid hormone-related peptide (PTHrP)-mediated skeletal resorption from distant tumors (squamous and renal cell carcinomas most commonly). Among inpatients with symptomatic hypercalcemia, 45% have malignancies, 25% have PHPT, and 10% have renal insufficiency. Remember that PHPT and malignancies may coexist in the same patient. In addition, there are a number of rare causes of hypercalcemia reported in the literature.

Symptoms of hypercalcemia depend on the severity of the calcium elevation as well as the rapidity of the rise. In general, rapid rises in calcium cause more symptoms than slower, more gradual increases. Patients with non-PTH-mediated hypercalcemia tend to have more severe symptoms affecting the central nervous (lethargy, psychosis, stupor, and coma), cardiovascular (bradycardia, asystole, and shortened QT intervals), and gastrointestinal (anorexia, nausea, vomiting, and constipation) systems, but accelerated PHPT can also cause severe symptomatology, particularly in a setting of renal failure. When serum-corrected calcium levels reach 14 mg/dL or higher, patients are generally quite symptomatic.

Workup of the symptomatic patient with hypercalcemia requires a very careful history and physical examination, followed by judicious laboratory testing (Table 51.1). Useful laboratory tests include routine complete blood count and chemistries, phosphorus, magnesium, intact PTH, 25-hydroxyvitamin D (the key test in vitamin D intoxication), 1,25-dihydroxyvitamin D (the key test in granulomatous diseases and some lymphomas), and serum protein electrophoresis (SPEP) and urine protein electrophoresis (UPEP; multiple myeloma). Serum PTHrP is rarely needed to make the diagnosis of humoral hypercalcemia of malignancy but can be confirmative in cases where the primary tumor is elusive. Vitamin A and serum cortisol should be ordered if clinically indicated. Other useful tests can be chest x-ray, bone scan, mammography, CT scans of chest/abdomen/pelvis, and lymph node or tissue biopsy.

**TABLE 51.1** Workup for Non-Parathyroid-Mediated Hypercalcemia

SPEP, UPEP	Chest X-Ray
25(OH)-vitamin D	Bone scan
1,25(OH) <sub>2</sub> -vitamin D	Mammography
Serum ACE (if indicated)	CT scan of chest, abdomen, pelvis
PTHrP Vitamin A Cortisol	Lymph node or tissue biopsy
PSA (rarely; usually osteoblastic)	

*ACE*, Angiotensin-converting enzyme; *PSA*, prostate-specific antigen; *PTHrP*, parathyroid hormone–related peptide; *SPEP*, serum protein electrophoresis; *UPEP*, urine protein electrophoresis.

Management of symptomatic, severe hypercalcemia, regardless of the cause, begins with vigorous hydration and restoration of the glomerular filtration rate to normal, if possible (Box 51.5). This enhances renal clearance of calcium and reduces serum calcium substantially. Loop diuretics should be used to enhance renal calcium excretion only after euolemia has been restored if there is evidence of heart failure or volume overload. In the milk-alkali syndrome, adequate hydration and cessation of the calcium source completely reverse the hypercalcemia. However, in most of the other conditions, antiresorptive therapy is needed to achieve and maintain normocalcemia. Intravenous bisphosphonates rapidly reduce resorptive and mixed hypercalcemia in the well-hydrated patient by causing apoptosis of activated osteoclasts. Either pamidronate or zoledronic acid may lower serum calcium to the normal range within a few days. Adverse side effects from intravenous bisphosphonates include acute-phase reactions, renal insufficiency, and hypocalcemia. Frequent, high-dose intravenous bisphosphonate therapy for malignant disease may result in osteonecrosis of the jaw. A newer option is denosumab, the human monoclonal antibody that targets RANK-ligand, a cytokine responsible for osteoclastic bone resorption. When given at a dose of 120 mg subcutaneously every 4 weeks, denosumab is FDA approved for the prevention and treatment of skeletal-related events in patients with metastatic solid tumors. It offers certain advantages over intravenous bisphosphonates including excellent tolerability, easier administration, and absence of renal toxicity. Profound hypocalcemia may occur when denosumab is given to patients with severe renal impairment. Rarely, osteonecrosis of the jaw has been reported with the drug. Finally, in patients with hypercalcemia from multiple myeloma, lymphoma, sarcoidosis, or vitamin A or D intoxication, glucocorticoids are extremely effective treatments. The success in treating non-PTH-mediated hypercalcemia ultimately depends on treatment of the underlying disorder (Stewart, 2005).

**• BOX 51.5** Management of Acute Hypercalcemia**Fluids**

0.9% NaCl intravenously  
Loop diuretic in those with CHF or evidence of volume overload

**Medications**

Pamidronate 60 to 90 mg intravenously over 1.5 to 6 hours  
Zoledronic acid 4 mg intravenously  
Calcitonin 4 IU/kg subcutaneously every 12 hours for 24 to 48 hours  
Glucocorticoids 20 to 100 mg prednisone daily  
Denosumab 120 mg subcutaneously every 4 weeks  
Cinacalcet 30 to 90 mg daily for PTH-mediated hypercalcemia

**Other**

Therapy directed at primary tumor  
Surgery  
Chemotherapy  
Radiation  
Decrease calcium and vitamin D intake  
Maintain hydration  
Mobilization

*CHF*, Congestive heart failure; *PTH*, parathyroid hormone.

**Hypocalcemia**

Hypocalcemic disorders can result from a number of abnormalities of the calcium regulatory system: PTH deficiency, abnormal responsiveness to PTH, vitamin D disorders, or complexation or deposition of calcium (Box 51.6). The rare inherited disorders of vitamin D resistance (vitamin D–dependent and vitamin D–resistant rickets) will not be discussed here. Note that hypoalbuminemia results in low total serum calcium because of a reduction in the protein-bound fraction of calcium; however, ionized calcium remains normal.

Hypocalcemia may present dramatically with symptoms of perioral numbness, paresthesias, carpopedal spasm, seizures, or tetany, or it may be relatively asymptomatic. Most of the symptoms are caused by increased neuromuscular excitability. The classic muscular manifestation of hypocalcemia is carpopedal spasm, a painful involuntary muscular contraction of the hands in which there is adduction of the thumb, flexion of the metacarpophalangeal joints, extension of the interphalangeal joints, and flexion of the wrists (Fig. 51.4). Tetany may also present as laryngospasm, which can be fatal. Latent tetany can be elicited by testing for Chvostek sign (tapping on the facial nerve to produce contraction of the ipsilateral facial muscles) and Trousseau sign (inflating a blood pressure cuff to 20 mm Hg above systolic pressure to elicit ipsilateral carpal spasm). Note that 25% of normal people can have a mild Chvostek sign. In addition to tetany, other serious manifestations of hypocalcemia can include seizures and prolongation of the QT interval on electrocardiogram testing (because of delay in repolarization), resulting in serious arrhythmias and congestive heart failure.

## • BOX 51.6 Differential Diagnosis of Hypocalcemia

### Hypoparathyroidism

Surgical  
Idiopathic  
Neonatal  
Familial  
Autoimmune  
Metal deposition (iron, copper, aluminum)  
Postirradiation  
Infiltrative  
Functional (severe hypomagnesemia)  
Abnormal regulation (CaSR mutations)

### Resistance to PTH Action

Pseudohypoparathyroidism  
Renal insufficiency

### Medications That Prevent Osteoclastic Bone Resorption

Plicamycin  
Calcitonin  
Bisphosphonates  
Denosumab

### Vitamin D Disorders

Deficiencies of 25-(OH)D and/or 1,25-(OH)<sub>2</sub>D  
Renal failure  
Severe substrate deficiency (malabsorption syndromes)  
Hereditary vitamin D–dependent rickets, type 1 (deficiency of renal 1- $\alpha$ -hydroxylase)  
Resistance to 1,25-(OH)<sub>2</sub>D action  
Hereditary vitamin D–dependent rickets, type 2 (defective vitamin D receptor)

### Acute Complexation or Deposition of Calcium

Acute hyperphosphatemia  
Crush injury with muscle necrosis  
Rapid tumor lysis  
Parenteral or enteral phosphate administration  
Acute pancreatitis  
Transfusions with citrated blood  
Rapid, excessive skeletal mineralization  
Hungry bones syndrome (postparathyroidectomy)  
Osteoblastic metastases

25-(OH)D, 25-Hydroxyvitamin; 1,25-(OH)<sub>2</sub>D, 1,25-dihydroxyvitamin D; CaSR; calcium-sensing receptor; PTH, parathyroid hormone. From Shoback D, Sellmeyer D, Bikle DD. Metabolic bone disease. In: Gardner DG. *Greenspan's Basic and Clinical Endocrinology*. 8th ed. New York: McGraw-Hill; 2007:281-345.

### Hypoparathyroidism

Syndromes of hypocalcemia associated with low PTH levels include postsurgical hypoparathyroidism, “hungry-bone syndrome” following parathyroid surgery, hypomagnesemia, critical illness, autoimmune or infiltrative destruction of the parathyroid glands, as well as inherited disorders including autosomal dominant hypocalcemia. In this disorder, the other side of FHH, activating mutations of the CaSR result in increased sensitivity to calcium and a lower set point for Ca and PTH.

• **Fig. 51.4** Carpal spasm in hypocalcemia. (From *Medical Show*. Latent tetany signs. <http://medicalshow.blogspot.com/2012/06/latent-tetany-signs.html>. June 8, 2012. Accessed 28.06.17.)

Surgical hypoparathyroidism is the most common cause of PTH deficiency. It results from removal or destruction of the parathyroid glands during surgery for cancer of the head or neck, total thyroidectomy, or parathyroidectomy. Laboratory studies show hypocalcemia, hyperphosphatemia, and undetectable or inappropriately low PTH. Other causes of hypoparathyroidism such as autoimmune destruction of the parathyroid glands and inherited disorders (familial hypoparathyroidism, DiGeorge syndrome) are far less common. Infiltrative destruction of the parathyroids by iron (thalassemia), copper (Wilson disease), metastatic disease, or infection is also unusual.

An important and reversible cause of hypoparathyroidism is severe, chronic magnesium deficiency that paralyzes the secretion of PTH from vesicles in the parathyroid glands while blunting the peripheral actions of PTH. The hypocalcemia responds quickly to administration of magnesium.

### Pseudohypoparathyroidism

This category includes two inherited, rare disorders of target-organ resistance to PTH, referred to as *pseudohypoparathyroidism (PHP) 1A and PHP 1B*. Biochemically, the syndromes present exactly like hypoparathyroidism with hypocalcemia and hyperphosphatemia, but PTH is elevated rather than undetectable. PHP 1A is associated with a classic phenotype known as *Albright hereditary osteodystrophy* in which patients are short, have round faces, short necks, mental retardation, and shortening of the fourth and/or fifth metacarpals. Patients with PHP 1B have no somatic phenotype and otherwise appear normal. The genetic mutations and inheritance of both syndromes have now been fully elucidated.

### Vitamin D Deficiency

Patients with hypocalcemia caused by vitamin D deficiency have elevated PTH levels (so-called secondary HPT). The most common causes of vitamin D deficiency are shown in **Box 51.7**. Note that hypocalcemia rarely occurs from depletion of 25-hydroxyvitamin D

### • BOX 51.7 Causes of Vitamin D Deficiency

Inadequate sun exposure  
 Inadequate dietary intake  
 Malabsorption syndromes  
 Anticonvulsants  
 Nephrotic syndrome  
 Chronic renal failure/end-stage renal disease  
 Inherited disorders (see [Box 51.5](#))

alone, even when levels are undetectable, because of the ability of high PTH levels to mobilize calcium from bone.

### Chronic Kidney Disease

One of the most important causes of secondary HPT is chronic kidney disease (CKD). Patients on dialysis often have extremely elevated levels of PTH and PTH fragments (not all are bioactive) caused by the decline in 1,25-dihydroxyvitamin D levels and increases in serum phosphate associated with progressive renal failure. The disordered mineral metabolism associated with CKD can result in renal osteodystrophy, soft tissue and vascular calcifications, cardiovascular disease, and high cardiovascular mortality. In the past, the only treatments available for secondary HPT resulting from CKD were large doses of calcium to serve as phosphate binders as well as vitamin D sterols to lower PTH. These interventions often aggravated the abnormal mineral metabolism by increasing the calcium  $\times$  phosphate product and worsening vascular and ectopic calcification. The calcimimetic cinacalcet has offered an attractive alternative to the traditional treatment of secondary HPT in CKD. By mimicking calcium at the CaSR, cinacalcet reduces PTH without raising serum calcium, phosphate, or the calcium  $\times$  phosphate product. It has greatly improved calcium-phosphate homeostasis in patients on dialysis.

### Miscellaneous

A number of other disorders can result in hypocalcemia, including hyperphosphatemia from rhabdomyolysis or tumor lysis syndrome, calcium malabsorption from celiac disease or other malabsorption states, transfusions with citrated blood, widespread osteoblastic skeletal metastases, and acute pancreatitis, among others. Acute respiratory alkalosis from hyperventilation can cause symptomatic, reversible hypocalcemia caused by a shift of ionized calcium onto albumin within the alkalotic environment.

### Treatment

Treatment of hypocalcemia depends on the cause, the severity, and the degree of symptomatology but generally

### • BOX 51.8 Management of Hypocalcemia

#### Acute

2 to 3 ampules of calcium gluconate (90 mg elemental calcium per 10-mL ampule) intravenously, followed by:  
 Infusion of 10 ampules calcium gluconate in 1 L of intravenously dosed fluids over 24 hours  
 Calcitriol 0.25 to 1  $\mu$ g orally daily  
 Calcium carbonate 1250 mg (500 mg elemental calcium per tab) 1 to 2 tablets three times daily with food  
 Correct Mg deficiency with parenteral magnesium

#### Chronic

Keep serum calcium in 8.5- to 9-mg/dL range  
 Monitor 24-hour urinary calcium excretion to detect hypercalciuria  
 Thiazide diuretics if significant hypercalciuria  $>4$  mg/kg/d  
 1.5 to 3 g of oral elemental calcium daily in divided doses  
 Calcitriol 0.25 to 0.75  $\mu$ g daily  
 Recombinant human PTH (1-84) SQ daily in refractory cases of hypoparathyroidism

*PTH*, Parathyroid hormone.

includes both calcium and vitamin D supplementation. Acute hypocalcemia associated with tetany or incipient tetany is a medical emergency and requires immediate intravenous calcium administration ([Box 51.8](#)). Two to three ampules of calcium gluconate (90 mg elemental calcium per 10-mL ampule) can be given intravenously over several minutes followed by an infusion of 10 ampules in 1 L of intravenous fluids over 24 hours. Simultaneously, the patient should be started on calcitriol (activated vitamin D) and oral calcium. For chronic hypocalcemia caused by hypoparathyroidism, the goal is to keep serum calcium in the 8.5- to 9-mg/dL range, high enough to prevent symptoms but low enough to avoid hypercalciuria. Periodic monitoring of 24-hour urinary calcium excretion is desirable to detect hypercalciuria. Treatment with thiazide diuretics can help reduce urinary calcium excretion. The goal is to maintain 24-hour urinary calcium levels below 4 mg/kg/d. At least 1.5 to 3 g of oral elemental calcium should be given daily in divided doses along with activated vitamin D (calcitriol). Large doses of ergocalciferol (vitamin D<sub>2</sub>) or cholecalciferol (vitamin D<sub>3</sub>) may be used in place of calcitriol but may accumulate and cause vitamin D intoxication.

In 2015 the FDA approved recombinant human PTH (1-84) for the treatment of patients with hypocalcemia resulting from permanent hypoparathyroidism. The drug is given as a subcutaneous injection daily and allows patients to achieve better calcemic control with lower doses of calcium and vitamin D. However, rhPTH (1-84) is quite expensive and comes with a warning about osteosarcoma in rats. It is useful for patients with hypoparathyroidism who are unable to achieve reasonable control of their deficiency syndrome with non-PTH therapies.

## Chapter Review

### Questions

1. A 55-year-old woman has a routine physical. She entered menopause at age 52 years and is doing well. She is not on any medications. She takes 500 mg calcium once daily and has very little dairy in her diet. Review of systems reveals some fatigue. Laboratory data reveal calcium 10.8 mg/dL (normal 8.6–10.4 mg/dL) and albumin 4 g/L. What is the next best step?
  - A. Check a 24-hour urine for calcium excretion.
  - B. Check PTH, SPEP, PTHrP, 1,25-D, and 25-hydroxyvitamin D.
  - C. Repeat serum calcium and intact PTH.
  - D. Stop all calcium intake, and repeat serum calcium in 2 months.
2. A 65-year-old woman is diagnosed with asymptomatic PHPT. Her serum calcium is 11 mg/dL (normal 8.6–10.4 mg/dL) with intact PTH 85 pg/mL (normal 1–65 pg/mL). What should you order next?
  - A. Bone mineral density (including one-third distal radius)
  - B. 25-hydroxyvitamin D
  - C. 1,25-dihydroxyvitamin D
  - D. A and B
  - E. All of the above
3. A previously healthy 55-year-old man is brought to the hospital because of nausea, vomiting, lethargy, and severe back pain. Laboratory data reveal serum calcium 15.8 mg/dL (normal 8.6–10.4 mg/dL), PTH <10 pg/mL, creatinine 2.8 mg/dL, and hematocrit 35%. In addition to checking vitamin D levels, what other key test should you order?
  - A. PTHrP
  - B. Prostate-specific antigen
  - C. SPEP
  - D. Phosphate
  - E. 24-hour urine calcium
4. A 43-year-old woman with end-stage renal disease on hemodialysis has serum calcium 11.4 mg/dL, intact PTH >1200 pg/mL, and evidence of osteitis fibrosa cystica on a skeletal survey. She is taken to surgery, where 3.5 parathyroid glands are removed. Postoperatively, her serum calcium plummets to 7 mg/dL with serum phosphate 2 mg/dL and magnesium 1.7 mEq/L. Despite treatment with high doses of oral calcium and calcitriol, she continues to require intravenous calcium infusions for over 5 days. What is the most likely cause of the persistent hypocalcemia?
  - A. Postoperative hypoparathyroidism
  - B. Hungry bone syndrome
  - C. Magnesium deficiency
  - D. 25-hydroxyvitamin D deficiency
  - E. Adynamic bone disease
5. A 35-year-old man is admitted because of nausea, vomiting, and dizziness. He has had epigastric pain for several months and admits to excess alcohol intake. His only medication is Tums for heartburn. On examination, he is alert and oriented  $\times 3$  with blood pressure 120/60 mm Hg, heart rate 110 beat per minute, epigastric tenderness, but is otherwise in no distress. Laboratory data reveal serum calcium 16.8 mg/dL, bicarbonate 38 mg/dL, intact PTH <10 pg/mL, and creatinine 3 mg/dL. The most likely cause of his hypercalcemia is:
  - A. Milk-alkali syndrome
  - B. Malignancy
  - C. Adrenal insufficiency
  - D. Renal failure

### Answers

1. C
2. D
3. C
4. B
5. A

## Diabetes Mellitus

RAJESH K. GARG AND MERRI PENDERGRASS

**D**iabetes mellitus (DM) is one of the most challenging problems facing health care providers today. According to the Centers for Disease Control and Prevention (CDC), an estimated 29 million people or 9.3% of the United States adult population had diabetes in the year 2012. An additional 86 million American adults had prediabetes, a condition that substantially increases the risk for future type 2 diabetes.

The high prevalence of diabetes leads to a tremendous overall burden of disease because diabetes is associated with multiple complications including cardiovascular disease (CVD), blindness, renal failure, lower extremity amputations, adverse pregnancy outcomes, increase in fractures, and premature death. The financial cost is staggering, with one in five health care dollars spent on treating diabetes or its complications. The true burden of the disease exceeds cost estimates because they do not include the social cost of intangibles such as pain and suffering, care provided by nonpaid caregivers, excess medical costs associated with undiagnosed diabetes, and diabetes-attributed costs for health care expenditure categories not studied.

This chapter begins with a discussion of the diagnosis and classification of diabetes. Strategies to prevent diabetes and its complications are reviewed. The major focus of the presentation will be glucose management.

### Classification

DM is a group of metabolic abnormalities characterized by hyperglycemia that results from defects in insulin secretion, insulin action, or both (Table 52.1). The majority of cases fall into two broad categories: type 1 diabetes (T1DM) and type 2 diabetes (T2DM). Some patients cannot be clearly classified into either category because of overlap between them (Table 52.2). It is clinically important to try to distinguish between the two types because this will affect choice of therapy. Patients with T1DM require insulin treatment for life. Patients with T2DM are frequently controlled with noninsulin agents, at least initially. Many ultimately may require addition of insulin to achieve optimal glycemic control.

### Type 1 Diabetes

T1DM accounts for about 5% of diabetes cases in the United States. The condition results from an absolute deficiency of insulin secretion, typically caused by cellular-mediated autoimmune destruction of pancreatic beta cells. Markers of the immune destruction include antibodies to biochemically characterized antigens such as insulin, glutamic acid decarboxylase (GAD), islet antigen 2 (IA-2), and zinc transporter 8 (ZnT8). One or more of these autoantibodies are present in most patients at the time of diagnosis. The rate of beta cell destruction can be quite variable, being rapid in some individuals (mainly infants and children) or slow in others (mainly adults).

### Type 2 Diabetes

T2DM, which accounts for about 95% of diabetes in the United States, is a heterogeneous disease resulting from multiple dysregulated metabolic pathways. The two major abnormalities are (1) insulin resistance in skeletal muscle, liver, and adipocytes and (2) a progressive decline in insulin secretion by beta cells. Insulin resistance results from both environmental factors (e.g., obesity and physical inactivity) and genetic factors that have yet to be fully identified. Early in the natural history of T2DM, insulin-resistant prediabetic individuals compensate by secreting increased amounts of insulin. Insulin levels therefore tend to be high in prediabetes and early T2DM. As the capacity of the pancreas to secrete insulin deteriorates, endogenous insulin production is insufficient to overcome insulin resistance, and hyperglycemia ensues. In later stages of T2DM, insulin levels may be low or absent. In addition to insulin resistance and relative insulin deficiency, other pathophysiologic factors that may contribute to hyperglycemia in T2DM include deficient incretin effect, high glucagon levels, rapid gastric emptying, increased central nervous stimulus for hepatic glucose production, and higher renal threshold for glucosuria.

### Gestational Diabetes Mellitus

Gestational DM (GDM) refers to glucose intolerance with onset or first recognition during pregnancy. GDM

**TABLE 52.1** Classification of Diabetes Mellitus

Type of Diabetes	Description
Type 1 diabetes mellitus	Pancreatic beta-cell destruction (usually autoimmune) results in absolute insulin deficiency
Type 2 diabetes mellitus	Combination of (1) insulin resistance and (2) relative insulin deficiency
Gestational diabetes mellitus	Any degree of glucose intolerance with onset or first recognition during pregnancy
Other specific types	Specific types of diabetes arising from other causes

**TABLE 52.2** Clinical Clues to Type 1 Diabetes Versus Type 2 Diabetes

	Type 1 Diabetes	Type 2 Diabetes
Age	~5% of newly diagnosed adults ~50% of newly diagnosed children	~95% of newly diagnosed adults ~50% of newly diagnosed children
Ethnicity	More common in non-Hispanic whites	More common in nonwhite groups
Weight	~20% overweight	~90% overweight
Family history	~10% have a relative with diabetes	>50% have a relative with diabetes
DKA	Frequently occurs	Sometimes occurs
Glucose levels	More variable	Less variable
Hypoglycemia	More frequent and severe	Less frequent and severe
Antibodies	Usually positive	Usually negative
C-peptide	Usually low or undetectable	Usually detectable

*DKA, Diabetic ketoacidosis.*

complicates approximately 4% of pregnancies in the United States, with a prevalence ranging between 1% and 14% depending on the population studied and the definition used. Patients who develop GDM tend to have risk factors for T2DM, including older age, obesity, and nonwhite ethnicity. GDM is typically recognized during the third trimester and resolves following delivery. However, GDM is a strong risk factor for the future development of T2DM.

### Other Specific Types

When diabetes occurs as the result of another medical condition or treatment, it is categorized as *secondary diabetes*

or *other specific type*. Examples include diseases of the exocrine pancreas (e.g., cystic fibrosis, chronic pancreatitis), monogenic diabetes syndromes (e.g., maturity-onset diabetes of the young), and drug- or chemical-induced diabetes (e.g., steroid use, treatment of HIV/AIDS, or after organ transplantation).

### Diagnosis

Diabetes in nonpregnant patients may be diagnosed by one of the following ways: hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>), a fasting plasma glucose (FPG), oral glucose tolerance test (OGTT), or a random glucose value (Table 52.3). Symptoms of hyperglycemia and random plasma glucose  $\geq 200$  mg/dL can be used to make the diagnosis without the need to repeat the test. For routine screening in asymptomatic people, HbA<sub>1c</sub> or FPG is most frequently used. The HbA<sub>1c</sub> is an attractive option because it can be obtained at any time of the day without fasting, is a measure of long-term glycemia, and can be used to make treatment decisions. However, clinicians must be aware that there are conditions that either will require a specific HbA<sub>1c</sub> assay method or will preclude HbA<sub>1c</sub> testing. For example, certain hemoglobinopathies interfere with some HbA<sub>1c</sub> assay methods. Furthermore, HbA<sub>1c</sub> will not accurately reflect glycemia in any condition that changes red cell turnover (e.g., hemolytic anemia, chronic malaria, major blood loss, or blood transfusions). Finally, HbA<sub>1c</sub> levels may vary with patients' race/ethnicity. For example, with similar fasting and postglucose load glucose levels, African Americans may have higher HbA<sub>1c</sub> levels than non-Hispanic whites. In the absence of unequivocal hyperglycemia, a positive test for diabetes must be repeated and confirmed. The American Diabetes Association (ADA) recommends repeating the same test that was obtained in the first instance. For example, if HbA<sub>1c</sub> was obtained for screening and found to be abnormal, HbA<sub>1c</sub> should be repeated. If FPG was obtained for screening and found to be abnormal, then FPG should be repeated. However, if two abnormal results are already available from different tests (e.g., FPG and HbA<sub>1c</sub>), diagnosis may be made without repeating the tests.

There is no consensus about how to best screen and diagnose GDM. Various strategies are used, and all require an OGTT for the majority of patients. Screening is typically done at the beginning of the third trimester. Lower glucose cutoffs than the ones used for nonpregnant patients are used to make the diagnosis of GDM.

### Categories of Risk for Diabetes

The ADA recognizes an intermediate group of people whose glucose levels do not meet criteria for diabetes but still are too high to be considered normal (see Table 52.3). These individuals are sometimes labeled as having prediabetes. Other important risk factors for diabetes include advanced age, excess adiposity, sedentary lifestyle, family history of diabetes, high-risk ethnic group, history of GDM, hypertension,

**TABLE 52.3** Categories of Glucose Tolerance

	Fasting Plasma Glucose (mg/dL)	2-Hour OGTT Glucose (mg/dL)	HbA <sub>1c</sub> (%)
Normal	≤100	≤140	<5.7
Categories of increased risk for diabetes	101–125 (impaired fasting glucose)	140–199 (impaired glucose tolerance)	5.7–6.4
Diabetes	≥126	≥200	≥6.5

*HbA<sub>1c</sub>, Hemoglobin A<sub>1c</sub>; OGTT, oral glucose tolerance test.*

**• BOX 52.1 Risk Factors for Type 2 Diabetes**

- Overweight or obese (BMI >25 kg/m<sup>2</sup>); in Asians BMI >23 kg/m<sup>2</sup>
- Physical inactivity
- First-degree relative with diabetes
- Members of a high-risk ethnic population (e.g., African American, Latino, Native American, Asian American, and Pacific Islander)
- Women who were diagnosed with gestational diabetes mellitus
- Hypertension (>140/90 mm Hg or on therapy for hypertension)
- HDL cholesterol level <35 mg/dL and/or a triglyceride level >250 mg/dL
- History of cardiovascular disease
- A<sub>1c</sub> >5.7, impaired glucose tolerance, or impaired fasting glucose
- Other clinical conditions associated with insulin resistance (e.g., acanthosis nigricans, polycystic ovarian syndrome)

*BMI, Body mass index; HDL, high-density lipoprotein.*

dyslipidemia, polycystic ovarian syndrome, and history of vascular disease (Box 52.1).

## Screening for Diabetes

Periodic screening for T2DM is recommended in asymptomatic adults who are overweight and have one or more additional risk factors as shown in Box 52.1. In individuals without these risk factors, testing should begin at age 45 years. If tests are normal, repeat testing should be carried out at least every 3 years.

## Prevention of Diabetes and Its Complications

### Prevention of Type 1 Diabetes

Multiple strategies to prevent T1DM (e.g., parenteral insulin, oral insulin, GAD-alum antigen, and oral nicotinamide) have been evaluated in large randomized controlled trials. Unfortunately, no strategy has been found to be effective. Nevertheless, this remains an area of intense investigation. Additional trials aimed to prevent T1DM or to delay

the progressive loss of beta-cell function in newly diagnosed patients are currently in progress.

### Prevention of Type 2 Diabetes

Individuals at high risk for developing T2DM can significantly decrease this risk with intensive lifestyle modification and with certain medications. The Diabetes Prevention Program (DPP) demonstrated that, after 3 years, the overall incidence of diabetes was reduced by 58% with lifestyle intervention and 31% with metformin. There were sustained reductions in diabetes incidence in the 10 years following DPP randomization—34% in the lifestyle group and 18% in the metformin group. Notably, DPP demonstrated certain subgroups differed in their response to the interventions. Metformin was similarly effective as lifestyle modification in participants with body mass index (BMI) ≥35 and in women with a history of GDM. Metformin was not significantly better than placebo in those age >60 years. Therefore metformin is recommended for diabetes prevention in patients with prediabetes age <60 years and BMI ≥35. Although multiple other pharmacologic agents (e.g., alpha-glucosidase inhibitors, orlistat, and thiazolidinediones) have been found to decrease the onset of diabetes in high-risk individuals, they are not generally recommended because of cost and/or side effects.

Lifestyle modification, with a goal of achieving moderate weight loss (~5%–10% body weight) and regular physical activity (~30 min/d of moderately increased physical activity), remains the preferred approach to diabetes prevention for most patients. However, because lifestyle modification is difficult to achieve and maintain, metformin should be considered in very high-risk patients, especially in those with BMI >35, those age <60 years, and women with prior GDM (Box 52.2).

### Prevention of Complications

Diabetes complications are generally categorized as resulting from microvascular disease (i.e., retinopathy, neuropathy, nephropathy) or macrovascular disease (i.e., CVD, peripheral vascular disease, cerebrovascular disease). Improved glycemic control clearly reduces diabetes microvascular complications in both T1DM and T2DM. Potential

benefits of glycemic control on macrovascular disease are not as well established and appear to be more modest. Therefore patients should be aggressively treated with other CVD risk reduction strategies (see later). [Table 52.4](#) summarizes the short- and long-term microvascular and macrovascular effects of intensive glycemic control seen in major clinical trials. Some specific antihyperglycemic medications (i.e., metformin, glucagon-like peptide 1 [GLP-1] receptor agonists, and sodium-glucose cotransporter 2 [SGLT-2] inhibitors) (see later sections) have been found to reduce cardiovascular events.

### General Preventive Care Practices

Patients with diabetes should be regularly screened for diabetes-related complications so that early treatment can be initiated when appropriate. Annual eye, foot, dental,

microalbumin, and creatinine examinations are recommended. Patients should be regularly assessed for signs and symptoms of CVD. However, cardiovascular imaging studies in asymptomatic diabetic patients is not recommended. Patients should also be evaluated and treated for comorbidities frequently associated with diabetes, including fatty liver disease, obstructive sleep apnea, cancer (especially liver, pancreas, endometrium, colon/rectum, breast, and bladder), bone fractures, low testosterone in men, periodontal disease, hearing impairment, cognitive impairment, and depression or diabetes distress. Annual influenza vaccine is recommended for all patients age >6 months. Pneumococcal polysaccharide vaccine 23 is recommended for patients age  $\geq 2$  years. Pneumococcal conjugate vaccine 13 is recommended for patients age >65 years. Hepatitis B vaccination is recommended for all adults.

### Treatment of Cardiovascular Risk Factors

Cardiovascular risk is about 2- to 4-fold higher in patients with diabetes. Aggressive treatment of established CVD risk factors remains an essential component of diabetes management. For most patients, blood pressure should be treated to achieve goals of <140/90 mm Hg. Pharmacologic regimens for patients with hypertension should include either an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker, but not both. Diabetic patients age >40 years should be considered for treatment with moderate- or high-intensity statins, depending on additional CVD risks. Aspirin therapy for primary prevention is generally recommended for diabetic men age >50 years and women age >60 years. Treatment of CVD risk factors is presented in detail in other chapters and will not be discussed further here.

#### • BOX 52.2 Recommendations for Diabetes Prevention

- All patients with prediabetes should be referred to an intensive diet and physical activity behavioral counseling program
  - Target a loss of 7% of body weight
  - Increase moderate-intensity physical activity (such as brisk walking) to at least 150 min/wk
  - Reduce sedentary time = break up every 30 minutes spent sitting
- Metformin therapy should be considered in those with prediabetes, especially if:
  - Body mass index >35 kg/m<sup>2</sup>
  - Age <60 years
  - Prior gestational diabetes mellitus

**TABLE 52.4** Summary of Microvascular and Macrovascular Effects of Intensive Glycemic Control

### Treatment of Hyperglycemia

The remainder of this chapter will focus on treatment for hyperglycemia. In the Diabetes Control and Complications Trial (DCCT), intensive glyemic control in T1DM (HbA<sub>1c</sub> 7.2% vs. 9.1%) reduced the risk of retinopathy by 76%, the risk of microalbuminuria by 34%, and the risk of neuropathy by 69%. Although CVD event rates were not reduced in the initial study, observational follow-up studies of DCCT participants after completion of the initial trial revealed significant reductions in CVD among the participants who had originally been assigned to intensive therapy. The benefits of initial intensive treatment have been maintained even after >20 years of end of DCCT.

In the UK Prospective Diabetes Study of patients with newly diagnosed T2DM, after about 10 years of follow-up, a 1% reduction in HbA<sub>1c</sub> was associated with a 25% reduction in microvascular complications in the intensively treated group (median HbA<sub>1c</sub> = 7.0%) compared with the conventionally treated group (median HbA<sub>1c</sub> = 7.9%). There was a nonsignificant (*p* = .052) trend for a 16% reduction in myocardial infarction (MI) in the groups intensively treated with sulfonylureas (SUs) or insulin. The rate of MI was significantly reduced only in the subgroup of patients treated with metformin (*p* = .01). Ten additional years of follow-up after the cessation of randomized interventions demonstrated persistent benefits, despite lack of an enduring difference in glucose control between the intensive- and standard-therapy groups. This has been referred to as a “legacy effect.” Furthermore, the 10-year posttrial monitoring demonstrated significant reductions in all-cause mortality (13%) and MI (15%) in patients treated with SUs and insulin (*p* = .01).

Recently, three large clinical trials (Action to Control Cardiovascular Risk in Diabetes [ACCORD], Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified Release Controlled Evaluation [ADVANCE], and Veterans Affairs Diabetes Trial [VADT]) failed to show a decrease in cardiovascular events by targeting HbA<sub>1c</sub> into the normal range (<6%–6.5%) in type 2 diabetic patients with CVD or at high risk of CVD. In fact, the ACCORD

trial showed increased overall mortality and mortality due to CVD in the intensive treatment group.

### Glycemic Goals

Recommended glyemic goals for nonpregnant adults are shown in Table 52.5. HbA<sub>1c</sub>, a measure of long-term glyemic control, is the primary predictor of diabetes complications and therefore the primary target of therapy. Some surrogate measures of CVD, such as inflammation and endothelial dysfunction, may be associated with increased postprandial glucose, independent of fasting glucose levels. However, no interventional studies have proven that specifically targeting postprandial hyperglycemia will improve outcomes. It is therefore recommended that postprandial glucose should only be targeted for treatment with a goal of reducing the HbA<sub>1c</sub>.

The glyemic goals outlined in Table 52.5 should be interpreted as general guidelines. Available data do not identify the optimal level of control for individual patients. Epidemiologic studies suggest a continuous association between HbA<sub>1c</sub> and diabetic complications, without any threshold. Thus there may be incremental (albeit, small) benefit to lowering HbA<sub>1c</sub> from 7% into the normal range in selected patients if achieved without significant hypoglycemia or lifestyle burden. On the other hand, some patients may have greater risks associated with hypoglycemia and other adverse effects of antihyperglycemic therapies. Glycemic goals therefore should be individualized, as outlined in Table 52.6.

**TABLE 52.5 Summary of Glycemic Goals**

HbA <sub>1c</sub>	<7.0% <sup>a</sup>
Preprandial plasma glucose	70–130 mg/dL
Peak postprandial plasma glucose	<180 mg/dL
<i>HbA<sub>1c</sub></i> , Hemoglobin A <sub>1c</sub> . <sup>a</sup> More or less stringent HbA <sub>1c</sub> goals may be indicated for some patients (see text and Table 52.6).	

**TABLE 52.6 Individualizing HbA<sub>1c</sub> Goals**

	More Stringent Control (HbA <sub>1c</sub> <7%)	Less Stringent Control (HbA <sub>1c</sub> >7%)
Motivation, self-care capacity	High	Low
Risk for hypoglycemia	Low	High
Diabetes duration	Short	Long
Life expectancy	Long	Short
Comorbidities	Absent or mild	Severe
Vascular disease	Absent or mild	Severe
Resources, support system	Available	Limited

*HbA<sub>1c</sub>*, Hemoglobin A<sub>1c</sub>.

**TABLE 52.7** Approximate Duration of Action of Commonly Used Insulins

Insulin Type	Products (Brand Names) <sup>a</sup>	Onset Action	Peak Action	Duration of Action
<b>Bolus</b>				
Rapid acting	Lispro, U-100, U-200 (Humalog) Aspart (Novolog) Glulisine (Apidra)	10–20 min	30–90 min	3–5 h
	Regular (Afrezza)		12–15 min	3 h
Short acting	Regular (Humulin, Novolin R, Relion)	30–60 min	2–4 h	5–8 h
<b>Basal</b>				
Intermediate acting	NPH (Humulin N, Novolin N, Relion N)	1–3 h	8 h	12–16 h
Long acting	Regular U-500 (Humulin R U-500)	30 min	8 h	Up to 24 h
	Detemir (Levemir)	1 h	3–9 h	20–26 h
	Glargine (Lantus, Basaglar)	1 h	No peak	20–26 h
Ultra-long acting	Glargine U-300 (Toujeo)	2 h	No peak	>30 h
	Degludec, U 100, U200 (Tresiba)	30–90 min	No peak	42 h

<sup>a</sup>U-100 except as noted.

Modified from March/April 2015 Diabetes Forecast; [diabetesforecast.org](http://diabetesforecast.org); Setty SG, Crasto W, Jarvis J, et al. New insulins and newer insulin regimens: a review of their role in improving glycaemic control in patients with diabetes. *Postgrad Med J.* 2016;92:152–164.

Whereas a goal of below 7% is reasonable in most adults, less stringent treatment goals may be appropriate for patients with limited life expectancies, serious comorbid conditions, and/or limited financial resources and support systems. Treatment of older patients is of particular concern, because they are at higher risk of adverse effects associated with polypharmacy and hypoglycemia. The American Geriatric Society, in conjunction with the ADA, recommends HbA<sub>1c</sub> goals of around <7.5% in patients with few coexisting chronic illnesses and cognitive and intact functional status. In patients with limited life expectancy HbA<sub>1c</sub> goals of <8.5% may be more appropriate.

### Hyperglycemia Treatment Strategies

Strategies for treatment of hyperglycemia in nonpregnant adults are reviewed in this section. Treatment for secondary forms of diabetes should be targeted at the underlying cause. If this is not possible, treatment strategies are similar to those outlined here for T1DM and T2DM.

#### Type 1 Diabetes

Because patients with T1DM make little or no insulin, insulin treatment is required. Treatment is initiated with a goal of mimicking physiologic insulin patterns as closely as possible.

#### Insulin Preparations

There are now more than 20 types of insulin sold in the United States. In addition to differences in the time of onset, peak, and duration of action, products differ in how they are made, how

concentrated they are, how much they cost, whether they contain one or two types of insulin, and whether they are mixed with another medication, such as a GLP-1 receptor agonist.

Characteristics of available insulins are summarized in [Table 52.7](#). Products identical to human insulin manufactured by recombinant DNA technology are the least expensive options. Analogue insulins are molecular-engineered formulations designed to improve pharmacokinetics, absorption profile, and duration of action. Although there is evidence that pharmacokinetic properties of insulin analogues may translate into improved clinical efficacy, potential advantages are modest, especially in T2DM. Potential clinical advantages that the analogues offer over human NPH and regular insulin may not outweigh the disadvantages of their considerably higher costs. “Biosimilar” products recently have become available. These are biologically similar to reference product, with the same protein sequence and similar glucose-lowering effect. They are more expensive to manufacture than traditional generics, and pricing typically is only 15% to 20% lower than the reference drug. Regulatory issues regarding substitution, nomenclature, interchangeability, and therapeutic equivalence for biosimilars remain unresolved. Several insulins are now in variable concentrations, including 100, 200, 300, or 500 U/mL. Higher concentrations of insulin allow patients using higher doses to inject smaller volumes. They are typically recommended when the total daily dose of insulin exceeds 200 U. Insulins are also available in fixed-dose mixtures with other insulin or noninsulin products ([Box 52.3](#)). These “premix” preparations may provide ease of use and improve adherence. At this time,

### • BOX 52.3 Premixed Insulins

- Intermediate- or long-acting insulin + short- or rapid-acting insulin
  - NPH/regular (Humulin or Novolin 70/30)
  - Lispro protamine/Lispro 75/25 (Humalog 75/25)
  - Lispro protamine/Lispro 50/50 (Humalog 50/50)
  - Aspart protamine/Aspart 70/30 (Novolog 70/30)
  - Degludec/Aspart (Ryzodeg 70/30)
- Long-acting insulin + glucagon-like peptide 1 receptor agonist
  - Insulin glargine/lixisenatide (Soliqua)
  - Insulin degludec/liraglutide (Xultophy)

products that contain GLP-1 receptor agonists (GLP-1 RAs) are not approved for use in T1DM.

### Insulin Delivery Options

Multiple insulin delivery options are now available. Syringes are the least expensive option. Insulin pens are generally associated with improved ease of use and patient satisfaction. Inhaled insulin is available but has not been widely adopted. Insulin can also be administered via an insulin pump.

### Insulin Regimens for Type 1 Diabetes

Effective insulin regimens for T1DM typically consist of multiple daily injections (MDIs) of insulin or insulin pump therapy. The choice between MDIs and insulin pump therapy depends on multiple considerations including cost, patient preference, and an individual's personal glycemic profile. Neither strategy can be considered superior for all patients.

A person with T1DM typically requires approximately 0.5 to 0.7 U/kg/d of insulin. There are three components of effective insulin regimens for patients with T1DM: (1) basal insulin, which is used to suppress hepatic glucose production and control glucose levels in the fasting state and between meals; (2) nutritional insulin, which is used to control the hyperglycemia that results from nutritional sources; and (3) supplemental insulin boluses, which are used to correct hyperglycemia that occurs despite basal and nutritional insulin treatment.

### Multiple Daily Injections

Most patients are treated with MDIs. Basal insulin is typically provided by one or two injections per day of an intermediate-acting to long-acting preparation (i.e., NPH, glargine, degludec, or detemir). Basal insulin controls fasting and premeal glucose values by inhibiting excessive hepatic glucose production. Nutritional and supplemental insulin is typically provided by a short- (i.e., regular) or rapid-acting (i.e., lispro, aspart, or glulisine) insulin preparation administered before meals.

### Insulin Pumps

Insulin pump therapy, also known as continuous subcutaneous insulin infusion (CSII), is an evolving form of insulin

delivery that is appropriate for select individuals who are motivated and fully engaged in self-care. Continuously infused short- or rapid-acting insulin is delivered subcutaneously via an insulin pump to provide basal insulin coverage. Pumps provide flexible dosing. Multiple basal rates can be programmed to account for varying basal needs at different times of the day; for example, less basal insulin may be needed during exercise or sleep, and more basal insulin may be needed to cover the dawn phenomena. Nutritional and supplemental insulin boluses are administered via the pump as well. For now, patients must be able and willing to properly insert and remove the infusion set and rotate sites every few days, adjust pump settings to accommodate physical activity, inactivity, sick days, and stress, safely untether their infusion set tubing for special events, implement a backup plan in case of equipment failure, protect themselves and their pump, infusion set, and infusion site during certain physical activities and when undergoing some medical tests, such as a CAT scan, MRI, or x-ray, upload data for review by their health care team at regular intervals, prepare for and pack necessary supplies for travel, and contact technical support and medical personnel when necessary. Increasingly automated “closed-loop” systems are being developed. Most pumps now have associated meters for self-monitoring of blood glucose that can automatically send blood glucose readings to the pump and contain algorithms for suggesting bolus doses based on user-estimated grams of carbohydrate and blood glucose levels. Other systems incorporate continuous glucose monitor systems trying to mimic an artificial pancreas. Insulin delivered by CSII can be associated with improved glycemic management and clinical outcomes in select individuals, primarily those with T1DM.

### Amylin Analogues

Pramlintide, a synthetic analogue of amylin, is the only agent besides insulin that is approved for treatment of T1DM. It is an injectable agent approved for use in both T1DM and T2DM. However, it is rarely used because of very modest efficacy, frequent side effects, and need for injection before each meal.

### Type 2 Diabetes

#### Lifestyle Measures

Diet and exercise are the central components of any therapeutic regimen for diabetes. Healthy eating and a physically active lifestyle improve insulin sensitivity and allow endogenous or exogenous insulin to exert a greater glucose-lowering effect.

**Diet.** It is recommended that the term “ADA diet” not be used because the ADA does not endorse a single nutrition plan. Meal plans should be individualized to accommodate personal preferences, medication regimens, and to provide flexibility and accommodate lifestyle, age, and overall health status.

Because most patients with T2DM are overweight, the primary dietary strategy to optimize glycemic control is decreased calorie intake to promote weight reduction. ADA

nutritional guidelines do not give specific targets for the amounts of dietary carbohydrate, protein, and fat. They instead focus on having patients improve patterns of eating (i.e., choose healthy options more frequently and minimize unhealthy options). Monitoring carbohydrates, whether by carbohydrate counting, exchanges, or experience-based estimation, remains a key strategy in achieving glycemic control for patients who are adjusting insulin before meals. However, carbohydrate restriction should not routinely be recommended for all patients. A diet that includes carbohydrates from fruits, vegetables, whole grains, legumes, and low-fat milk is encouraged.

**Exercise.** Exercise in diabetes is associated with potential risks as well as benefits. Patients should be counseled about what types of exercises can be performed and how much exercise is recommended. A preexercise evaluation should be conducted to determine whether the patient has any long-term diabetes complications that may constitute a contraindication for certain exercises. For example, patients with severe diabetic retinopathy should use caution with exercises that involve Valsalva (e.g., lifting heavy weights), pounding (e.g., tennis), or contact sports (e.g., boxing). Patients with severe peripheral neuropathy should avoid repetitive stepping exercise (e.g., jogging), which may increase the risk of a foot ulcer. Because of the high prevalence of CVD in patients with diabetes, all patients should be assessed to determine whether formal cardiac testing is indicated. Those with typical or atypical cardiac symptoms or an abnormal resting electrocardiogram should undergo further cardiac testing.

In the absence of contraindications, the exercise program should include both aerobic and resistance exercises (Box 52.4). Patients should also be counseled about how to coordinate timing of exercise, meals, medications, and glucose monitoring. Fortunately, low-intensity to moderate-intensity exercise, such as walking, has been shown to have significant benefits and minimal associated risks. As long as there are no contraindications, the benefits of walking almost certainly outweigh the risks in the majority of people with diabetes. Nevertheless, high-risk patients should be encouraged to start with short periods of low-intensity exercise and increase the intensity and duration slowly.

#### • BOX 52.4 Summary of Exercise Recommendations

Exercise programs should include:

- $\geq 150$  min/wk moderate-intensity aerobic activity (50%–70% max heart rate), spread over  $\geq 3$  d/wk with no more than two consecutive days without exercise
- Resistance training  $\geq 2$  times/wk (in absence of contraindications)
- Reduce sedentary time = break up  $>30$  minutes spent sitting

#### Noninsulin Medications

Eleven classes of noninsulin medications are currently approved for treating hyperglycemia in T2DM. Within each class, numerous agents are available. Six classes (i.e., alpha-glucosidase inhibitors, colesevelam, bromocriptine, pramlintide, meglitinides, and thiazolidinediones) are used infrequently because of their modest efficacy, high cost, inconvenient dosing, and/or limiting side effects. The most commonly used agents are summarized subsequently and in Table 52.8.

#### Commonly Used Noninsulin Agents for Type 2 Diabetes

**Biguanides.** Metformin, the only biguanide available in the United States, works primarily by decreasing hepatic glucose production. Metformin is a potent glucose-lowering agent that has a low cost and few side effects. Metformin has the advantages of not causing hypoglycemia and of being associated with weight loss. It is associated with fewer CVD events and death. The most common adverse effects are gastrointestinal. Lactic acidosis, a potentially fatal adverse effect, is extremely rare and is associated almost exclusively with other risk factors such as renal or hepatic disease.

**Sulfonylureas.** Although SUs have been a mainstay of T2DM pharmacotherapy for many years, potential adverse effects of SUs have been raised by numerous studies, dating back to the 1970s. Package labels for all SUs bear a warning for increased cardiovascular risk. Nevertheless, their efficacy in lowering blood sugar, tolerability, and low cost has contributed to their success and continued use. Their major adverse effect is hypoglycemia, which appears to occur most frequently in the elderly. A weight gain of approximately 2 kg is commonly associated with SU therapy, and this potentially could have an adverse impact on CVD risk.

**Glucagon-Like Peptide 1 Receptor Agonists.** Exenatide, exenatide extended-release, liraglutide, dulaglutide, lixisenatide, and albiglutide are members of this class of agents that works by stimulating the effects similar to GLP-1. GLP-1 is a hormone normally produced in the gut that enhances glucose-dependent insulin secretion, suppresses glucagon secretion, slows gastric emptying, and reduces food intake. GLP-1 RAs are resistant to degradation by dipeptidyl peptidase IV (DPP-IV), the enzyme that normally inactivates GLP-1. These drugs do not cause hypoglycemia by themselves and are associated with significant weight loss. One of these agents, liraglutide, has in fact received US Food and Drug Administration (FDA) approval as an obesity drug for nondiabetic individuals. The dose approved for obesity is higher than the dose of hyperglycemia. The major limitations of this class are the relatively high frequency of gastrointestinal side effects and the requirement for injections once (liraglutide) or twice (exenatide) daily or once a week (exenatide extended-release). There are persistent concerns about the association of GLP-1 agonists with acute pancreatitis and acute renal failure and also the association of liraglutide with medullary thyroid carcinoma. However, if these adverse effects do occur, they are very rare.

**TABLE 52.8**

**Characteristics of Commonly Used Antihyperglycemic Medications**

Class/Primary Mode of Action	Generic Names	Route	Dosing Frequency	Renal Dose Adjustment	A <sub>1c</sub> Reduction (%)	Primary Advantages	Primary Disadvantages

CVD, Cardiovascular disease; CrCl, creatinine clearance; DKA, diabetic ketoacidosis; DPP-4, dipeptidyl peptidase 4; eGFR, estimated glomerular filtration; ER, extended release; ESDR, end-stage renal disease; GI, gastrointestinal; GLP-1, glucagon-like peptide 1; GU, genitourinary; HD, hemodialysis; MEN2, multiple endocrine neoplasia 2; SGLT-2, sodium-glucose cotransporter 2; SubQ, subcutaneous.

GLP-1 RAs have recently received much attention for their potential beneficial effects on cardiovascular outcomes. For example, The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial demonstrated significant cardiovascular benefits with liraglutide in patients with T2DM and established or high CVD risk. The composite outcome of the first occurrence of death from cardiovascular causes, nonfatal MI, or nonfatal stroke, occurred less frequently in the liraglutide group compared with placebo (13% vs. 14.9%, respectively), and there were fewer deaths from cardiovascular causes in the liraglutide group compared with placebo (4.7% and 6.0%, respectively). Other trials investigating the cardiovascular outcomes of this class are in progress. The manufacturer is currently seeking an indication for CVD risk reduction for liraglutide, and an FDA decision is expected in late 2017.

**Dipeptidyl Peptidase IV Inhibitors.** Sitagliptin, linagliptin, alogliptin, and saxagliptin are currently approved in the United States. By inhibiting DPP-IV, these agents prolong the glucoregulatory actions of endogenous GLP-1. DPP-IV inhibitors modestly reduce HbA<sub>1c</sub> levels, are generally very well tolerated, are not associated with hypoglycemia, and are weight neutral.

**Sodium-Glucose Cotransporter 2 Inhibitors.** Canagliflozin, dapagliflozin, and empagliflozin are currently approved in the United States. By inhibiting SGLT-2, these drugs prevent reabsorption of glucose in the proximal renal tubules thus increasing glycosuria. As a result of net calorie loss, use of these drugs is associated with moderate weight loss. SGLT-2 inhibitors also lower blood pressure, presumably by causing a mild osmotic diuresis. In a recent cardiovascular outcome study, empagliflozin significantly lowered the composite of cardiovascular death, nonfatal MI, or nonfatal stroke in T2DM patients with high cardiovascular risk compared with placebo (10.5% and 12.1%, respectively). The FDA recently approved empagliflozin for the indication of reducing the risk for cardiovascular death in adults with T2DM and established CVD. There are several large ongoing studies evaluating CVD effects of other SGLT-2 inhibitors.

### Less Commonly Used Noninsulin Agents for Type 2 Diabetes

**Glinides.** Two agents, repaglinide and nateglinide, are available in this class. Similar to SUs, they stimulate insulin secretion by binding to the SU receptor. They have a more rapid onset and shorter duration of action than the SUs and are designed to target postprandial hyperglycemia. They should be taken just before meals. Compared with SUs, the risk for hypoglycemia is similar with repaglinide but less frequent with nateglinide. Glinides are not commonly used in the United States because of their higher cost, more frequent dosing, and reduced efficacy (nateglinide) compared with SUs.

**Thiazolidinediones.** Two thiazolidinediones (TZDs; also known as glitazones), rosiglitazone and pioglitazone, are currently available. They improve glycemia primarily by

increasing insulin-mediated glucose uptake in muscle and adipocytes. To a lesser extent, they decrease hepatic glucose production. TZDs do not cause hypoglycemia when used as monotherapy. The major side effects are weight gain, fluid retention, and bone fracture. The use of TZDs is characterized by recent steep declines in the United States over the past several years. Since 2010 several countries have suspended sales, owing to concerns that the overall risks of rosiglitazone and pioglitazone exceed their benefits.

**Alpha-Glucosidase Inhibitors.** Acarbose and miglitol are the two agents in the alpha-glucosidase inhibitor (AGI) class of antihyperglycemic compounds. AGIs reduce the rate of digestion of polysaccharides in the proximal small intestine. When used before meals, they delay the absorption of complex carbohydrates and blunt postprandial hyperglycemia, resulting in modest reductions in HbA<sub>1c</sub>. They are not associated with weight changes or hypoglycemia. AGIs are infrequently used in the United States. The main limitations to their widespread use are the need for frequent dosing, poor tolerability caused by frequent gastrointestinal side effects, and only modest antihyperglycemic effects.

**Bile Acid Sequestrants.** Colesevelam, a bile acid sequestrant that has been used for some time as a lipid-lowering agent, received FDA approval for the indication of improvement of glycemic control in patients with T2DM. The exact mechanism by which colesevelam improves glycemic control is unknown. It has been shown to reduce HbA<sub>1c</sub> levels by approximately 0.3%, relative to baseline.

**Dopamine Agonists.** Bromocriptine is approved for treatment of T2DM. Its mechanism of action for the glucose-lowering effect is not clear but involves dopaminergic effects in the hypothalamus. It has been shown to reduce HbA<sub>1c</sub> levels by 0.4% compared with placebo. In addition, it has a proven safety record for CVD.

### Insulin Regimens in Type 2 Diabetes

In contrast to patients with T1DM, most patients with T2DM secrete some endogenous insulin. Because of this, they frequently can be controlled with only a single daily injection of insulin. The patients' residual endogenous insulin secretion helps fine-tune glycemic control. In later stages of T2DM, patients may make very little insulin. Thus they may require MDIs of insulin similar to the regimens used for T1DM.

The most widely recommended strategy for initiating insulin in T2DM is to add a single bedtime injection of basal insulin (i.e., NPH, glargine, detemir, degludec) (Box 52.5). This regimen has been found to be effective in numerous studies and controls hyperglycemia in up to 60% of patients. Despite a prevailing misconception that NPH must be given twice a day, it has long been recognized that in T2DM, a single daily injection of NPH yields similar improvements in control as two daily injections. Although initial treatment with MDIs of insulin may also be effective, this initial strategy has not been shown to be superior to a single injection and may be less acceptable to patients. If the

**• BOX 52.5 Potential Strategy for Insulin Initiation and Advancement in Type 2 Diabetes**

1. Start basal insulin (e.g., 10 units NPH or glargine or detemir or degludec).
2. Continue metformin and GLP-1 RA, if already taking them. May stop other antihyperglycemic medications.
3. Have patient check daily FBG.
4. Increase insulin frequently (e.g., every day or few days) until the FBG averages <100 mg/dL.
5. If HbA<sub>1c</sub> remains above goal and FBG has been ~70–130 mg/dL for 2–3 months:  
Add a premeal rapid-acting insulin before the largest meal of the day.  
Increase premeal insulin dose until BG 1–2 hours after meal is <180 mg/dL.
6. If HbA<sub>1c</sub> remains high, consider adding rapid-acting insulin before additional meals.

FBG, Fasting blood glucose, GLP-1 RA, glucagon-like peptide 1 receptor agonist; HbA<sub>1c</sub>, hemoglobin A<sub>1c</sub>.

patient is treated with a single bedtime injection of insulin and the fasting glucose level is within the target range, but the HbA<sub>1c</sub> level remains above goal, additional insulin injections are likely to be beneficial. Additional injections typically are given as premeal boluses of rapid-acting insulin (i.e., lispro, aspart, glulisine).

The key factor contributing to the success of the regimen is not what type of insulin is given or the number of injections that are initially used. Rather, the key factor to success is whether enough insulin is given. For a regimen to be effective, the insulin dose must be increased frequently until targets are achieved. Multiple protocols for initiating and increasing insulin have been found to be effective. Furthermore, having patients self-titrate their own doses, according to protocol, appears to be similarly effective as having the insulin adjusted by a health care provider.

**Selection and Progression of Therapy in Type 2 Diabetes**

Choice of therapy is complex and depends on multiple factors including the patient’s initial HbA<sub>1c</sub>, the agent’s effect on glucose lowering, side effects, contraindications, dosing frequency, acceptability to patients, and cost of medication. An example strategy for initiating and intensifying therapy is shown in Table 52.9.

There is strong consensus that metformin is the preferred drug for monotherapy because of its long-proven safety record, low cost, weight-reduction benefit, and potential cardiovascular advantages. If there are no contraindications (i.e., estimated glomerular filtration rate <30 mL/min/1.73 m<sup>2</sup>), metformin should be recommended concurrent with lifestyle intervention at the time of diabetes diagnosis. Other than metformin, evidence is limited for the optimal use of the burgeoning array of available agents, especially in dual or triple combinations. Research is now starting to focus more on what the ideal number and sequence of drugs should be. The Glycemic Reduction Approach in Diabetes

**TABLE 52.9 Potential Treatment Algorithm for Hyperglycemia in Type 2 Diabetes**

Step 1	Step 2	Step 3
Strong Consensus	No Consensus	
Initial therapy	Add second agent	Add third agent from different class
Metformin	SU	GLP-1 receptor agonist or DPP-4 inhibitor or SGLT-2 inhibitor or basal insulin
	DPP-4 inhibitor	SU or SGLT-2 inhibitor or basal insulin
	GLP-1 receptor agonist	
	SGLT-2 inhibitor	SU or DPP-4 inhibitor or GLP-1 receptor agonist or basal insulin
	Basal insulin	GLP-1 receptor agonist, premeal insulin

*DPP-4*, Dipeptidyl peptidase 4; *GLP-1*, glucagon-like peptide 1; *SGLT-2*, sodium-glucose cotransporter 2; *SU*, sulfonylurea.

(GRADE) study, which will compare long-term benefits and risks of the four most widely used antihyperglycemic medications in combination with metformin, is now under way. The four classes to be studied are SU, DPP-IV inhibitors, GLP-1 RAs, and a basal, long-acting insulin.

Even if oral agent monotherapy is initially effective, glycemic control is likely to deteriorate over time because of progressive loss of beta-cell function in T2DM. There is currently no consensus as to what the second-line agent should be. Selection of a second agent should be made based on potential advantages and disadvantages of each agent for any given patient. A patient-centered approach is preferred over a fixed algorithm. SUs are the most commonly used second-line agents, although SGLT-2 inhibitors, incretin mimetics, and DPP-IV inhibitors are increasingly being used. Basal insulin may be preferred if the patient has very high initial blood glucose levels, is underweight, is losing weight, or is ketotic.

If patients progress to the point where dual therapy does not provide adequate control, either a third noninsulin agent or insulin can be added. In patients with modestly elevated HbA<sub>1c</sub> level (below ~8%), addition of a third noninsulin agent may be equally effective as (but more expensive than) addition of insulin. Patients with significantly elevated HbA<sub>1c</sub> levels on two noninsulin agents usually should have insulin added to their regimens.

**Metabolic (Weight-Loss) Surgery**

Metabolic, or weight-loss, surgery has been found to be associated with rapid and dramatic improvements in blood glucose control. Metabolic surgery has been shown to improve glucose control more effectively than any

known pharmaceutical or behavioral approach. Bariatric surgery has been shown to lead to near or complete normalization of glycemia in ~40% to 95% of patients with T2DM, depending on the study and the surgical procedure. A 2016 joint statement by numerous international diabetes organizations recommends *considering* metabolic surgery as a treatment for T2DM and obesity. Metabolic surgery should be *recommended* to treat T2DM in patients with BMI  $\geq 40$  and in those with BMI 35.0 to 39.9 when hyperglycemia is inadequately controlled by lifestyle and optimal medical therapy. Surgery should also be *considered* for patients with T2DM and BMI 30.0 to 34.9 if hyperglycemia is inadequately controlled despite optimal treatment with either oral or injectable medications. These BMI thresholds should be reduced by 2.5 for Asian patients.

### Obesity Medications

Because weight loss is associated with improved glycemic control, an area of emerging interest is the use of antiobesity medications for managing diabetes. Although most older weight-loss medications were only approved for short-term use, some newer agents are approved for longer-term use. Lorcaserin and the combination drugs topiramate/phentermine and naltrexone/bupropion are approved for chronic therapy, provided certain conditions are met. The antiobesity medications are discussed elsewhere.

### Special Populations

#### Pregnancy

Patients with diabetes in pregnancy typically are considered as having either pregestational diabetes or GDM. Hyperglycemia during the first trimester, which may occur with pregestational diabetes, increases the risk for congenital malformations in the fetus. Diabetic patients therefore should be counseled to use effective contraception until HbA<sub>1c</sub> is controlled. Hyperglycemia occurring during the third trimester, when GDM is typically diagnosed, increases the risk for fetal macrosomia and associated complications. Strict glucose control during pregnancy reduces this risk. Although expert opinion varies about the specific target glucose levels, glucose goals during pregnancy are

**TABLE 52.10** Glucose Goals in Inpatients

	Goal (mg/dL)
Critically ill patients	140–180
Noncritically ill patients	
Premeal	<140
Random	<180

considerably lower than for nonpregnant adults. Recommendations for fasting and premeal values are generally <95 mg/dL, and recommendations for postprandial values are generally <120 mg/dL at 2 hours after eating. Preferred medications in GDM are insulin. Glyburide may be used but may have a higher rate of neonatal hypoglycemia and macrosomia than insulin. Metformin can also be used for GDM but is less effective than glyburide in controlling hyperglycemia. Other agents have not been adequately studied.

#### Hospitalized Patients

DM and/or inpatient hyperglycemia are common comorbid conditions in hospitalized patients. Observational studies have shown that hyperglycemia in hospitalized patients is associated with adverse outcomes including infections, increased length of stay, and increased mortality. Based on the available data, the ADA recommends moderate metabolic control as shown in [Table 52.10](#). Insulin is the preferred agent in view of the rapidly changing requirements. Insulin drips are recommended for patients in the intensive care unit (ICU). In non-ICU patients, subcutaneous insulin regimens should include each of three components: (1) basal insulin, which controls fasting and between-meal glucose levels; (2) nutritional insulin, which controls glucose from nutritional sources such as discrete meals or tube feeds; and (3) supplemental insulin (also known as “sliding scale”), which controls unexpected hyperglycemia that occurs despite scheduled basal and nutritional insulin. Regimens that use sliding scale insulin alone are not effective and should not be used.

## Chapter Review

### Questions

- A 40-year-old patient with T2DM and no other past medical history has been taking the maximal dose of an SU and metformin for the past 6 months. The HbA<sub>1c</sub> is now 11.5%. Which of the following should be added?
  - Canagliflozin (Invokana)
  - Exenatide (Byetta)
  - Sitagliptin (Januvia)
  - Insulin
- A patient with T2DM is taking metformin and bedtime NPH. The fasting blood glucose ranges from 80 to 100 mg/dL, and the HbA<sub>1c</sub> is 7.5%. What would you do now?
  - Add morning NPH.
  - Stop NPH, and start bedtime glargine (Lantus).
  - Add aspart (NovoLog) before the largest meal of the day.
  - Change to an insulin pump.
- A nondiabetic patient is 5 ft 3 in tall and weighs 200 lb (BMI 34.4). The patient should be advised he will reduce his risk of diabetes if he:
  - Loses at least 30 lb
  - Loses 5% to 10% of his body weight

- C. Loses enough weight to reduce his BMI to <30  
 D. Loses enough weight to reduce his BMI to <27
4. Which of the following diets will be most likely to improve glycemic control in an obese patient with T2DM?
- A. Reduced calorie intake  
 B. Low carbohydrate  
 C. Low glycemic index  
 D. ADA diet
5. A patient with T2DM is admitted to the hospital (non-ICU) with sepsis. He has been treated at home with glyburide. A recent HbA<sub>1c</sub> was 7.5%. Admission glucose (nonfasting) is 250 mg/dL. His appetite is poor. What medication regimen should be prescribed?
- A. Continue glyburide, and start sliding scale regular insulin before meals and bedtime.  
 B. Stop glyburide, and start sliding scale regular insulin before meals and bedtime.  
 C. Stop glyburide, and start NPH, premeal aspart, and premeal sliding scale aspart before meals and bedtime.  
 D. Stop glyburide, and start an insulin drip.

### Answers

1. D
2. C
3. B
4. A
5. C

## Diabetes Mellitus: Control and Complications

MARGO HUDSON AND MARIE E. MCDONNELL

**D**iabetes mellitus and its complications have a tremendous impact on quality of life, functional health status, and mortality. Even with excellent glucose control, patients with type 1 diabetes (T1D) were recently reported to have double the risk of death and triple the risk of cardiovascular death compared with nondiabetic peers. On average, individuals with type 2 diabetes (T2D) have a lower life expectancy by 6 years, and up to 80% of deaths are from cardiovascular causes. Complications associated with diabetes such as kidney, eye, and nerve damage may significantly decrease quality of life. Control of glucose, blood pressure (BP), and lipids can improve these outcomes. Recent studies have shown improvement in mortality trends and complication rates in patients with diabetes, likely demonstrating the benefits of current therapeutic paradigms.

### Control

#### Real-Time Glucose Measurements

Measuring glucose control is of paramount importance in managing diabetes. Glucose can be measured accurately by patients with home glucose monitors. According to the US Food and Drug Administration (FDA), approved meters must meet the following accuracy thresholds: for results  $\geq 75$  mg/dL, 95% of meter test results must be within 20% of the actual blood glucose level, and for results  $< 75$  mg/dL, 95% of test results must be within 15 points of the actual blood glucose level. However, most devices are more accurate than this, with the average difference from reference range being 5% and with 99% of values being within 20% of reference when using good technique.

Self-monitoring is mandatory for patients at risk for hypoglycemia. For patients on insulin, self-monitoring at various times of the day will assist in recognizing patterns of hypoglycemia and hyperglycemia, and many insulin regimens require the patient to calculate dosing based on glucose values. For patients not on insulin and not at risk for hypoglycemia, the role of self-monitoring is less critical but may help the patient to recognize the impact of daily activities

such as diet and exercise on glucose levels. Devices are now available that measure glucose “continuously” (approximately every 5 minutes) with a small catheter inserted subcutaneously and changed every 1 to 2 weeks. Most of these continuous glucose monitoring (CGM) devices still require glucose to be tested by fingerstick twice daily for calibration and accuracy. Individual values derived from most CGM products available are not as accurate as the most-accurate glucose meters, with the average difference from reference being about 10%. They mainly serve to help patients see real-time trends in glucose (rising or falling). Patients with T1D who used CGM in some clinical trials have been shown to reduce hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) levels as well as episodes of hypoglycemia. An increasing number of subcutaneous insulin pump devices have integrated CGM to assist the patient in insulin administration, and at this time, two devices are programmed to suspend insulin delivery in the setting of actual or predicted hypoglycemia.

#### Measuring Long-Term Glucose Control

The HbA<sub>1c</sub> level has been the primary measurement to inform providers and patients as to the level of chronic glycemia. HbA<sub>1c</sub> is a product of an irreversible nonenzymatic glycosylation of the hemoglobin molecule. HbA<sub>1c</sub> levels generally correlate well with mean glucose over 3 months as determined by CGM, although this relationship can be altered in the setting of anemia, renal dysfunction, hepatic disease, and possibly race. Despite some concerns about interpretability in individual patients, HbA<sub>1c</sub> levels have had excellent predictive correlation in many studies of diabetic complications. The HbA<sub>1c</sub> test must be done in a laboratory using standardized equipment. Because of its dependence on hemoglobin, any condition that impacts red cell life span (splenectomy, hemolysis, blood loss) will impact the HbA<sub>1c</sub> level. Also, hemoglobinopathies may have variable effects on HbA<sub>1c</sub> measurement depending on the method used to measure HbA<sub>1c</sub>. In a situation in which the HbA<sub>1c</sub> may not reflect long-term glycemia, other glycosylated proteins may be measured. The most commonly available test is a measure of fructosamine (primarily

reflecting glycosylated albumin), which gives a “look back” on average glucose levels of about 2 weeks.

Of importance, although the HbA<sub>1c</sub> is a convenient method of determining overall glycemic status, it does not identify patterns of glycemic variability and can mislead providers in the evaluation of hypoglycemia risk. In one small study, 40 patients treated with insulin (70% T2D) age  $\geq 69$  years with HbA<sub>1c</sub> values of  $\geq 8\%$  were evaluated with blinded CGM for 3 days. Nearly 75% of subjects experienced a glucose level  $< 60$  mg/dL despite the elevated HbA<sub>1c</sub>, and importantly, of the 102 hypoglycemic episodes recorded, 93% were unrecognized by finger-stick glucose measurements performed four times a day or by symptoms.

## Complications of Diabetes: General Overview

### Acute Complications

#### Hypoglycemia

Hypoglycemia is the primary limiting factor in normalizing glucose levels in diabetes. Patients usually will begin to have adrenergic symptoms such as diaphoresis, tremor, and palpitations as glucose levels drop  $< 70$  mg/dL and will develop neuroglycopenic symptoms such as altered mental status and seizure with glucose levels  $< 40$  mg/dL. Some patients with long-standing diabetes or frequent episodes of hypoglycemia may lose the adrenergic symptoms and be at greater risk of severe hypoglycemia; this is called *hypoglycemia unawareness* or *hypoglycemia-associated autonomic failure* (HAAF). Hypoglycemia, particularly in the setting of HAAF, is associated with higher mortality rate and with cardiac arrhythmias. Patients treated with medications that may cause hypoglycemia should be taught to prevent hypoglycemia in predictable situations (e.g., exercise, missed meals, reduced carbohydrate intake). Patients need to learn how to treat hypoglycemia with oral ingestion of simple sugars. For those at particular risk, family members or caregivers should receive instruction on how to administer glucagon.

#### Hyperglycemia

Hyperglycemic crises include diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic syndrome (HHS) and the overlap syndrome that has been called *hyperosmolar ketoacidosis* (HK). These syndromes are characterized by hyperglycemia, dehydration, and severe electrolyte depletion although their natural histories and associated mortality risk vary. DKA has the lowest mortality, reported now to be  $< 5\%$  across institutions in the United States and  $< 1\%$  in several reported institutions. HHS, however, is associated with a mortality  $> 15\%$  in several studies, and the concomitant presence of ketoacidosis yields mortality rates as high as 30% for HK. In the past, mortality caused by hyperglycemic crisis has been reported to be the highest at extremes of age, but more recent studies suggest that mortality rates for

those age  $> 75$  years have markedly improved and are lower than that of the youngest patients.

In DKA, acidosis and ketosis accompany dehydration. In HHS, profound dehydration is the predominant metabolic derangement with minimal ketosis, and in HK both conditions exist. All conditions are driven by a relatively low insulin level that cannot meet the metabolic demand and/or overcome acute insulin resistance, which leads to persistent hyperglycemia and glycemic osmotic diuresis. In DKA, an extremely low insulin level in the setting of dehydration and elevated counter-regulatory hormones (i.e., glucagon, epinephrine, and cortisol) promote lipolysis and ketoacid formation. In HHS, the inability to replace fluids lost through the osmotic diuresis of hyperglycemia leads to dehydration, acute decrease in glomerular filtration rate (GFR), and progressive rise in glucose concentration followed by symptomatic hyperosmolarity caused by severe free water deficit and marked hyperglycemia. Whereas in the past it was assumed that only patients with T1D develop DKA and patients with T2D develop HHS, this is no longer a useful clinical delineation. Patients with T1D can develop HHS, which in pediatric populations has the highest associated mortality among these disorders. Likewise, those with either classical or alternative forms of T2D can develop DKA. The metabolic derangement on presentation depends more on the degree of insulin deficiency, renal dysfunction, and hydration status than on the underlying type of diabetes. In any patient presenting with a hyperglycemic crisis, a precipitating cause (nonadherence to medication, new medications, infection, cardiovascular event) should be sought. Treatment algorithms are proven effective and readily available through many sources (Fig. 53.1).

### Chronic Complications

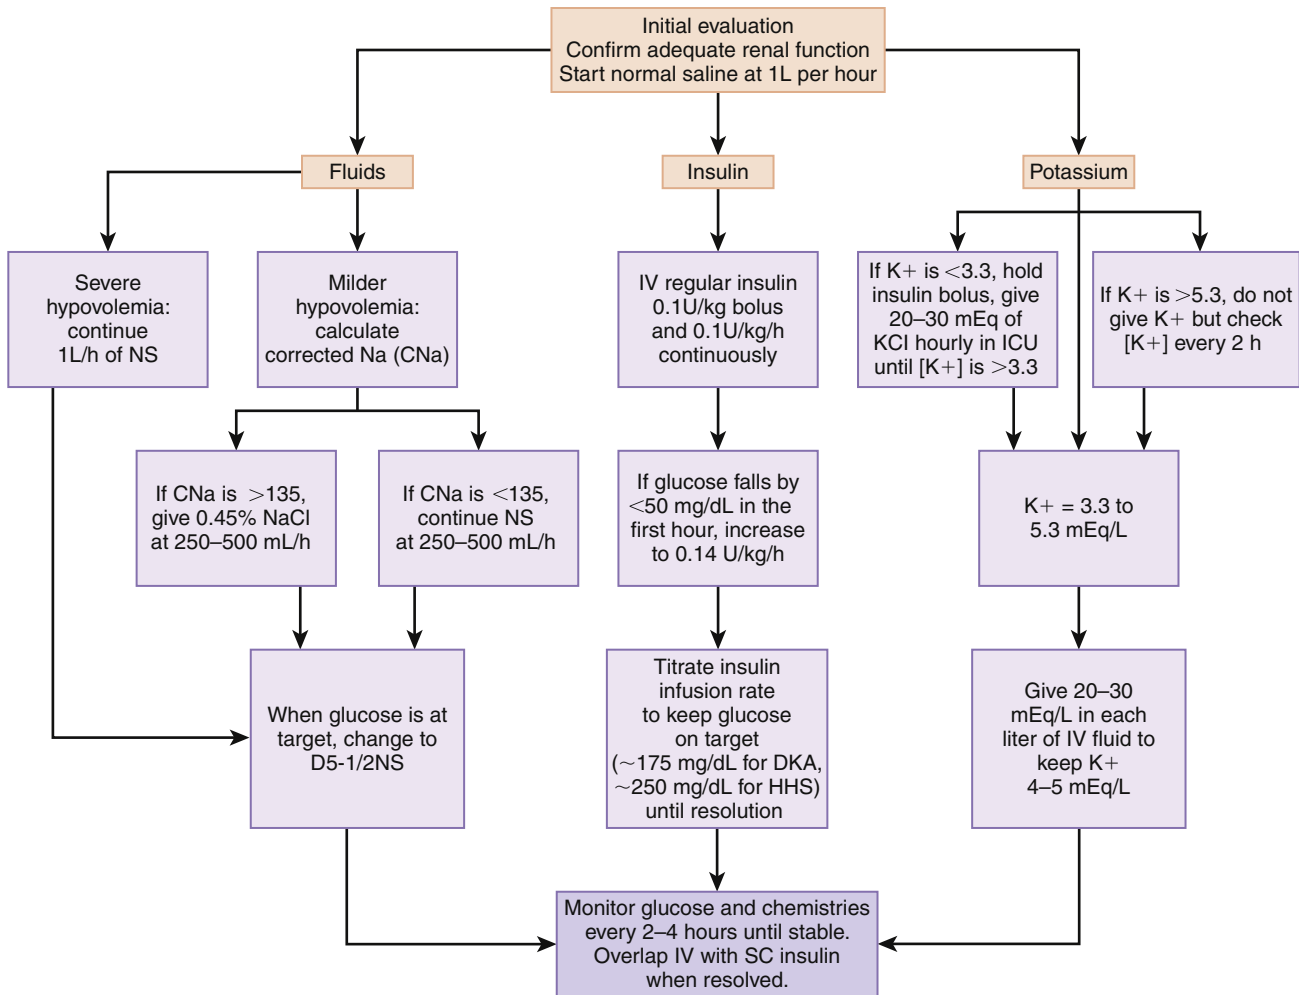

#### Overview

Chronic complications have generally been divided into two categories: microvascular and macrovascular. Microvascular complications resulting from diabetes include retinopathy, nephropathy, and neuropathy. Macrovascular complications include coronary artery disease, cerebrovascular disease, and peripheral vascular disease. However, damage associated with diabetes may extend to other more recently recognized areas such as skin, musculoskeletal tissues and myocardium, and the liver. The next section will discuss pathophysiologic mechanisms for this wide-reaching impact, as well as trial data associating outcomes with glucose, BP, lipid control, and lifestyle changes. Finally, recognition and management options for select complications will be discussed individually.

#### Glucose Hypothesis

Elevated levels of glucose have been correlated with multiple cellular abnormalities that may contribute to complications associated with diabetes. For many tissues in the body, glucose transport across the cell membrane is not regulated by insulin, and in hyperglycemia the cell is confronted with high intracellular glucose and glucose metabolites.

• **Fig. 53.1** Schemata for the management of diabetic ketoacidosis (DKA). HHS, Hyperosmolar hyperglycemic syndrome; ICU, intensive care unit; IV, intravenous; NS, normal saline; SC, subcutaneous. (Modified from Kitabchi AE, Umpierrez GE, Miles JM, et al. Hyperglycemic crises in adult patients with diabetes. *Diabetes Care*. 2009;32(7):1335–1343.)

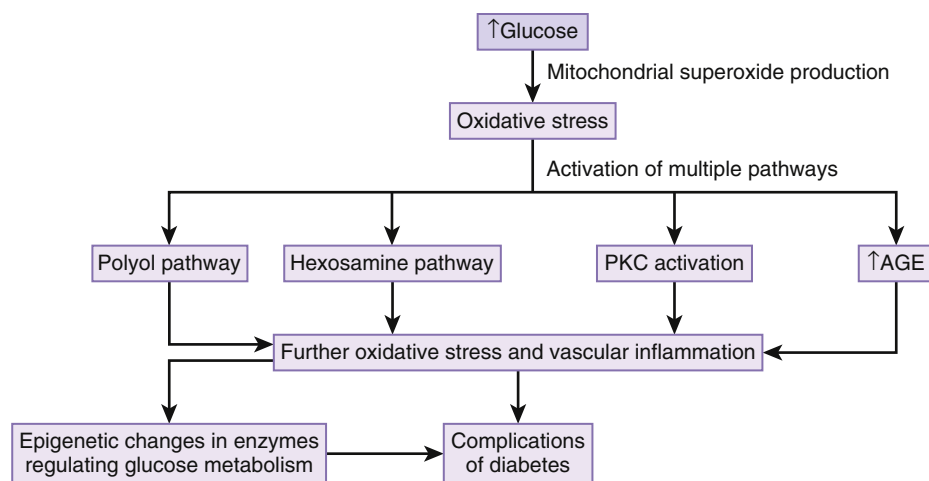

Mitochondria, in response to high glucose, produce reactive oxygen species (ROS), which can lead to damage in DNA and other subcellular components through oxidative stress. Four downstream pathways have been identified to further contribute to tissue injury (Fig. 53.2): an increase in intracellular sorbitol (polyol pathway), which reduces the level of antioxidant glutathione; an increase in prothrombotic mediators (hexosamine pathway) such as plasminogen activator inhibitor-1 (PAI-1); an increase in protein kinase C levels, which impairs vasodilation and perfusion; and finally an increase in glycosylation of proteins analogous to HbA<sub>1c</sub>, which are called *advanced glycation end products* (AGEs).

Hypoglycemia has also been noted to increase ROS and inflammatory mediators. Glucose variability itself has also been hypothesized to contribute to end-organ damage leading to long-term complications.

### Major Trials Examining the Glucose Hypothesis

Two major trials published in the 1990s examined the impact of glucose control on long-term complications in

diabetes in patients who were early in the course of their disease and without significant preexisting complications. The Diabetes Control and Complications Trial (DCCT) recruited 1400 patients with T1D and no or minimal complications and randomly assigned them to “intensive treatment” with multiple ( $\geq 3$ ) daily insulin injections or insulin pump therapy and “conventional treatment” with two injections a day. The goal of therapy in the intensive group was normalizing glucose and in the conventional group maintaining glucose in an asymptomatic range. The patients were followed for a mean of 6.5 years, and there was a clear difference in the average HbA<sub>1c</sub> achieved: 7% in the intensively treated patients compared with 9% in the conventionally treated patients. There was a reduction in risk for all three of the microvascular complications in the intensively treated group. For retinopathy, the risk reduction was 50% to 75%, nephropathy 40% to 50%, and neuropathy 60%. For cardiovascular disease (CVD), the risk in both groups during the course of the study was very low and not significantly different. The patients have

• **Fig. 53.2** Glucose algorithm. AGE, Advanced glycation end products; PKC, protein kinase C.

been followed now for up to 30 years since the start of the trial. After randomization ended, HbA<sub>1c</sub> in both groups converged to 8%. However, despite similar control now for many years, the intensively treated group continues to have lower risk for microvascular complications, a phenomenon termed *metabolic memory*. The reduction in risk persists at 50% for retinopathy, 60% to 80% for albuminuria, and 50% for decrease in GFR and for neuropathy 30%. Analysis of cardiovascular events 18 years after the start of the trial showed that risk was reduced significantly by 42% in the intensively treated cohort, and even at 30 years, cardiovascular risk still was reduced by 30%.

The second major clinical trial, the United Kingdom Prospective Diabetes Study (UKPDS) was performed in patients with new-onset T2D. The study had several arms but essentially looked at treatment with insulin or sulfonylurea agents (intensive) versus diet (conventional group) or, for obese patients, metformin versus diet. In intensively treated patients, the goal was to maintain fasting glucose <108 mg/dL; in the control groups, medications were added for glucose levels >270 mg/dL (clearly not current standard practice). The patients were followed on average for 10 years. As expected, a high number of subjects in the conventional group required glucose-lowering medications, but HbA<sub>1c</sub> differences were maintained between the groups: 7% for intensive group and 7.9% for conventional group. With this more modest difference than achieved in the DCCT, there was a less robust impact on microvascular complications with a 25% reduction for the composite end-point. However, when looked at by HbA<sub>1c</sub> reduction, it is estimated that for every 1% decrease in HbA<sub>1c</sub>, risk of microvascular disease decreased by 37%. Ten years after the trial ended, HbA<sub>1c</sub> levels in the two groups also converged at 7.5%, and microvascular risk reduction persisted at 25%, confirming the concept of long-lasting impact of defined periods of glucose control, metabolic memory. Evaluation of cardiovascular events showed a 16% reduction in the intensively treated group, which did not quite reach statistical significance during the trial but did reach significance

after 10 years. In the metformin treatment arm, although the HbA<sub>1c</sub> reduction differential between the two groups was only 6% (7.4% vs. 8%), the cardiovascular benefit was large with approximately a 30% risk reduction, demonstrable even during the original study time period and persistent in the follow-up period. This finding introduced the concept that diabetes medications may exert cardiovascular benefit beyond the glucose-lowering effect of the drug (see section on CVD later for further discussion).

Two large randomized trials published in 2008—Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease: Preterax and Diamicon MR Controlled Evaluation (ADVANCE)—evaluated cardiovascular and microvascular outcomes in patients with long-standing T2D and at high risk or with known preexisting CVD. The HbA<sub>1c</sub> goals were lower than prior studies, with <6.5% (intensive groups) compared with 7% to 7.9% (conventional groups), and multiple treatment options were available to providers to achieve glucose goals. After about 5 years, ADVANCE and ACCORD found 20% to 30% risk reduction in nephropathy and retinopathy, respectively, but no improvement in composite cardiovascular outcomes. In ACCORD the intensive treatment group had a 20% significantly higher rate of mortality, and subsequent analysis indicated that the excess mortality was seen in the group of subjects who were unable to reach the intensive HbA<sub>1c</sub> target and was not clearly related to hypoglycemia; the implication is that not all patients are able to reach tight control, and aggressive therapy in some may be harmful. The renal benefits in ADVANCE have persisted through 5 years of follow-up. Recent data from the follow-on study from ACCORD showed a persistent increased mortality in the intensive arm, which had diminished (1.3% over 10 years), but a continued 30% decreased risk of progression of retinopathy, further highlighting the clinical conundrum caregivers face when balancing the risk of hypoglycemia and the benefit of tight glucose control (Fig. 53.3).

Interpretation of these studies has been controversial, but it seems reasonable to conclude that (1) tight glycemic

• **Fig. 53.3** The clinician's conundrum. As first noted in The Diabetes Control and Complications Trial (DCCT), achieving a lower mean glucose comes at both the cost of increased hypoglycemia risk and the benefit of controlling microvascular disease, specifically, retinopathy. *HbA<sub>1c</sub>*, Hemoglobin A<sub>1c</sub>. (Modified from The Diabetes Control and Complications Trial Research Group. The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med.* 1993;329:977–986.)

control of T1D and T2D for the first 10 years of the disease will decrease risk of chronic complications; (2) maintenance of good control beyond 10 years continues to have benefit; and (3) treatment goals need to be individualized for older patients with advanced diabetes.

### Role of Blood Pressure, Lipids, and Lifestyle

The UKPDS study included a randomized trial of BP goals. Subjects were assigned to tighter goals versus less-stringent goals and achieved a BP mean of 144/82 mm Hg and 154/87 mm Hg, respectively. Microvascular risk reduction was 37%, and cardiovascular risk improved by 40% to 50% in the tightly treated group. ACCORD had an embedded randomized BP trial looking at the difference in outcomes between goal BP of <120/80 mm Hg versus <140/80 mm Hg. No significant risk reductions were noted. In ADVANCE, however, the addition of angiotensin-converting enzyme (ACE)-inhibitor therapy did lower BP and improve nephropathy outcomes by 18%. Unlike glucose control, there has been no legacy effect identified from BP control in these large clinical trials of diabetes, but rather when randomization ends and BP control converges the risk reduction does not persist.

The onset of the statin era has had a tremendous impact on cardiovascular outcomes in diabetes. One of the earlier studies in large numbers of patients with diabetes was the Heart Protection Study. Subjects with an average low-density lipoprotein (LDL) at the start of the trial of 125 mg/dL were randomized to simvastatin 40 mg or placebo. Within just 5 years, significant reduction in any cardiovascular event in the treatment group was noted. Multiple subgroups including patients with T1D, known CVD, no

CVD and those with LDL at the start <116 mg/dL all experienced a 25% to 30% risk reduction in events. Later studies have shown improvements in primary prevention with 10 mg atorvastatin versus placebo in type 2 patients and for secondary prevention with 80 mg atorvastatin versus 10 mg atorvastatin. Fibrates, on the other hand, have been tested in the ACCORD-lipid trial as “add-on” therapy to statins for cardiovascular outcomes in type 2 patients. There was risk reduction only in a subgroup of patients with triglycerides >204 mg/dL and high-density lipoprotein <34 mg/dL and possible harm noted in women, limiting recommendations for use.

Finally, the long-held hope that intensive lifestyle change would impact mortality was tested in the Look AHEAD (Action for Health in Diabetes) randomized trial of those with diabetes and high cardiovascular risk. Cardiovascular outcomes were not improved after 10 years, but microvascular risk reduction, particularly in nephropathy progression, was demonstrated.

## Complications of Diabetes: Specific Conditions

### Retinopathy

Diabetes is the leading cause of blindness in the United States and other developed countries. Diabetic macular edema (DME) is the most common cause of visual impairment, but blindness from diabetes is more commonly from proliferative diabetic retinopathy (DR) and neovascular glaucoma. DR affects >4 million American adults with nearly 1 million at risk for vision

loss. Approximately 40% of adults with diabetes will develop some degree of DR, and 14% of those will also have DME. DR is thought to be the most diabetes-specific complication, and its presence has been used to help redefine glycemic thresholds for diagnosis of diabetes. Diabetes also increases risk for other ocular complications such as cataracts and glaucoma. It remains unclear if diabetes increases the risk of macular degeneration.

Hyperglycemia and inflammation (see Fig. 53.1) lead to tissue damage, causing retinal endothelial cell loss and breakdown in the blood-retina barrier. This causes secretion of vascular endothelial growth factor (VEGF), leakage of proteins and lipids, ischemia, and cellular proliferation as well as macular edema. This process is progressive and has been classified into stages: nonproliferative retinopathy, characterized by microaneurysms, hemorrhages, and hard exudates; severe nonproliferative or preproliferative retinopathy, recognized by cotton wool spots (formerly “soft exudates”), venous beading, or four quadrants of intraretinal hemorrhage; and proliferative retinopathy, with neovascularization, preretinal hemorrhages, and vitreous hemorrhages. Macular edema can be seen in all stages of retinopathy.

Dilated funduscopic examination is the cornerstone of diagnosis (Fig. 53.4). This can be combined with fundus photography and fluorescein angiography. Macular edema is difficult to detect with funduscopy alone, hence standard assessment of DME includes specialized testing by an ophthalmologist. Screening is currently recommended after 5 years of T1D but at onset of T2D (because of potential delay in diagnosis). Screening should be annual, but, if after several years no retinopathy is noted, frequency can be decreased to every 2 years.

Duration of diabetes, HbA<sub>1c</sub>, and systolic BP are the primary factors correlated with severity of DR and DME. In an Australian study of patients with T2D, for every 10 years of diabetes, retinopathy risk more than doubled; for every 1% increase in HbA<sub>1c</sub>, risk increased 40%; and for every 10 mm Hg of systolic BP, risk increased 20%. However,

the outlook for retinopathy may be improving. A longitudinal analysis of nationally representative Medicare data has suggested that the incidence of background and proliferative DR after diagnosis of diabetes is declining, as well as the rates of surgical procedures for retinopathy. In a Medicare study comparing 119 pairs of patients who did receive guideline care versus the closest matched control who did not, low vision/blindness was substantially reduced over a 3-year period among persons who received recommended levels of care. It is thought that the decline in prevalence and incidence of retinopathy and vision impairment is the result of improved management of hyperglycemia, hypertension, and dyslipidemia.

Paradoxically, short-term intensive control has been reported to potentially worsen retinopathy. In the DCCT study, 13% of patients in the intensively treated group had worsening of baseline retinopathy compared with 6% of conventionally treated patients in the early months of randomization, but this difference was not seen by 18 months into the study and as discussed previously, long-term, intensive therapy improves outcome of DR.

Renin-angiotensin system inhibition has been shown to be effective for primary prevention in type 1 patients. In the ACCORD trial, fibrate therapy lowered risk for retinopathy by 40%, but, as noted with BP control in other studies, there is no legacy effect of short-term fibrate therapy.

Advances in knowledge of the pathophysiology of retinopathy have led to some novel treatment approaches. Treatment options for DR include laser photocoagulation, anti-VEGF therapies, and surgery, depending on the specific type and severity of the condition. Once proliferative DR is established, treatment with retinal laser photocoagulation has been shown to reduce risk of vision loss by 50%. Technology has evolved from using a diffuse Xenon arc to using well-focused laser in photocoagulating retinal tissue in high-risk proliferative DR. Severe preproliferative retinopathy and proliferative retinopathy are usually treated with panretinal photocoagulation. Laser therapy causes loss of peripheral visual fields and diminishes night

• **Fig. 53.4** (A) Normal fundus with clear and crisp optic disc and fovea in the macula and normal blood vessels. (B) Nonproliferative diabetic retinopathy (DR) with tortuosity of vessels, dot and blot hemorrhages, and cotton wool microinfarctions. (C) Proliferative DR with neovascularization on the retina including the macula and optic disc. Retinal scarring caused by detachment.

vision. Although laser therapy was once the standard treatment for DME, anti-VEGF treatments injected intraocularly have been shown in multiple clinical trials to produce better visual results than photocoagulation, hence establishing this therapy as standard of care for DME. In one trial of the anti-VEGF therapy ranibizumab in macular edema, visual acuity improved in 40% of patients treated for 24 months compared with 15% in the sham arm, some of whom received rescue laser treatment. For DR, 24 months of treatment with ranibizumab resulted in progression of retinopathy in 11% of patients compared with 34% in the sham arm. More recently anti-VEGF injections have been studied to potentially replace panretinal laser for proliferative DR, and while visual acuity and visual field results were better, many injections would be required, and the duration of treatment is unclear. Risks of anti-VEGF injections include infection (endophthalmitis) in 1 in 1000 injections and retinal detachment in 1 in 100 injections.

### Nephropathy

Diabetic kidney disease (DKD) or diabetic nephropathy manifests itself clinically as increased urinary albumin excretion, decline in GFR, or both. DKD is the leading cause of end-stage renal disease (ESRD) in the United States, accounting for 44% of new cases. In a recently reported large epidemiologic study in patients with T1D diagnosed before 1970, almost 20% developed ESRD after 25 years, yet in those diagnosed after 1970 this has decreased to 9%. In another large cohort of US patients with primarily T2D, rates of ESRD declined from 28 in 10,000 in 1990 to 20 in 10,000 in 2010, a 28% improvement. These improvements are thought to primarily reflect improved treatment of glucose and BP.

Early histologic changes of DKD may be seen as soon as 2 years after diagnosis. Diabetes initially causes a phase of glomerular hyperfiltration. Glomerular changes are progressive and start with podocyte loss, glomerular basement membrane thickening, mesangial expansion, and finally nodular sclerosis. Tubular hypertrophy and other changes also occur early in early DKD. The earliest clinical sign of DKD is an increase in urinary albumin excretion. A spot urine albumin mg/dL-to-creatinine g/dL ratio (MALB/CR) is widely used as an accurate replacement of a 24-hour urine collection. An MALB/CR <30 mg/g is considered normal, and a level of 30 to 300 mg/g (microalbuminuria) is abnormally high and approximately corresponds to a 24-hour collection of 30 to 300 mg of albumin. Low levels of albuminuria spontaneously regress in up to 40% of patients with T1D, and this can occur in T2D as well as in response to metabolic control. Early studies showed that 75% of patients with microalbuminuria progressed to ESRD in 10 years. A MALB/CR ratio of >300 mg/g (macroalbuminuria) predicts faster rates of decline in GFR. Increased albumin excretion is also a strong predictor of CVD and in the DCCT study accounted for a significant portion of the risk for heart disease.

Serum creatinine should be used to estimate GFR. Several formulae are available to do this, with the modification

of diet in renal disease (MDRD) being most frequently used. Decline in estimated GFR (eGFR) in the absence of albuminuria can be seen in up to 50% of patients with diabetes, especially in the type 2 population. The etiology of the decline in eGFR in normoalbuminuric patients may be related to coexisting conditions, especially hypertension.

As with retinopathy, screening for DKD should begin at diagnosis in type 2 patients and after 5 years in type 1 patients and in any patient with coexisting hypertension. Screening should include annual measurement of MALB/CR and eGFR. When eGFR is <60 mL/min, screening should increase to every 6 months and include measures of bone health. If eGFR is <45 mL/min, measurement of eGFR should increase to every 3 months, and medication adjustments should be considered. A referral to nephrology is reasonable at this point to discuss interventions that slow progression and when appropriate to introduce kidney or combined kidney/pancreas transplant options. Because smoking increases risk and rate of disease progression, smoking cessation is important to address. At eGFR <30 mL/min, patients should be referred to nephrology.

Primary prevention trials of DKD, such as DCCT (glucose control) and UKPDS (glucose and BP control), have been highly successful. However, studies using specific agents such as fibrates, angiotensin receptor blockers (ARBs), and angiotensin-converting enzyme (ACE) inhibitors have not shown adequate safety and benefit outcomes to indicate them for primary prevention of DKD. For this reason, routine use of fibrates and renin angiotensin aldosterone-inhibiting medications is not currently recommended in the absence of other indications. However, ACE inhibitors and ARBs have been shown to decrease albumin excretion and slow renal decline in type 1 and type 2 patients who “already have microalbuminuria” with higher doses being more effective. Combination therapy of ACE inhibitors and ARBs can decrease albumin excretion further but causes significant hyperkalemia, more acute kidney injury, and no mortality benefit so this approach is not recommended. These studies show the limits of using albumin excretion as a surrogate for renal outcomes. There may be a unique benefit of the sodium glucose transporter-2 inhibitors, specifically empagliflozin. In the recent 4-year cardiovascular outcome trial EMPA-REG OUTCOME, 7000 subjects with GFR as low as 30 were randomized to receive empagliflozin or placebo as adjunctive diabetes treatment. The investigators reported a 39% relative risk reduction in incident or worsening nephropathy (12.7% treatment, 18.8% placebo). Currently, the drug is not FDA approved for GFR <45 mL/min, and more studies are under way to understand the mechanism of this renoprotective effect.

### Neuropathy

Diabetic neuropathies (DNs) are a mixed group of disorders with a myriad of symptoms. In general, DN is a diagnosis of exclusion, and other potential causes of symptoms should be ruled out. DN is the most common of the diabetic

microvascular complications. Prevalence varies in studies from 10% to 90% based on criteria used. Twenty-five percent of patients may report symptoms, up to 50% may have physical findings present, and 90% may have abnormalities detectable with advanced testing. DN contributes to risk for amputation as well as to poor quality of life. Duration of diabetes and level of glucose control are primary correlates for neuropathy through mechanisms previously mentioned. Proximal and distal nerves, large and small nerve fibers, and single and multiple nerves may all be involved.

Distal symmetric polyneuropathy (DSP) is the most commonly recognized form of neuropathy. This is nerve length dependent so that feet are affected first, and it evolves to a “stocking-glove” distribution. “Positive” symptoms may include pain, burning, and tingling, and “negative” symptoms may include loss of sensation, numbness, and weakness. Motor neuropathies including mononeuropathies (cranial nerve III, IV, VI palsies for example) and focal sensory neuropathies caused by entrapment (ulnar and lateral femoral cutaneous nerves are particularly vulnerable) are self-limiting, usually lasting from 6 to 12 weeks, but may require symptomatic and supportive treatment. Multifocal motor neuropathy (MFMN), specifically amyotrophy, is rare and presents as a syndrome similar to spinal stenosis with proximal thigh pain and weakness. Intrinsic muscle wasting of the hands and feet is also a manifestation of MFMN. Autonomic neuropathies (ANs) can impact nearly any and all systems of the body. Patients may have symptoms or signs involving cardiac, gastrointestinal, and genitourinary systems. AN contributes to hypoglycemia unawareness, resting tachycardia, orthostatic hypotension, gastroparesis, constipation and diarrhea, neurogenic bladder, impotence, and sudomotor dysfunction. AN also predicts mortality in several investigations possibly because of increased risk of sudden cardiac death.

Because of the lack of a specific test abnormality defining neuropathy, other causes of symptoms should be excluded. These can include but are not limited to excess alcohol use, hypothyroidism, B<sub>12</sub> deficiency, heavy metal exposure, cancers, and inflammatory conditions. Prediabetes as formally defined by the American Diabetes Association (ADA) and even metabolic syndrome independent of glycemic status may be associated with higher rates of sensory polyneuropathy in several population-based studies.

Early physical findings of neuropathy include loss of distal deep tendon reflexes, loss of normal sinus rhythm, and diminished detection of vibration with a 128 Hz tuning fork. Loss of detection of a 10-g monofilament pressed on the foot until the monofilament bends correlates with high risk for ulceration and should prompt referral to podiatry. Cotton to test light touch and a cold tuning fork to detect temperature sensation are easily available additional tests. Patients should be screened with these bedside tests annually. Advanced testing with nerve conduction velocity should only be needed when the clinical picture is not clear.

Diabetic foot disease is multifactorial and is caused by both neuropathy and peripheral vascular disease. Sensory

• **Fig. 53.5** Charcot foot. (From Jeffcoate WJ. Charcot foot syndrome. *Diabet Med.* 2015;32(6):760–770.)

neuropathy leads to a lack of recognition of trauma, which in combination with motor neuropathy may lead to foot deformities such as hammer toes and claw feet. Dry skin arising from sudomotor dysfunction leads to thickened and cracked skin that predisposes to infection. Charcot foot deformity (Fig. 53.5), in which the bones of the foot develop localized osteoporosis and collapse leading to “rocker bottom” foot, is seen with DSP in the setting of normal arterial vasculature and can be recognized by a swollen, erythematous foot with characteristic changes on MRI. Ulceration, bony deformity, osteomyelitis, and amputation are the consequence of diabetic foot disease.

Treatment of T1D with intensive control in the DCCT showed 30% risk reduction for neuropathy in long-term follow-up. Long-term studies of glucose control in type 2 patients have not been as conclusive. No disease-modifying drugs have been released for management of neuropathy so treatment is entirely oriented to symptom relief. Drugs that have been found to be beneficial for symptom relief include the anticonvulsants pregabalin, gabapentin, and topiramate; antidepressants duloxetine, venlafaxine, amitriptyline, and nortriptyline; opioids tapentadol and tramadol; and topical capsaicin. Opioids such as sustained-release morphine should be reserved for patients in whom other options have failed.

### Cardiovascular Disease

CVD, including myocardial infarction (MI), acute coronary syndrome, angina, stroke or transient ischemic attack (TIA), and peripheral arterial disease, is the leading cause of death and morbidity in patients with diabetes. Heart failure (HF) is also recognized as a complication of diabetes with each 1% increase in HbA<sub>1c</sub> increasing risk of HF up to 20%. Patients with diabetes have two to four times the risk of patients without diabetes for cardiovascular death and stroke. The greatest benefit for primary prevention comes from traditional approaches such as smoking cessation, BP control, and lipid control. However, as noted in studies mentioned previously, in long-term studies, glucose control early in disease course will also lower risk.

Screening for CVD should include a BP check at every visit and at least an annual check on peripheral pulses with specific attention to feet. Trials have looked at routine use of more advanced screening such as stress testing and have not found any benefit. Choice of glucose-lowering therapy can have an impact on cardiovascular outcomes, but this area of medicine is not without controversy. Many population-based studies have found improved cardiovascular outcomes in patients on metformin, but selection bias may play a role in the findings. A recent randomized study showed improved cardiovascular outcomes with metformin compared with glipizide. Sulfonylurea agents have long raised concern for worsening cardiovascular outcomes. Glyburide was associated with worse outcomes after MI than was glimepiride. Despite a randomized trial showing cardiovascular benefit of the thiazolidinedione pioglitazone in 2005, another drug in this class, rosiglitazone, was associated with increased risk for MI in pooled data analyses. Because of the experience with cardiovascular outcomes and the thiazolidinediones, the FDA now requires large cardiovascular outcome studies for all new diabetes medications.

As for some of the newer agents, increased risk for HF has been noted with saxagliptin (3.5% vs. 2.8% on placebo) whereas improved cardiovascular outcomes are now reported with empagliflozin (38% risk reduction in cardiovascular death) and liraglutide (13% risk reduction in composite cardiovascular outcomes). More study is likely required to determine the optimal drug therapy for patients with diabetes and CVD, and it may be that specific therapies ought to be selected for patients based on individual clinical characteristics.

For both primary and secondary prevention of CVD, several associations including the ADA have published recommended clinical parameters, therapeutic thresholds, and approaches. Meeting goals for HbA<sub>1c</sub>, BP, and lipids as outlined by the ADA Standards of Medical Care in Diabetes has been shown to lower cardiovascular risk by 60%, but <10% of patients achieve all recommended targets. In contrast with glucose-lowering agents, all BP-lowering agents have been found to be effective at reducing cardiovascular events. ACE inhibitors and ARBs may be superior to calcium channel blockers or beta-blockers at reducing events in patients with diabetes. Statins remain the lipid-lowering drugs of choice in diabetes

because there is a direct relationship between degree of LDL lowering and relative reduction in cardiovascular mortality and events. A recent study showed that primary prevention with statin therapy reduces risk of CVD and CVD death by up to 44% in type 1 patients. Statins, however, can increase risk of diabetes in patients with prediabetes by 9%, although the mortality and morbidity benefit of statins in patients with established diabetes far outweighs any potential metabolic risk. Niacin is no longer recommended for use in patients with diabetes, but ezetimibe in combination with moderate-dose statin therapy may offer modest benefit over statin therapy alone. A novel class of lipid-lowering drugs, proprotein convertase subtilisin-kexin type 9 inhibitors, is recently available with significant LDL-lowering capability and some preliminary positive cardiovascular outcomes reported. Finally, aspirin for primary prevention of CVD is recommended for patients with T1D or T2D who have a calculated 10-year risk for a cardiovascular event of >10%. This includes most men and women age >50 years who have at least one other major risk factor.

### Musculoskeletal Complications of Diabetes

Musculoskeletal complications in diabetes are underrecognized. Accumulation of AGEs (see earlier) in collagen may be contributory. Upper extremities seem primarily involved. Diabetic cheiroopathy is characterized by thickened skin and limited mobility in fingers and hands (prayer sign) and leads to flexion contractures, such as Dupuytren contracture and flexor tenosynovitis. Adhesive capsulitis of the shoulder and carpal tunnel are other common manifestations of musculoskeletal involvement. Charcot foot has been previously discussed. Reflex sympathetic dystrophy, muscle infarction, and diffuse idiopathic skeletal hyperostosis are increased in diabetes. In the DCCT/EDIC (Epidemiology of Diabetes Interventions and Complications) trial, 70% of patients were found to have some form of musculoskeletal complication with longer duration of disease and worse glycemia correlating with severity.

### Acknowledgment

The authors wish to thank John Loewenstein, MD, for his kind assistance with the retinopathy section.

## Chapter Review

### Questions

1. A 44-year-old man with T2D diagnosed 4 years ago returns for follow-up of recent laboratory tests showing an HbA<sub>1c</sub> of 8.2% and a urinary MALB/CR of 45 mg/g. He is taking metformin, sitagliptin, aspirin, atorvastatin, and fenofibrate. He smokes 1 pack of cigarettes per day. Recent dilated funduscopy is normal. He has well-controlled dyslipidemia and sleep apnea. On examination, his body mass index (BMI) is 34, and BP is 152/88 mm Hg.

In addition to suboptimal glucose control, which of the following elements of this patient's history increases risk of progressive DKD?

- A. Metformin treatment
- B. Cigarette smoking
- C. Fenofibrate treatment
- D. Normal funduscopy
- E. Sleep apnea

2. A 60-year-old woman returns for routine diabetes follow-up and is concerned about gradual onset of blurred vision occurring over months. She has had diabetes for 20 years, treated initially with oral agents, but she is now taking a multidose regimen of insulin analogues. She has background retinopathy noted on regular funduscopic examinations, although her last examination was 2 years ago.

Her glucose control is suboptimal with HbA<sub>1c</sub> of 7.6% to 8.2% for the last 8 years.

Visual fields are intact to confrontation, tests of extraocular muscles are normal, and your nondilated funduscopic examination shows microaneurysms and cotton wool spots.

Which of the following is the most likely cause of this woman's visual symptoms?

- A. Retinal detachments
  - B. Vitreous hemorrhage
  - C. Macular edema
  - D. Cataracts
  - E. Mononeuritis of the third cranial nerve
3. A 62-year-old woman with T1D for 25 years presents to your office for an urgent walk-in consultation. She reports waking up with pain and tingling occurring on the lateral aspect of her left thigh. She has never felt this before. There is no weakness, and she has no difficulty walking or climbing stairs.

She has a history of TIA and MI and had well controlled BP and lipids. She takes acetylsalicylic acid 81 mg per day.

On physical examination, her BP is 128/78 mm Hg, heart rate is 82 beats per minute, and BMI is 24. She is alert and oriented. Her cranial nerve examination is normal. The painful area is nontender, and skin is smooth and intact. Neurologic examination is consistent with recent examination showing polyneuropathy, with poor vibration sensation in fingertips and below the ankle, but is otherwise unremarkable. Vascular examination of the lower extremities reveals normal skin tone and peripheral pulses without notable edema or tenderness.

What is the best next step?

- A. Refer to vascular medicine for urgent lower extremity catheterization to rule out muscle ischemia or infarct.
- B. Reassure patient that this is a self-limited condition that usually resolves within 6 to 12 weeks.
- C. Nerve conduction study
- D. Doppler ultrasound to rule out venous thromboembolism

## Metabolic Syndrome

RAJESH K. GARG

### Definition

Metabolic syndrome (MetS), also referred to as *insulin resistance (IR) syndrome* or *syndrome X*, is a constellation of metabolic abnormalities that tend to cluster together and lead to a substantial increase in the risk of type 2 diabetes mellitus and atherosclerotic cardiovascular disease (CVD). Although the manifestations of MetS have been recognized since the 1920s, it was first described as a syndrome by Gerald Reaven in 1988. There are many different ways to define MetS. The most used definition of MetS in the United States is the one proposed by the National Cholesterol Education Program's Adult Treatment Panel III (NCEP ATP III). This definition was first published in 2001 and then updated in 2004 (Box 54.1); however, there are other commonly used definitions (Table 54.1). Some definitions of MetS require the presence of IR or abdominal obesity as the essential feature. Although NCEP definition does not require the presence of IR or obesity as an essential criterion, most individuals diagnosed with MetS according to the NCEP definition are both obese and insulin resistant. There have been attempts at harmonizing the definition of MetS, but the confusion in literature continues.

The reason for a myriad of definitions of MetS is the uncertainty about its pathogenesis. Although some experts consider IR to be the central abnormality in MetS, others consider visceral adiposity as the primary defect. Patients

#### • BOX 54.1 NCEP ATP III Definition of Metabolic Syndrome

#### Presence of Three of the Following Five Criteria Qualifies for Metabolic Syndrome

Waist circumference >102 cm (40 in.) in men and >88 cm (35 in) in women

Serum triglycerides  $\geq$ 150 mg/dL (1.7 mmol/L)

Serum HDL cholesterol <40 mg/dL (1 mmol/L) in men and <50 mg/dL (1.3 mmol/L) in women

Blood pressure  $\geq$ 130/85 mm Hg

Fasting plasma glucose  $\geq$ 100 mg/dL (5.6 mmol/L)

*HDL*, High-density lipoprotein; *NCEP ATP III*, National Cholesterol Education Program's Adult Treatment Panel III.

with MetS are almost always obese, but the criteria for obesity are variable and depend on the definition being used and the population being studied. For example, the NCEP definition uses waist circumference to determine obesity. However, the World Health Organization's definition uses body mass index (BMI) or waist-to-hip ratio as the criterion for obesity. Moreover, while among the Caucasian populations "overweight" is defined as a BMI of >25, "obesity" as a BMI >30, and "central obesity" as waist circumference >88 cm for women and >102 cm in men, in Asian populations "overweight" is defined as a BMI of >23, "obesity" as BMI >25, and "central obesity" as waist circumference >80 cm for women and >90 cm in men. These cutoffs are based on outcomes data comparing Asian with Caucasian populations. For example, Asians with BMI >23 have CVD risk factors equivalent to Caucasians with BMI >25.

### Prevalence

According to National Health and Examination Survey data, from 2003 to 2012, the overall prevalence of MetS in the United States was 33%, with significantly higher prevalence in women compared with men (35.6% vs. 30.3%). The highest prevalence was seen in Hispanics (35.4%), followed by non-Hispanic whites (33.4%) and blacks (32.7%). The prevalence of MetS increased from 32.9% in 2003–2004 to 34.7% in 2011–2012. However, prevalence of MetS seems to be stabilizing or may even be decreasing in recent years as demonstrated by change from 36.1% in 2007–2008 to 34.7% in 2011–2012.

### Pathogenesis

The original descriptions of MetS had implicated IR as the central defect. There are several reasons to consider IR as the common pathophysiologic defect in MetS. IR leads to hyperinsulinemia, glucose intolerance, type 2 diabetes, hypertriglyceridemia, and low high-density lipoprotein (HDL) concentrations due to impaired carbohydrate and lipid metabolism. IR in muscle decreases use of glucose and IR in liver increases hepatic gluconeogenesis, thus causing

hyperglycemia. IR is associated with decreased disposal of the ingested triglycerides due to decreased lipoprotein lipase activity. Moreover, there is an upregulation of very-low-density lipoprotein (VLDL) production from the liver. Besides these metabolic effects, IR may lead to hypertension as a result of decreased endothelial nitric oxide (NO) bioavailability.

However, many experts consider obesity as the central pathophysiologic abnormality and IR as the consequence of obesity. Besides causing IR, obesity is often a direct cause of dyslipidemia. Obesity is also associated with hypertension caused by vasoconstriction and sodium retention through multiple mechanisms. Increased generation of reactive oxygen species reduces bioavailability of endothelial NO, leading to vasoconstriction. Obese individuals also have increased sympathetic tone and overactive renin-angiotensin-aldosterone system. Excess adipose tissue also releases other products including cytokines and prothrombotic factors and is associated with low adiponectin. High tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) levels are present in adipose tissue as well as in plasma of obese individuals and can cause a proinflammatory state that is both insulin resistant and atherogenic. Elevated plasminogen activation inhibitor (PAI-1) levels in obesity contribute to a prothrombotic state, again increasing the risk of atherosclerotic cardiovascular events. Low adiponectin levels that accompany obesity are associated with worsening of IR. Visceral obesity seems to be more important in inducing

these changes than generalized obesity. Excessive fatty acids released by visceral adipose tissue can contribute to IR by making more fuel available to liver and muscle. Free fatty acids have also been shown to interfere with the insulin signaling pathway. Obesity and IR generally go hand in hand, and it is difficult to pinpoint the primary versus secondary pathophysiologic defect. However, all obese individuals are not necessarily insulin resistant. Similarly, IR can be present in nonobese individuals. In general, MetS criteria are satisfied only when obesity and IR are present together. Although visceral adipose tissue is more important in producing MetS changes, the underlying mechanisms for the association between visceral obesity and MetS are not fully understood. Whether a single underlying abnormality is responsible for clustering of the components of MetS remains unclear.

Insights into the mechanistic connection between MetS and its complications are also limited. The risks for CVD and diabetes are greater in individuals with MetS than in those with obesity alone. Presence of MetS is associated with higher levels of C-reactive protein (CRP) and PAI-1 than the presence of individual metabolic abnormalities. The greater the number of MetS components, the higher the levels of CRP and PAI-1. Thus inflammation may be the common link between MetS and its clinical consequences, CVD and diabetes. Alternatively, a yet unrecognized common abnormality may be responsible for MetS as well as for CVD and diabetes.

**TABLE 54.1** Comparison Among Various Definitions of Metabolic Syndrome

	NCEP	WHO	IDF	EGIR	AACE
Obesity	WC >102 cm in men; >88 cm in women	BMI >30 and/or waist:hip ratio >0.9 in men, >0.85 in women	WC depends on ethnicity	WC $\geq$ 94 cm in men; $\geq$ 80 cm in women	BMI >25 and/or WC: >102 cm in men, >88 cm in women
IR		Type 2 diabetes or impaired glucose tolerance or IR on insulin clamp studies		Fasting hyperinsulinemia	Clinical evidence of IR
Glucose	FPG >100 mg/dL		FPG >100 mg/dL	FPG >110 mg/dL	FPG >100 mg/dL or 2-hour OGTT >140 mg/dL
Blood pressure (mm Hg)	>130/85	$\geq$ 140/90	>130/85	>140/90	>130/85

## Clinical Significance

The clinical significance of MetS has been questioned because multiple studies demonstrate that the risk for CVD in MetS is no greater than the cumulative risk associated with its individual components. Indeed, data from the San Antonio Heart Study and the Framingham Heart Study suggest that the Framingham Risk Score (FRS) is better at predicting CVD than a diagnosis of MetS. Framingham Risk Scoring considers other risk factors that are not part of MetS but clearly associated with increased risk of CVD—for example, age, sex, serum total or LDL cholesterol, and smoking status. Therefore FRS is a preferred method for CVD risk prediction. However, the presence of MetS in nondiabetic individuals is a strong predictor of their developing type 2 diabetes in the future. In the Framingham Heart Study, individuals without type 2 diabetes mellitus at baseline had a 5-fold increase in risk of developing diabetes if they had MetS as compared with people without MetS. Thus based on these data, a diagnosis of MetS does not help in CVD risk prediction, but it may help in prediction of type 2 diabetes. In clinical practice, a diagnosis of MetS may lead to a more aggressive recommendation for a healthy lifestyle and drug therapy for CVD risk reduction.

## Management of Metabolic Syndrome

### General Considerations

Management of the MetS is aimed at reducing the risk of CVD and new-onset diabetes. In general, the management strategy is based on targeting individual risk factors and is not different from that of a patient without MetS (Table 54.2). Lifestyle interventions are the mainstay of therapy to reduce metabolic risk factors. Weight loss by modification of diet and increased physical activity is advised. A healthy lifestyle will help in reduction of all components of MetS. However, drug therapy may be required in many patients

to achieve the goals for individual risk factors. Framingham risk scoring is necessary to set the goals and to decide about drug therapy.

### Management of Obesity in Metabolic Syndrome

Abdominal obesity is the hallmark of MetS and is considered an essential component in many of the definitions as described earlier. There is no specific treatment for abdominal obesity. General weight loss reduces IR, lowers other risk factors including triglycerides and blood pressure, and raises HDL cholesterol. Furthermore, weight loss decreases serum levels of CRP, TNF- $\alpha$ , and PAI-1 and is associated with a decrease in oxidative stress. Therefore NCEP ATP III guidelines recommend obesity to be the primary target of intervention in MetS. Weight loss should be achieved with dietary changes and increased physical activity. Nutrition counseling by a trained nutritionist is recommended. The dietary plan should be individualized by considering an individual's habits and sociocultural factors. Low-carbohydrate diets may be more successful in short-term weight loss; however, long-term weight loss is equivalent with various types of diets and depends more on cutting down the total caloric intake. Replacing saturated fat with unsaturated fat, as is common on switching from an American diet to the Mediterranean diet, may help in correcting dyslipidemia, reducing IR, and improving inflammatory markers. It should be noted that most weight loss trials have been conducted for 1 to 2 years only, and even in this short period, participants have shown a gradual weight gain after an initial weight loss. Therefore it is more important to improve eating habits in a sustainable way. More emphasis is needed on eating regular meals but cutting down the portion sizes. Social support and stress management are also important components of treatment for sustained weight loss.

The importance of a regular exercise regimen cannot be overemphasized. Thirty minutes of moderate-intensity physical activity on most days of the week is recommended for most adults. Higher levels of physical activity will be more beneficial in MetS. Physical activity does not have to be all at one time. Short multiple bouts of 10 to 15 minutes of exercise that accumulate to about 1 hour per day are a practical and effective strategy for weight control in MetS.

A realistic goal for weight reduction is to reduce body weight by 5% to 10% over a period of 6 to 12 months. Most data show a very significant reduction in CVD risk factors with a very small reduction in weight. After initial weight loss, long-term maintenance of weight is extremely important.

Drug therapy may be useful for weight loss in some patients, but the long-term effects are unknown. Bariatric surgery is being used more often for morbidly obese subjects or obese subjects with comorbidities. Although bariatric surgery is very effective in causing weight loss, correcting abnormalities of MetS, and controlling diabetes, it should be recommended cautiously because of its invasiveness and unknown long-term effects.

**TABLE 54.2** Management of Metabolic Syndrome

Abnormality	Recommended Treatment
Obesity	Lifestyle interventions
Insulin resistance/glucose intolerance	Lifestyle intervention Optional metformin
Hypertension	Joint National Commission-8 guidelines
Hypertriglyceridemia	Fibric acid derivatives Nicotinic acid
High-density lipoprotein cholesterol	Nicotinic acid

## Reduction of Insulin Resistance With Drug Therapy

Some experts believe that IR plays a central role in the pathophysiology of MetS and should be the primary focus of treatment. Although weight loss and increased physical activity reduce IR and should be the primary mode of therapy, drug therapy to reduce IR is also an option. Currently, biguanides (metformin) and thiazolidinediones (pioglitazone or rosiglitazone) are the available agents to reduce IR. Although these drugs are approved for use in type 2 diabetes mellitus, they have also been shown to decrease the incidence or delay the onset of type 2 diabetes. Metformin may be a more attractive option in MetS because it helps in weight loss, corrects dyslipidemia, and lowers blood pressure. However, its use in MetS has not been studied in clinical trials. Metformin reduced the incidence of type 2 diabetes in the diabetes prevention program and was associated with fewer CVD events in the United Kingdom Prospective Diabetes Study. The American Diabetes Association recommends considering the use of metformin in prediabetic patients who have impaired fasting glucose as well as impaired glucose tolerance. Thiazolidinediones reduce IR and may also correct dyslipidemia of MetS. However, their use is associated with weight gain and a high risk of heart failure.

## Treatment of Dyslipidemia in Metabolic Syndrome

Fibric acid derivatives and nicotinic acid can lower triglycerides and increase HDL cholesterol. Some studies suggest a reduction in CVD endpoints with fibrates in patients with MetS. However, according to NCEP the primary goal of treatment is reduction of LDL cholesterol. Lowering triglycerides and raising HDL cholesterol are considered secondary goals of lipid therapy. Therefore in most patients, fibrates and/or nicotinic acid are used in combination with a statin. Clinical trials failed to show the benefits of this combination on CVD events. Nicotinic acid is more efficacious than fibrates in raising HDL cholesterol, but it can also cause a rise in plasma glucose levels. In general, triglyceride-lowering drug therapy is held off until triglyceride levels are >500 mg/dL.

## Treatment of High Blood Pressure

Guidelines for treatment of hypertension in MetS are the same as in the Eighth Joint National Commission guidelines for non-MetS patients (it is likely that blood pressure guidelines will change in light of the SPRINT [Systolic Blood Pressure Intervention Trial] study). Lifestyle changes described previously for weight loss also help reduce blood pressure. No specific class of antihypertensive drugs is recommended for use in patients with MetS. However, diuretics and beta-blockers are known to worsen IR and cause

dyslipidemia. Clinical trials with angiotensin-converting enzyme inhibitors and angiotensin receptor blockers have shown a reduction in IR and a decrease in incidence of type 2 diabetes. Therefore these drugs may be more useful in patients with MetS. However, the majority of clinical trials indicate that the main reason for reduction in CVD events associated with antihypertensive drugs is lowering of blood pressure. Therefore it is more important to use a drug that effectively lowers blood pressure.

## Treatment for Proinflammatory and Prothrombotic State

No specific drugs are available to control the proinflammatory and prothrombotic state in MetS. However, more and more drugs are being tested for these effects. Low-dose aspirin reduces CVD events, and its risk-benefit profile favors its use in patients with MetS. When otherwise indicated, drugs with demonstrated suppressive effects on inflammatory cytokines and prothrombotic factors should preferably be used in MetS.

## Unusual Conditions Associated With Metabolic Syndrome

Rare disorders such as lipodystrophy caused by single-gene mutations may be associated with MetS. However, for the general population, MetS is probably a polygenic disorder. MetS is being detected more and more often in HIV patients, where it may be caused by side effects of protease-inhibitor drugs. Lipodystrophy and IR are also often present in these patients. In addition, MetS is being increasingly recognized as a side effect of other commonly used drugs—for example, corticosteroids, antidepressants, antipsychotics, and antihistamines. All these drugs can cause weight gain and IR. In most clinical situations, these drugs cannot be stopped despite their side effects. Therefore special attention should be paid to control the metabolic abnormalities associated with their use.

## Summary

There is lack of consensus on the definition, clinical significance, and management of MetS. A common underlying pathophysiologic mechanism has not been identified. Obesity and/or IR seem to be the central defect. With increasing prevalence of obesity, the prevalence of MetS is also increasing. Clinically, MetS predicts the risk of CVD similar to that predicted by combining the risks associated with individual abnormalities. Therefore treatment guidelines include treatment of individual risk factors. Whether a diagnosis of MetS will lead to more aggressive risk reduction and improve clinical outcomes remains to be determined.

## Chapter Review

### Questions

- Which one of the following is not included in the NCEP ATPIII diagnostic criteria of metabolic syndrome?
  - HDL
  - Blood pressure
  - Glucose
  - LDL
  - Waist circumference
- How many abnormal features are required for a diagnosis of metabolic syndrome according to the NCEP ATPIII definition?
  - One
  - Two
  - Three
  - Four
  - Five
- Metabolic syndrome is the strongest predictor for which of the following conditions?
  - Myocardial infarction
  - Diabetes mellitus
  - Stroke
  - Heart failure
  - Renal failure
- Which one of the following is the mainstay of the treatment of metabolic syndrome?
  - Lifestyle interventions
  - Insulin sensitizers
  - Antiinflammatory drugs
  - Lipid-lowering drugs
- The decision about drug therapy in metabolic syndrome depends on which of the following?
  - Number of abnormal components
  - CRP levels
  - Abnormal values of individual components
  - All patients should be treated with metformin

### Answers

- D
- C
- B
- A
- C

## Metabolic Bone Diseases

MERYL S. LEBOFF

**B**one is a dynamic and complex organ that undergoes constant remodeling. It consists of an organic matrix (collagen and some noncollagenous proteins), minerals (calcium and phosphate in hydroxyapatite crystals), and water. Normally, bone mass is maintained by a tight coupling of bone breakdown by osteoclasts followed by bone formation by osteoblasts. Osteoporosis is characterized by decreased bone mass and architectural changes in normal mineral-to-matrix ratio and superimposed skeletal fragility and fractures; osteomalacia occurs when there is a reduced mineralization of the matrix; and Paget's disease is a disorder in which there is excessive, disorganized bone resorption and formation.

### Osteoporosis

Osteoporosis is the most prevalent metabolic bone disease that results in 200 million fractures per year worldwide. In the United States, there are 2 million incident fractures each year, which is greater than the incidence of new myocardial infarctions, breast cancer, and stroke combined. Characterized by reduced bone mass and structural deterioration, osteoporosis results in increased risk of fragility fractures often occurring with minimal trauma such as falling from a standing height. An estimated 1 in 2 women and 1 in 4 men age  $\geq 50$  years will sustain a fragility fracture in their remaining lifetime. Fractures rise exponentially with age in women and men; the increase in fractures in women is generally shifted 10 years before that of men. A rise in the occurrence of wrist fractures takes place first, followed by increases in spine and hip fractures. Spine fractures are the most common osteoporotic fractures, but they are often asymptomatic and found incidentally during imaging performed for other reasons. Only one-third of spine fractures are clinically evident without an x-ray; spine fractures lead to loss of height, kyphosis, abdominal distention, restrictive lung disease, and an increased risk of subsequent spine and hip fractures. Vertebral fractures are associated with a 5-fold increased risk of future spine fractures and a 2-fold increased risk of other fragility fractures. Hip fractures are the most serious osteoporotic fractures because they are associated with substantial morbidity and mortality. Approximately 50% of patients

who sustain a hip fracture lose the ability to walk independently; an estimated 12% to 24% of women and 33% of men often die within 1 year of having a hip fracture.

There is a crisis in osteoporosis because there is a large care gap in treating osteoporosis in the aging populations around the world. Although there are effective therapies for osteoporosis, <30% to 40% of patients who sustain a fragility fracture are evaluated or treated for their underlying osteoporosis. Even in adults who are prescribed an osteoporosis medication, more than 50% stop therapy and many do not start the treatment because of fears about rare side effects. Despite the health consequences of osteoporosis and evidence that fragility fractures are expected to increase worldwide, osteoporosis is markedly underdiagnosed and undertreated.

Peak bone mineral density (BMD) is achieved after puberty by age 25 to 30 years, after which bone loss ensues in both sexes. In women, there is accelerated loss of bone for 5 to 10 years following menopause resulting in a 20% to 30% loss of trabecular and 10% to 20% reduction in cortical bone. Over a lifetime, women lose an estimated 50% of the bone in the spine and proximal femur and 30% of the bone in the appendicular skeleton; men lose one-half to two-thirds of these amounts of bone. Thus optimization and maintenance of peak bone mass may reduce the risk of fractures later in life. The advent of bone density testing using dual-energy x-ray absorptiometry (DXA) makes it possible to quantify the amount of bone in the spine, hip, forearm, and total body with little radiation exposure. The BMD in a patient is compared with that of (1) age-matched controls to determine whether the BMD is diminished relative to an age-matched cohort (e.g., Z-score; Fig. 55.1) and (2) young-normal controls to assess whether there is a decrease in BMD from peak bone mass (T-score). Low bone mass (osteopenia) is defined as a T-score between 1 and 2.5 standard deviations (SD) below bone density of young healthy individuals. Osteoporosis is defined as a T-score  $\geq 2.5$  SD below that of young normal, healthy individuals. Adults who are age  $\geq 50$  years with a fragility fracture of the spine, hip, or wrist/arm also have osteoporosis. DXA also provides a useful technique called *vertebral fracture assessment* to identify the presence of spinal fractures. In addition, the Trabecular Bone Score (TBS) derived from a spinal

• **Fig. 55.1** Dual-energy x-ray absorptiometry (DXA) of the hip. Bone mineral density (BMD) is compared with the young adult mean at peak bone mass and age-matched controls. The T-score and Z-score are indices of the number of standard deviations compared with young-normal and age-matched controls, respectively.

bone density test is now approved by the US Food and Drug Administration (FDA) because it is associated with microarchitecture and predicts the risk of fractures independent of bone density measures.

In the United States, it is estimated that 54 million adults have osteopenia (low bone mass) or osteoporosis, which increases the risk of fractures. Although there is an inverse relationship between BMD and future fracture risk, more than half of fragility fractures occur in patients with osteopenia. This is because more adults have osteopenia than osteoporosis, and other clinically important factors contribute to the risk of fracture. The evaluation of patients for osteoporosis should include a measurement of height preferably with a stadiometer, a careful evaluation including a family history and physical examination to identify risk factors and clinical signs and symptoms of secondary causes of osteoporosis; a bone density test should be performed to assess the severity of the osteoporosis and to monitor the effects of therapeutic interventions. Secondary causes of osteoporosis are common and affect an estimated 40% to 65% of women and men and up to 80% of adults with hip fractures.

Table 55.1 lists some of the secondary causes of low bone mass and osteoporosis. In each of these disorders, bone loss results from a net increased bone resorption, deficient bone formation, or both. Supraphysiologic levels of exogenous or endogenous (Cushing disease/syndrome) glucocorticoids produce an early loss of trabecular bone with a smaller effect on cortical bone resulting in a decrease in bone formation, an increase in bone resorption, and a negative calcium balance.

Glucocorticoids produce a dose-dependent increase in fracture risk, particularly at prednisone doses of  $\geq 5$  mg per day; very high doses of inhaled corticosteroids can also lead to a decrease in bone mass. In long-standing hyperthyroidism or supraphysiologic thyroid hormone replacement, which can be detected by a very suppressed thyroid-stimulating hormone (TSH), the resulting accelerated bone turnover may produce bone loss. A number of hypogonadal states (e.g., anorexia nervosa, athlete triad, or gonadal suppression) may result in bone loss and an

**TABLE 55.1** Causes of Low Bone Mass and/or Osteoporosis

Endocrinologic abnormalities	Glucocorticoid excess, hyperthyroidism, hypogonadism (androgen insensitivity, Turner and Klinefelter syndrome, hyperprolactinemia, premature menopause), anorexia, athlete triad, vitamin D deficiency, hyperparathyroidism, diabetes mellitus (types 1 and 2)
Cardiovascular, renal, pulmonary, and miscellaneous disorders	Chronic kidney disease, hypercalciuria, posttransplant bone disease, congestive heart failure, chronic obstructive lung disease, AIDS/HIV
Connective tissue disorders	Osteogenesis imperfecta, Ehlers-Danlos syndrome, Marfan syndrome, ankylosing spondylitis, homocystinuria
Gastrointestinal diseases	Celiac disease (i.e., sprue), inflammatory bowel disease, postgastrectomy, primary biliary cirrhosis or alcoholic cirrhosis, bariatric surgery
Hematologic disorders	Multiple myeloma, mastocytosis, leukemia, hemophilia, sickle cell disease, leukemia, lymphoma, thalassemia, Gaucher disease
Other genetic disorders	Homocystinuria, cystic fibrosis, hemochromatosis, hypophosphatasia
Rheumatologic disorders	Ankylosing spondylitis, rheumatoid arthritis
Medications	Aromatase inhibitors, heparin (long term), anticonvulsants, methotrexate, Cytoxan, gonadotropin-releasing hormone agonists and antagonists, tamoxifen (in premenopausal women), excess thyroid hormone, lithium, cyclosporine A, tacrolimus, glucocorticoids, thiazolidinediones, depo-medroxyprogesterone (premenopausal women), proton-pump inhibitors, selective serotonin reuptake inhibitors, tenofovir
Other	Paraplegia, immobilization

early risk of fractures. In connective tissue disorders, the abnormal collagen is the basis for compromised skeletal integrity. Renal disease is associated with an increased risk of fractures even in patients with moderate renal insufficiency with an estimated glomerular filtration rate (eGFR)  $<60$  mL per minute. In advanced renal disease, the increased fracture risk may result from osteoporosis, but this condition must be distinguished from aplastic bone disease, secondary hyperparathyroidism, or osteomalacia. Although rheumatoid arthritis affects only approximately 1% of the population, it is associated with an elevated fracture risk through multiple mechanisms.

Low BMD and increased fracture risk also occur in patients with a variety of gastrointestinal and hepatic disorders in association with many factors including malabsorption, nutritional deficiencies, and/or increased inflammatory markers. In patients with celiac disease, adherence to a gluten-free diet results in a reversal of the disease process and an increase in bone mass. As shown in Table 55.1, a growing list of medications are associated with osteoporosis, including drugs that suppress endogenous sex steroid production (i.e., aromatase inhibitors and gonadotropin-releasing hormone agonists), proton-pump inhibitors, selective serotonin reuptake inhibitors, cyclosporine A or tacrolimus, and others.

In the presence of osteoporosis according to DXA, a fragility fracture, or low bone density compared with age-adjusted controls, a workup to look for secondary causes of osteoporosis should be considered. The evaluation for secondary causes of osteoporosis is directed at identification of treatable disorders and includes the determination of serum calcium, 25-hydroxyvitamin D (25[OH]D), parathyroid hormone (PTH), sensitive TSH levels (especially in adults on thyroid hormone), liver tests, complete blood count, possibly serum and urinary protein electrophoresis, and measurement of 24-hour urinary calcium and creatinine levels. Additional endocrinologic or neoplastic processes should be considered in patients with progressive bone loss and fractures and those in whom fragility fractures are uncommon, such as young adults, premenopausal women, and men <60 years. Correction of the underlying cause of osteoporosis may result in improvements in bone.

Current guidelines generally recommend bone density testing of the spine and hip in women age  $\geq 65$  years and men age  $\geq 70$  years (in some but not all guidelines), postmenopausal women with risk factors, and men age  $\geq 50$  years with clinical risk factors including a history of a fragility fracture. Bone density testing is also recommended in adults who are being considered for osteoporosis therapy and whose response to therapy needs to be monitored. In 1997, Medicare mandated coverage for BMD testing every 2 years in estrogen-deficient women, patients with radiologic evidence of low bone mass or a fracture, glucocorticoid-treated subjects, patients with primary hyperparathyroidism (forearm bone density also indicated here), and for monitoring the response to an approved osteoporosis treatment.

There is an association between spinal fractures and height loss. According to the 2013 National Osteoporosis Foundation Clinical Guide, vertebral imaging should be performed to identify any spinal fractures (using vertebral fracture assessment or radiography) in the presence of height loss of 1.5 inches or more, prospective height loss of 0.8 inches or more in postmenopausal women and men aged 50 to 69 years, or recent or current long-term glucocorticoid use. Assessment for the presence of spinal fractures is also recommended in women age  $\geq 70$  years and men age  $\geq 80$  years who have a T-score  $\leq -1.0$ , as well as in women age 65 to 69 years and men age 70 to 79 years who have a T-score  $\leq -1.5$ .

A clinical tool, the FRAX calculator (<http://www.shef.ac.uk/FRAX>), uses epidemiologic data from many countries to estimate absolute fracture risk among the large number of individuals with low bone mass (osteopenia). FRAX incorporates clinical risk factors and hip BMD to predict the 10-year probability of a hip fracture or four osteoporotic fractures (hip, wrist, proximal humerus, and clinical spine fractures). Clinical risk factors incorporated in the FRAX calculator summarized by the World Health Organization (WHO) include age, ethnicity, body mass index (BMI), prior fracture history (i.e., fracture in adult life that occurred spontaneously or in association with trauma, which in a healthy individual would not have resulted in a fracture), current use of glucocorticoids, excessive alcohol use ( $\geq 3$  U per day), smoking, rheumatoid arthritis, parental hip fracture, and certain secondary causes of osteoporosis (yes/no). Secondary causes specified in FRAX include type 1 diabetes mellitus, osteogenesis imperfecta, hypogonadism, premature menopause, long-standing hyperthyroidism, malabsorption, and chronic liver disease. Several limitations to FRAX are important to consider for clinical decisions regarding treatment. On the assumption that secondary causes of osteoporosis lead to changes in BMD, entering a BMD in the FRAX calculator removes the impact of the secondary cause on the absolute fracture risk. Falls and many medical conditions and treatments that increase fracture risk are not included in FRAX. FRAX is available on bone density machines and in many BMD reports to guide recommendations for treatment in patients with low bone mass (see Fig. 55.1).

The TBS is a clinically available, FDA-approved measure that is generated from lumbar spine DXA images with TBS iNsight software (Medimaps Group, Geneva, Switzerland). TBS uses structural variations in the spinal BMD to estimate three-dimensional texture characteristics. A low TBS is associated with structural deterioration of bone and increased fracture risk independent of BMD. TBS is now available for use in conjunction with the FRAX score to identify those adults at high risk of fracture.

Risk-factor analysis and physical examination are essential in deciding which patients may benefit from therapy to prevent or treat osteoporosis. Therapy is recommended in patients with evidence of osteoporosis with a spine, hip, or wrist fracture or a spine or hip T-score  $\leq -2.5$ . Using a cost-benefit analysis, the National Osteoporosis Foundation provided treatment thresholds (calculated by FRAX using the United States database) for adults with a 10-year risk of major osteoporotic fracture of  $\geq 20\%$  or a hip fracture of  $\geq 3\%$ . Patients with osteopenia age  $\geq 50$  years and/or with physician concerns about secondary causes of osteoporosis should also be considered for treatment. To reduce the high prevalence of osteoporotic fractures, lifestyle changes (e.g., smoking cessation, avoidance of excessive alcohol use, and healthy weight maintenance), reversal of modifiable risk factors, and optimization of calcium and vitamin D intake should be implemented.

**TABLE 55.2 Dietary Reference Intakes for Calcium and Vitamin D**

Life Stage Group	Calcium Recommended Dietary Allowance (mg/d)	Vitamin D Recommended Dietary Allowance (IU/d)
9–18 years old	1300	600
19–50 years old	1000	600
51–70-year-old men	1000	600
≥51-year-old females	1200	600
≥71-year-old females and men	1200	800
14–18-year-old, pregnant/lactating individuals	1300	600
19–50-year-old, pregnant/lactating individuals	1000	600

Modified from Ross AC, Manson JE, Abrams SA, et al. The 2011 Report on dietary reference intakes for calcium and vitamin D from the Institute of Medicine: what clinicians need to know. *J Clin Endocrinol Metab.* 2011;96(1):53–58.

### Role of Calcium

Because 99% of calcium is stored in bone, adequate calcium intake is essential to prevent mobilization of calcium from the bone. Longitudinal studies show that supplemental calcium is modestly helpful in retarding bone loss. The 2011 Institute of Medicine's (IOM) recommendations for calcium intake that meet the daily requirements of 97% of the population are shown in Table 55.2. Although dairy products are naturally enriched with calcium, many juices, cereal bars, and cereals contain added calcium. An 8-ounce glass of milk or calcium-supplemented orange juice contains ~300 mg of elemental calcium, calcium-supplemented soy and almond milk contains ~450 mg, one ounce (or 1 cubic inch) of cheese contains ~200 mg, and certain cereals contain as much as 1000 mg per serving. Resources helpful for patients to calculate their calcium intake include the National Osteoporosis Foundation (NOF) website (<https://www.nof.org/patients/treatment/calciumvitamin-d/steps-to-estimate-your-calcium-intake/>), US Dairy Council of California website (<https://www.healthyeating.org/Healthy-Eating/Healthy-Eating-Tools/Calcium-Quiz.aspx?action=quiz>), and the International Osteoporosis Foundation website (<https://www.iofbonehealth.org/calcium-calculator>). Although obtaining calcium through diet is preferred, supplemental calcium should

be added when an individual's dietary calcium intake does not meet the IOM's recommended dietary allowance (RDA) for calcium. According to the IOM Committee Report, children and adolescents age 9 to 18 years and pregnant women age 14 to 18 years require a total calcium intake of 1300 mg elemental calcium daily. To prevent a negative calcium balance, premenopausal women and men age 19 to 50 years require 1000 mg per day, and women age ≥51 years and men age ≥71 years require 1200 mg per day. In the absence of underlying disorders of calcium homeostasis, these calcium intakes are generally safe. However, in the Women's Health Initiative (WHI) calcium and vitamin D clinical trial, 1000 mg of daily supplemental calcium and 400 IU of vitamin D was associated with a 17% increased risk of kidney stones in postmenopausal women. Among women in the WHI who adhered to the calcium and vitamin D supplements, however, there was a 29% reduction in the risk of hip fractures. Recent metaanalyses support the benefit of calcium plus supplemental vitamin D on fracture reduction. Thus the risk of renal stones with calcium supplementation needs to be balanced with fracture reduction.

### Role of Vitamin D

Vitamin D increases calcium absorption, and vitamin D deficiency has been associated with rickets/osteomalacia and osteoporosis. Vitamin D is activated in the skin by sunlight or absorbed from nutritional sources or supplements in the intestine and then converted to 25(OH)D in the liver. Nutritional sources of vitamin D include salt water fish, cod liver oil, and egg yolk. The 1,25-dihydroxyvitamin D (1,25[OH]<sub>2</sub>D) metabolite is synthesized in the kidney from 25(OH)D through activation of the 1-hydroxylase enzyme, which is stimulated by hypophosphatemia, hypocalcemia, and PTH; 1,25(OH)<sub>2</sub>D is also synthesized from 25(OH)D in many cells including osteoblast precursors and then inactivated internally, resulting in important cellular effects.

Vitamin D insufficiency and deficiency have previously been documented at all ages (children and adults) because of inadequate exposure to ultraviolet light, insufficient intake, use of sunblock, increased skin pigment, obesity, chronic kidney disease, use of medications that increase the metabolism of vitamin D, or impaired absorption (biliary or gastrointestinal diseases). Nursing home residents, adults with hip fractures, patients with malabsorption, or those not exposed to ultraviolet light or on vitamin D supplements are at high risk for vitamin D deficiency. Mild vitamin D insufficiency may not cause symptoms, but it can contribute to low bone mass. Severe vitamin D deficiency causes osteomalacia (see later). In addition, vitamin D deficiency has been associated with impaired muscle function, increased risk of falls, and possibly some malignancies (e.g., colorectal, breast, and prostate cancer). There are however, inconsistent data on effects of supplemental vitamin alone on bone, physical performance measures, cancer risk, and cardiovascular disease. Additional data are needed from randomized controlled trials to assess the benefit of vitamin D supplementation alone on these outcomes.

**TABLE 55.3****Calcium Calculator From the National Osteoporosis Foundation Clinical Guide 2013**

Product	Servings/d	Elemental Calcium (mg)	Total
Milk (8 oz.)	_____	× 300	= _____

Total daily calcium intake, in mg			= _____

Modified from Cosman F, de Beur SJ, LeBoff MS, et al. Clinician's guide to prevention and treatment of osteoporosis. *Osteoporos Int.* 2014;25:2359–2381.

There are currently differing recommendations regarding the optimal 25(OH)D level for bone health with the IOM committee recommending a 25(OH)D level >20 ng/mL whereas several other societies recommend a 25(OH)D level >30 ng/mL. At present, deficient levels of vitamin D are generally defined as a 25(OH)D <20 ng/mL, relative insufficiency as 21 to 29 ng/mL, and sufficient levels of vitamin D as ≥30 ng/mL to prevent the rise in PTH levels. The National Health and Nutrition Examination Survey report showed that 32% of Americans have vitamin D deficiency. Studies of women hospitalized with hip fractures showed a substantial number of women with low vitamin D levels according to both thresholds. Some prospective, placebo-controlled studies and a metaanalysis support the recommendation that patients should also have a minimum of 800 IU of vitamin D daily to reduce the risk of fractures. The NOF recommends 800 to 1000 IU vitamin D daily for adults age ≥50 years, as do the International Osteoporosis Foundation and Endocrine Society. As summarized in [Table 55.3](#), the IOM Committee determined that the RDA for vitamin D for 97.5% of the population is 600 IU per day for individuals age 9 to 70 years and 800 IU per day for those age ≥71 years. For individuals with osteoporosis and bone disease, several societies currently recommend 800 to 1000 IU per day of vitamin D and higher doses as needed for vitamin D deficiency. The upper limit of safety for vitamin D for adults is 4000 IU per day.

For osteoporosis prevention and treatment, individuals should be advised to consume adequate vitamin D and calcium (see [Table 55.2](#)) and to participate in a regular exercise program. Multivitamins generally contain 400 to 1000 IU of vitamin D. Many calcium preparations also contain vitamin D. Approaches to restore very low levels of 25(OH)D to sufficient levels with high doses of vitamin D<sub>2</sub> and close monitoring are shown in [Table 55.4](#). The goals of therapy for osteoporosis are to reduce bone resorption and to enhance bone formation.

### Exercise

Exercise and approaches to prevent falls are essential components of osteoporosis care. Skeletal loading from muscle forces have important effects on bone strength. Clinical studies and

**TABLE 55.4****Vitamin D Repletion**

25-(OH) Vitamin D	Recommended Treatment Dose
<10 ng/mL	Evaluation by a bone specialist
<20 ng/mL	50,000 IU vitamin D <sub>2</sub> weekly for 8 weeks and then recheck level. Once a sufficient level is reached, consider maintenance with 600–1000 IU of vitamin D <sub>3</sub> daily or 50,000 IU vitamin D <sub>2</sub> once or twice monthly as needed.

From Holick MF, Binkley NC, Bischoff-Ferrari HA, et al. Evaluation, treatment, and prevention of vitamin D deficiency: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2011;96(7):1911–1930.

metaanalyses show that weight-bearing and muscle-strengthening exercises produce modest increases in bone density ranging from 1% and 3%. Exercise recommendations often include weight-bearing, muscle-strengthening, and balance training exercises for 30 minutes 5 days per week or 75 minutes twice weekly, consistent with other general health guides. Weight-bearing exercises are walking, dancing, jogging, practicing Tai Chi, and playing tennis, among others. In patients with vertebral fractures or a low spinal bone density, it is important to avoid flexion of the spine and twisting movements. In addition to balance training, fall prevention interventions should be implemented including correction of vision and elimination of medications or hazards in the home (loose rugs, cords, poor lighting) that can increase the risk of falls.

### Bone Remodeling and Treatment of Osteoporosis

There are a number of FDA-approved ([Table 55.5](#)) and emerging therapies for the prevention and treatment of osteoporosis. Bone undergoes constant remodeling. Osteoporosis, in turn, results when there is a net increase in bone breakdown relative to bone formation and structural and microarchitectural deterioration resulting in skeletal fragility.

Important regulators of this process include the receptor activator of nuclear factor-kappa B (RANK)/RANK ligand (RANKL)/osteoprotegerin (OPG) system for bone resorption. RANKL, produced by the osteoblast lineage, binds to the RANK receptor and stimulates osteoclastic differentiation and activity; the endogenous decoy receptor, OPG, made by osteoblasts, binds to RANKL and inhibits bone resorption. The Wnt signaling pathway plays a key role in bone formation because this pathway is involved in the activation of transcription of genes that direct the differentiation and proliferation of osteoblasts. Sclerostin is a protein produced by the osteocyte that binds to the LRP5/6 receptor and inhibits Wnt signaling and bone formation.

Therapeutic interventions that are anabolic for bone include PTH 1-34, PTH 1-84, and PTHrP. In addition, a number of FDA-approved osteoporosis therapies suppress bone resorption, and these include bisphosphonates, estrogen, selective estrogen receptor modulators, and calcitonin. New therapeutics have been developed that bind to RANKL (e.g., denosumab) and suppress bone resorption or bind to sclerostin (e.g., romosozumab) and stimulate bone formation. At the present time, romosozumab is being reviewed by the FDA.

It is critically important to initiate therapy to reduce subsequent fractures in these osteoporotic individuals. At Brigham and Women's Hospital, endocrinologists and members of the Department of Orthopedic Surgery have worked together since 2004 to create the interdisciplinary Brigham Fracture Intervention Team Initiative to correct vitamin D deficiency and advance treatment of the underlying osteoporosis; this interdisciplinary collaboration to advance hip fracture care includes modifications in the electronic health record. The National Bone Health Alliance (NBHA) is a public and private sector partnership in the United States that is seeking to implement hospital-based fracture liaison services to identify patients with fractures and initiate bone density testing and treatment. The goal of the NBHA is to reduce hip and other fractures by 20% by the year 2020 and the associated high health care costs.

## Hormone Therapy

Estrogen replacement decreases bone resorption and increases BMD. Data from the large WHI show that oral conjugated estrogen plus progestin (Prempro) or estrogen (Premarin) alone decreased the risk of clinical spine fractures by 35% and 38% and hip fractures by 33% and 39%, respectively. Estrogen and progestin, however, increased the risks of heart disease, stroke, pulmonary embolism, and breast cancer; the women treated with estrogen alone had a nonsignificant reduction in risk of breast cancer. In more recent studies, women starting hormone therapy within 10 years of menopause did not show an increased risk of cardiovascular disease. Hormone therapy is very effective in controlling moderate or severe menopausal symptoms but should be used at the lowest dose for the shortest duration of time

to control symptoms. Although hormone therapy is FDA approved for the prevention of osteoporosis, the FDA recommends that nonestrogen medications be considered first.

## Estrogen Agonists/Antagonists

Estrogen agonists/antagonists, previously called selective estrogen receptor modulators (SERMs), are a class of drugs that bind to estrogen receptors and can selectively function as agonists or antagonists in different tissues. Raloxifene (Evista) is approved by the FDA for the prevention and treatment of osteoporosis and prevention of invasive breast cancer. A large, randomized, placebo-controlled study of raloxifene treatment for 3 years increased BMD at the spine and hip by 2.6% and 2.1%, respectively, and reduced spine fractures by 55% in women without prevalent vertebral fractures; there was no effect on wrist or nonspine fractures. Side effects of raloxifene include small increases in leg cramps, hot flashes, deep vein thrombosis, and stroke. Raloxifene was approved by the FDA in 2007 for reduction in the risk of invasive breast cancer in postmenopausal women with osteoporosis and postmenopausal women at high risk for invasive breast cancer. Tamoxifen, which has estrogen agonist-like effects on bone and the endometrium (including some cases of endometrial carcinoma), produces a small increase in BMD in postmenopausal women with a history of breast cancer, although it is associated with bone loss in premenopausal women. There is a new combination therapy of the SERM bazedoxifene (20 mg) and conjugated estrogen (0.45 mg). Combined bazedoxifene and estrogen is FDA approved in women with a uterus to decrease moderate-to-severe hot flashes and help prevent bone loss.

## Calcitonin

Calcitonin is a 32-amino acid peptide produced by the parafollicular cells of the thyroid that inhibits bone resorption through direct effects on the osteoclasts. Calcitonin nasal spray (200 IU/d) increases spinal BMD by only 1% to 1.5% and decreases spine fractures by 33% but not other fractures. Side effects of calcitonin include nausea, flushing, and rhinorrhea with the nasal preparation. Current use is limited because of the availability of other more effective medications. An FDA panel in 2013 advised against use of calcitonin for treatment of osteoporosis because of new data that show an increased risk of cancers.

## Bisphosphonates

Bisphosphonates are analogues of pyrophosphate that are adsorbed onto the hydroxyapatite of bone and inhibit bone resorption through various mechanisms; bisphosphonates reduce the depth of resorption pits and new bone remodeling, thereby producing positive bone balance. Oral

**TABLE 55.5** FDA-Approved Drugs for Prevention and Treatment of Osteoporosis: Effects on Fracture

Drug	Most Common Dosage	Fracture Risk Reduction	FDA Indications
Estrogen therapy, hormone therapy	Many oral and transdermal preparations	Spine, total hip	PMO prevention
Estrogen agonists/antagonists Raloxifene (Evista)	60 mg PO once daily	Spine	PMO prevention and treatment; reduce risk of invasive breast cancer in patients with osteoporosis and increased risk of breast cancer
Alendronate (Fosamax)	70 mg PO weekly	Spine, nonspine, hip	PMO prevention in women; PMO and GIO treatment in women and men
Ibandronate (Boniva)	150 mg PO monthly; 3 mg IV every 3 months	Spine	PMO prevention and treatment
Risedronate (Actonel)	35 mg PO weekly; 150 mg PO monthly	Spine, nonspine, hip	PMO prevention in women; PMO treatment and GIO prevention and treatment in women and men
Zoledronic acid (Reclast)	4 mg IV/year (treatment) 4 mg every other year (prevention)	Spine, nonspine, hip	PMO treatment in women and men; prevention and treatment of GIO in women and men
RANKL inhibitor Denosumab (Prolia)	60 mg SC every 6 months	Spine, nonspine, hip	PMO treatment in women and men at high fracture risk; patients intolerant to other osteoporosis treatments
PTH Teriparatide (PTH 1-34) (Forteo)	20 µg SC daily (for maximum of 2 years)	Spine, nonspine	PMO and GIO treatment in women and men at high risk of fracture
Abaloparatide (Tymlos)	80 µg SC daily (for a maximum of 2 years)	Spine, nonspine	Treatment of postmenopausal women at high risk of fracture
Calcitonin (Miacalcin, Fortical, Calcimar)	100–200 IU (nasally or subcutaneously) once daily	Spine	PMO treatment in women at least 5 years postmenopausal (in 2013, FDA advised against use because of increased cancer risk)

FDA, US Food and Drug Administration; GIO, glucocorticoid-induced osteoporosis; IV, intravenous; PMO, postmenopausal osteoporosis; PO, oral; PTH, parathyroid hormone, SC, subcutaneous.

preparations of bisphosphonates include alendronate, risedronate, and ibandronate, which increase spine and femoral neck BMD by 8% and 3.5%; 5.4% and 1.6%; and 5.7% and 2.4%, respectively. Table 55.5 shows the FDA-approved indications for bisphosphonate therapy and their antifracture effects. When choosing a bisphosphonate, data on the best available antifracture efficacy (in the absence of head-to-head comparisons) indicate that oral alendronate, risedronate, or intravenous zoledronic acid reduce spine, hip, and nonspine fractures. Alendronate decreases spine fractures by 47%, hip fractures by 51%, and nonvertebral fractures by 50%. Risedronate reduced the risk of new vertebral fractures by 41% to 49%, hip fractures by 40%, and nonvertebral fractures by 36% in 3 years, with reductions in spine fractures in the first year. In contrast, intermittent or daily-dose ibandronate decreased spine fractures by 50% to

62% in 3 years without an effect on nonspine fractures in the overall cohort.

Once-yearly intravenous zoledronic acid substantially decreased the incidence of clinical spine, hip, and nonspine fractures by 77%, 41%, and 25%, respectively, over 3 years, with a benefit in fracture reduction within the first year of treatment. Oral risedronate and ibandronate are available as a once-a-month therapy. A form of oral risedronate (Atelvia) can be taken with food and without needing to sit upright pre-dose and post-dose. Zoledronic acid intravenously (IV) (5-mg infusion once a year) should be considered in patients who show poor compliance with oral bisphosphonates (>50% of patients stop oral bisphosphonate therapy) and for patients with esophageal disorders, inability to sit or stand upright for 30 minutes, or intolerance to oral bisphosphonates. In patients with a hip fracture, once-yearly

zoledronic acid (administered 2 weeks to 90 days after the hip fracture and after administration of 50,000 to 125,000 IU of vitamin D) reduced clinical fractures and prolonged survival. This treatment is FDA approved in hip fracture patients for secondary fracture prevention. Bisphosphonates are excreted renally and should not be used for patients with a creatinine clearance  $<35$  mL/min; for patient safety, the author's practice is to ensure an eGFR above this range, a sufficient 25(OH)D level  $\geq 30$  ng/mL, and normal calcium level before each zoledronic acid infusion.

Side effects of oral bisphosphonates include upper gastrointestinal symptoms and rare esophagitis. Use of intravenous bisphosphonates is associated with acute-phase reactions (e.g., flu-like syndrome, malaise, myalgias) in approximately 20% to 30% of patients, which may be attenuated with administration of oral acetaminophen for 24 hours; these symptoms are less common after the first infusion. Bisphosphonate use has been associated with very rare osteonecrosis of the jaws (ONJ), which is characterized by exposed poorly healing, necrotic bone in the mandible, or maxilla lasting  $>6$  to 8 weeks. Risk factors for ONJ include tooth extraction, invasive dental surgery, incorrectly fitting dentures, poor dental hygiene, and long-term bisphosphonate use. The risk of ONJ is greater in individuals with a history of malignancy treated with high doses of bisphosphonates to reduce skeletal metastases. The estimated prevalence of ONJ is 1 in 10,000 to 1 in 100,000 patient-treatment years. Rare cases of atypical femur fractures have been reported in patients treated with bisphosphonates on longer-term therapy. These are transverse or oblique fractures located below the lesser trochanter that occur with minimal or no trauma and may have a medial spike on bone imaging. In some patients, there are prodromal symptoms including pain or discomfort in the thigh or groin; these fractures may also be bilateral. Other features that may be present are increased cortical thickness and delayed healing. Although studies show an increased risk of these fractures with prolonged bisphosphonate use (usually  $>5$  years), the absolute risk of an atypical femur fracture ranges from 3 to 50 per 100,000 person-years. In contrast, the risk of an incident hip fracture is much greater at 350 per 100,000 person-years. Physicians should ask patients on bisphosphonates about a history of groin or thigh pain that may indicate the presence of an atypical femur fracture. In 2005 the FDA implemented a precaution regarding ONJ for bisphosphonates and in 2010 the FDA issued a precaution about the possible risk of atypical femur (subtrochanteric) fractures in patients treated with bisphosphonates. A low risk of atrial fibrillation (AF) was reported with zoledronic acid, but in a recent review, the FDA did not identify a risk of AF for this class of drugs. Among the bisphosphonates, generic alendronate has the lowest cost; zoledronic acid and some risedronate preparations are also available in a generic form.

### Bisphosphonate Holiday

Bisphosphonates have robust effects on fracture reduction, but there are concerns about prolonged use. According to

post-hoc analyses of long-term extension studies, zoledronic acid and alendronate can be discontinued in some patients after 3 and 5 years, respectively. On the basis of the available literature, subgroups of high-risk individuals who may benefit from continued therapy of zoledronic acid for 6 years or alendronate for 10 years are those with a T-score of  $\leq -2.5$  at the end of 3 to 5 years of therapy or those with a previous major osteoporotic fracture and a T-score of  $\leq -2.0$ . According to the 2011 FDA review, there is no global regulatory restriction on duration of bisphosphonate therapy although more data are needed. Therefore evaluate the risk and benefit of long-term use in each patient. When osteoporosis therapy is stopped, it is prudent to monitor patients and obtain bone density testing and/or tests of bone remodeling. Alternatively, high-risk individuals and those with ongoing fractures may be treated with another class of osteoporosis therapy (e.g., denosumab, teriparatide, or raloxifene).

### Parathyroid Therapy

PTH is an anabolic agent that, when given intermittently, enhances bone formation instead of suppressing bone resorption. Continuous secretion of PTH, as in hyperparathyroidism, results in bone loss (particularly in the forearm and hip). Intermittent PTH injections (daily), however, produce robust increases in bone mass and improve bone microarchitecture. PTH stimulates bone formation and remodeling through multiple mechanisms, with an early increase in markers of bone formation before bone resorption and the development of an "anabolic window."

In a large, multicenter, randomized, placebo-controlled study in postmenopausal women, teriparatide (PTH1–34) increased spinal BMD by 9.7% and femoral neck BMD by 2.8%, with a small decrease in the distal radial site that was similar to placebo-treated subjects. PTH (20  $\mu$ g/d) reduced the risk of spine fractures by 65% and nonspine fractures by 53%. PTH also showed beneficial effects on bone in men and glucocorticoid-treated subjects. The biologically active fragment, PTH1–34, has properties similar to the full-length intact PTH1–84, which is approved for use in Europe. Concurrent treatment with alendronate and PTH attenuates the anabolic action of PTH. PTH therapy is best used before a bisphosphonate, and bisphosphonate therapy should be started immediately upon completion of PTH to consolidate the anabolic effects of PTH on bone.

Teriparatide (20  $\mu$ g) is administered as a daily subcutaneous injection for up to 24 months, using a pen that contains a one-month supply (see Table 55.5). Side effects include transient redness at the injection site, headache, nausea, hypotension (rare), and mild hypercalcemia. Rodents treated with nearly life-long, daily teriparatide have an increased risk of osteosarcoma. Teriparatide is FDA approved for the treatment of postmenopausal women and men with osteoporosis at high fracture risk. Teriparatide has a black-box warning about the risk of osteosarcoma documented in rodents; an increased prevalence has not, to date, been

observed in humans. For this reason, teriparatide should not be used in patients with Paget's disease, an elevated alkaline phosphatase, bone metastases, prior x-ray therapy, hypercalcemia, or in children or young adults with open epiphyses. Alternative modes of administration of PTH such as a nasal spray of PTH1–34 and oral and transdermal preparations are under investigation.

### Abaloparatide

Abaloparatide is a selective activator of the parathyroid hormone type 1 receptor that was FDA approved in 2017 for the treatment of postmenopausal women at high risk for a future fracture. High risk here is characterized by a history of a fragility fracture, many risk factors for osteoporosis, or intolerance to other treatments. In a randomized controlled study, 2463 postmenopausal women with osteoporosis were treated with a daily injection of abaloparatide (80 µg) or identical placebo for 18 months. Teriparatide (20 µg) was given for the same interval in an open label study. Compared with placebo, abaloparatide significantly reduced the risk of new vertebral fractures by 86% and nonvertebral fractures by 43%. Abaloparatide therapy resulted in increases from baseline of 11.2% and 3.6% in the spine and femoral neck BMD, respectively; these changes were significantly greater than those observed with placebo but not with teriparatide. Adverse events were similar in all treatment groups, but hypercalcemia was greater in those participants treated with teriparatide compared with abaloparatide. Similar to teriparatide, osteosarcoma was observed in rodent models that received high doses of abaloparatide. According to the guidance from the FDA, lifetime treatment with these medications is limited to 2 years.

### Denosumab

Denosumab is the first FDA-approved human monoclonal antibody that binds to the RANKL, an important regulator of bone remodeling. RANKL is secreted by osteoblast precursors, binds to its RANK receptor on osteoclasts, and plays an important role in activation and proliferation of osteoclasts. A human monoclonal antibody to RANKL, denosumab, administered as a subcutaneous injection of 60 mg every 6 months, inhibits osteoclastogenesis and leads to suppression of bone turnover, with a greater increase in BMD than placebo or alendronate. In 2010 denosumab was FDA approved for the treatment of postmenopausal osteoporosis in women at high risk for fracture. It has also been approved for treatment of bone disease associated with breast and prostate cancer. Denosumab is contraindicated in hypocalcemia; baseline calcium should be performed along with a dental examination before initiation of therapy.

Denosumab may have advantages over current osteoporosis therapies because of large increases in bone density, infrequent dosing (every 6 months), and rapid, effective, but reversible antiresorptive activity. Drug adherence, however, is important to prevent the increase in bone turnover

markers and the possibility of a rebound in fractures now reported in patients who stopped this therapy. Adverse effects of denosumab include hypocalcemia, nausea, musculoskeletal pain, serious skin infections (small risk), infections, dermatologic reactions, cystitis, and rare osteonecrosis of the jaw and atypical femur fractures.

### Other Emerging Osteoporosis Therapies

Other new therapies for the prevention and treatment of osteoporosis under investigation for safety and efficacy include use of sclerostin antibody (romosozumab), an anabolic treatment, for one year followed by inhibition of bone resorption with denosumab. New modes of delivery of PTH and abaloparatide are also being studied.

### Osteomalacia

Similar to osteoporosis, osteomalacia is a treatable disease and should not be overlooked. Osteomalacia develops from a deficiency of vitamin D, phosphate, or calcium and decreased incorporation of calcium and phosphate in the hydroxyapatite of bone (Box 55.1). Reduced availability of vitamin D or abnormal metabolism of vitamin D with low 25(OH)D levels (in severe liver disease and nephrotic syndrome or with use of anticonvulsant drugs) and low 1,25(OH)<sub>2</sub>D levels (in chronic kidney disease) may produce osteomalacia. Osteomalacia is frequently manifested by generalized bone pain. In more pronounced cases, bony

#### • BOX 55.1 Causes of Osteomalacia and Rickets in Children

##### Alteration in the Metabolism of Vitamin D

- Reduced 25-hydroxyvitamin D: severe liver disease, nephrotic syndrome, anticonvulsant drugs
- Reduced 1,25-dihydroxyvitamin D or altered action on target tissues: kidney disease, vitamin D–dependent rickets type I, vitamin D–dependent rickets type II

##### Phosphate Deficiency

- Decreased phosphate availability: dietary deficiency, phosphate-binding antacid
- Impaired intestinal phosphate absorption: pancreatic insufficiency, intrinsic bowel disease, short bowel syndromes
- Decreased renal tubular phosphate reabsorption: familial X-linked hypophosphatemic rickets/osteomalacia; osteomalacia, oncogenic osteomalacia
- Generalized renal tubular disorders, renal tubular acidosis, ureterosigmoidosis, carbonic anhydrase inhibitors (acetazolamide)

##### Miscellaneous Mineralization Defects

- Inhibitors of mineralization: fluoride, bisphosphonates (e.g., etidronate), aluminum (e.g., TPN, CRF)
- Hypophosphatasia (low alkaline phosphatase levels)

CRF, Chronic renal failure; TPN, total parenteral nutrition.

deformities (e.g., bowing in children), pseudofractures with radiolucent stress fractures perpendicular to the periosteum (located on the proximal, medial aspects of the long bone or pubic rami), osteopenia, or fragility fractures may occur. In vitamin D deficiency, the calcium and phosphate levels are usually slightly decreased or in the low-normal range, with an upper-normal range or elevated PTH level. An elevated serum alkaline phosphatase level also suggests vitamin D deficiency.

Phosphate deficiency leads to osteomalacia most commonly in syndromes characterized by decreased renal phosphate conservation and increased fibroblast growth factor-23 (FGF-23), a major regulator of phosphate homeostasis. The familial X-linked hypophosphatemic vitamin D-resistant rickets in children or osteomalacia in adults usually presents with hypophosphatemia, a renal phosphate leak, and rachitic or osteomalacial changes, respectively, and an inappropriately normal or low-normal  $1,25(\text{OH})_2\text{D}$  level. Decreased renal tubular phosphate reabsorption is also a feature of oncogenic osteomalacia, associated largely with small benign mesenchymal tumors, hemangiomas, or giant cell tumors located in the bone, skin, oral cavity, or sinuses and rarely with malignant tumors (e.g., prostate cancer or small cell carcinoma). Studies show that some of these tumors express FGF23 messenger RNA with normalization of the FGF23 levels after surgical removal. Such patients typically present with hypophosphatemia, reduced renal phosphate tubular reabsorption, normocalcemia, and inappropriately low  $1,25(\text{OH})_2\text{D}$  levels (in the setting of low phosphate levels). Clinically, patients with oncogenic osteomalacia present with muscle weakness, bone pain, and, in some instances, fractures. Although many of these tumors are small and difficult to find, their removal results in complete resolution of this disorder. Generalized renal tubular disorders and inhibitors of mineralization are also associated with osteomalacia.

A disease that can produce mineralization defects is hypophosphatasia, which is characterized by low alkaline phosphatase levels. Hypophosphatasia results from a deficiency of tissue-nonspecific alkaline phosphatase (TNSALP). There is a spectrum of this disease ranging from severe manifestations in infancy and childhood to milder presentations later in life. Symptoms of hypophosphatasia include muscle weakness, rickets (in children), skeletal deformities, pathologic fractures, dental caries, premature loss of primary teeth, respiratory complications, vitamin B<sub>6</sub> responsive seizures, and early mortality (in the severe forms of this disease). In addition to the low alkaline phosphatase level, elevated concentrations of organic pyrophosphate and pyridoxyl-5'-phosphate (a circulating form of vitamin B<sub>6</sub>) may be present. A milder form of the disease presents in adults with osteomalacia, fractures, muscle and joint pain, and premature loss of primary teeth. In a variant called odontohypophosphatasia, the dental manifestations and tooth loss can occur without skeletal involvement. Enzyme replacement therapy with asfotase alfa, recombinant human TNSALP, has transformed the care of children and some

adults with hypophosphatasia, resulting in improved muscle, respiratory, and skeletal symptoms. Thus early diagnosis of hypophosphatasia and treatment with the FDA-approved asfotase alfa replacement may reduce the burden of this musculoskeletal disease.

Treatment of osteomalacia is generally directed at correction of the underlying alterations in mineral homeostasis. Vitamin D deficiency may be treated with physiologic doses, but higher doses are effective in raising the serum  $25(\text{OH})\text{D}$  level (see Table 55.4). With intestinal malabsorption, very high doses of vitamin D (e.g., 50,000 IU several times a week) may be necessary until the underlying process is treated. In patients with disorders of renal tubular reabsorption (e.g., X-linked hypophosphatemic rickets/osteomalacia, oncogenic osteomalacia), phosphate therapy with  $1,25(\text{OH})_2\text{D}$  (to prevent an increase in PTH levels following phosphate) improves bone healing. In chronic kidney disease,  $1,25(\text{OH})_2\text{D}$  or vitamin D analogues are used; maintenance of the serum calcium phosphate product  $<55$  is recommended. Reduction of phosphate absorption with phosphate binders should be provided.

## Paget's Disease of Bone

Paget's disease, the second most common bone disease after osteoporosis, affects 2% of the population age  $>55$  years. An estimated 5% to 40% of patients have a family history of this disease, and some new gene mutations have been identified (e.g., in sequestosome gene among others). Paget's disease is a chronic bone disease characterized by increased bone resorption by multinucleated osteoclasts and formation of disorganized, weakened woven bone.

Although many patients are asymptomatic, the clinical signs and symptoms of Paget's disease include bone pain and increased warmth of affected bones, associated joint symptoms, skeletal deformities (e.g., bowing), pathologic fractures, increased cardiac output, hearing loss and other nerve compression, and, rarely, osteogenic sarcoma. The pelvis, sacrum, vertebrae, lower extremities, and skull are commonly involved sites. Although serum calcium and phosphorus levels are usually normal, hypercalcemia can ensue with immobilization. The serum total and bone-specific alkaline phosphatase levels, markers of bone formation and turnover, are usually elevated in patients with Paget's disease; in the absence of liver disease, the total alkaline phosphatase is a good marker for monitoring disease activity and the response to therapy. Urine and/or serum markers of bone resorption (N-telopeptide of type 1, C-telopeptide of type 1 collagen) may also be elevated in patients with Paget's disease, but they are not routinely measured. X-ray studies characteristically show enlarged bones, thickened cortices, and osteolytic, osteoblastic, and/or combined changes. Bone scans are useful to diagnose the overall disease activity and to determine whether there is localized monostotic or polyostotic disease. Plain radiographs should be performed in patients

with suspected Paget's disease; bone scans are helpful in determining whether multiple skeletal sites are involved and to monitor the course of therapy.

Treatment is very effective and is instituted for bone pain, neurologic complications, hypercalcemia, increased cardiac output, or fractures. Other indications are directed at prevention of disease progression or involvement of the vertebral body, skull, weight-bearing bones, and disease involvement adjacent to a major articular region. Although there are a number of effective oral and intravenous therapies for the treatment of Paget's disease, a bisphosphonate should be started as the treatment of the underlying disease (shown in [Box 55.2](#)). According to the Endocrine Society practice guideline for Paget's disease, zoledronic acid 5 mg IV is the treatment of choice unless there are contraindications to its use. Patients with Paget's disease should also be treated with calcium, vitamin D (see osteoporosis section earlier), and acetaminophen or

nonsteroidal antiinflammatory drugs for degenerative joint symptoms. Treatment for Paget's disease can now result in marked improvements in disease activity, symptoms, and prolonged remissions.

## Chapter Review

### Questions

1. A 50-year-old man with severe Crohn's disease presents with generalized bone pain and an elevated alkaline phosphatase. An x-ray of his proximal femurs shows bilateral pseudofractures indicative of osteomalacia. The most likely laboratory features compatible with this clinical picture would be:
  - A. High calcium and low PTH levels
  - B. Low phosphate, high calcium, and normal 25(OH)D levels
  - C. Low calcium, low phosphate, and low PTH levels
  - D. Normal phosphate, normal calcium, and low 25(OH)D levels
2. A 78-year-old woman fell and was admitted to the hospital with a right femoral neck hip fracture. She has lost 4 inches in height, and she states that her mother had a hip fracture. She went through menopause at age 39 years. Her BMI is 18. How should you evaluate her?
  - A. Orthopedic surgery, physical therapy, and fall prevention
  - B. Bone density test
  - C. Treatment of her osteoporosis
  - D. Evaluation for secondary causes of her osteoporosis
  - E. All of the above
3. The FRAX calculator (<https://www.sheffield.ac.uk/FRAX/tool.jsp>) incorporates risk factors in a model to predict the 10-year absolute fracture risk for a hip fracture or major osteoporotic fractures (hip, wrist, proximal humerus, and clinical spine fractures). This tool helps guide clinical decisions to treat a woman or man with:
  - A. A fragility fracture
  - B. Low bone mass or osteopenia
  - C. Osteoporosis
  - D. All of the above

### Answers

1. D.
2. E.
3. B.

## Board Simulation: Endocrinology

ALEXANDER TURCHIN

### Questions

1. A 68-year-old man is being treated with heparin for pulmonary embolism. Four days after admission, he has sudden onset of severe abdominal/flank pain and tenderness. He is found to be hypotensive. Laboratory testing shows hyponatremia and hyperkalemia, and his hematocrit is 35% as compared with 40% at the time of admission.

The most appropriate next step is to:

  - A. Measure serum aldosterone.
  - B. Measure serum cortisol.
  - C. Measure serum cortisol before and after administration of corticotropin (ACTH).
  - D. Measure urinary cortisol excretion.
  - E. Start total fluid restriction at 1200 mL/24 hours.
2. A 52-year-old woman is brought to the office after falling and striking her abdomen on the edge of a chair. She had abdominal pain soon thereafter, but it has subsided. She is normotensive. Physical examination is unremarkable except mild abdominal tenderness. CT of the abdomen reveals a 3-cm hypodense left adrenal mass with smooth borders. Serum electrolytes are normal. The most appropriate next step is:

  - A. Measurement of plasma metanephrines
  - B. Fine-needle aspiration of the mass
  - C. Measurement of 8 AM serum cortisol level following administration of 1 mg of dexamethasone at midnight
  - D. Both A and C
  - E. Repeat abdominal CT in 6 months.
3. A 24-year-old veterinary student has had symptoms of hypoglycemia before breakfast for several months. Laboratory studies early one morning reveal the following:  
Serum glucose 28 mg/dL  
Serum insulin 65  $\mu$ U/mL (normal 5–15  $\mu$ U/mL)  
Serum C-peptide 0.1 ng/mL (normal 0.5–3.0 ng/mL)  
Serum cortisol 27  $\mu$ g/dL (normal 8–25  $\mu$ g/dL)  
What is the most likely cause of these results?

  - A. Adrenal insufficiency
  - B. A non-islet cell tumor
  - C. An insulinoma
  - D. Surreptitious administration of insulin
  - E. Surreptitious ingestion of glyburide
4. A 65-year-old woman is found to have hypercalcemia at the time of her annual examination. She has been well but admits to some weakness and fatigue and thinks that her memory may be declining. Her appetite is good, her weight is stable, and she has no history of nephrolithiasis or fracture.

Her physical examination is normal. Her serum calcium is 10.8 mg/dL (normal 8.6–10.5 mg/dL), parathyroid hormone (PTH) 52 pg/mL (normal 15–65 pg/mL), serum creatinine 0.7 mg/dL, and 25-(OH)-vitamin D 42 ng/mL (normal 30–60 ng/mL).

What is the most appropriate next step?

  - A. Bone densitometry
  - B. Measurement of urinary calcium
  - C. Referral to a surgeon for parathyroidectomy
  - D. Repeat measurements of serum calcium in 4 and 8 weeks
  - E. Pertechnetate-sestamibi parathyroid imaging
5. In the case described in Question 4, repeat serum calcium concentration is 10.9 mg/dL. The sestamibi imaging study is normal. The most appropriate next step is:

  - A. Bone densitometry in hip, spine, and distal radius
  - B. Measurement of serum alkaline phosphatase
  - C. Reevaluation in 3 months
  - D. Referral to a parathyroid surgeon
  - E. Treatment with alendronate (Fosamax)
6. A 56-year-old woman who has had diabetes mellitus for 10 years under good control on metformin 1000 mg twice a day (bid) and glyburide 5 mg bid is admitted to the hospital with pneumonia. Her hospitalization is complicated by sepsis, acute renal failure, and a stroke. A nasogastric tube is placed, and a 24-hour enteral tube feeding is initiated. Her diabetes treatment should:

  - A. Remain the same.
  - B. Change to glargine (Lantus) once daily.
  - C. Change to isophane (NPH) 3 times a day.
  - D. Change to regular insulin every 6 hours.
  - E. All scheduled medications should be stopped and sliding-scale lispro (Humalog) insulin started.

7. A 44-year-old woman has had weakness and nervousness for several months. She also has noted occasional palpitations and has lost 5 lb. Her heart rate is 108 beats per minute. She has mild eyelid retraction and a tremor of her hands but no thyroid enlargement or nodules. Her serum thyroid-stimulating hormone (TSH) concentration is 0.01  $\mu\text{U}/\text{mL}$  (normal 0.4–4.0  $\mu\text{U}/\text{mL}$ ) and serum free thyroxine concentration is 2 ng/dL (normal 0.8–1.6 ng/dL). Her thyroid radioiodine uptake at 24 hours is 52% (normal 15%–35%) with diffuse pattern.  
The next step is to:
- Measure serum C-reactive protein.
  - Administer  $^{123}\text{I}$  radioiodine isotope.
  - Administer  $^{131}\text{I}$  radioiodine isotope.
  - Start propylthiouracil.
  - Start methimazole.
8. A 32-year-old woman has had erratic menstrual periods since adolescence and amenorrhea for about 4 months. She has had mild facial hirsutism for more than 10 years. She recently gained about 5 lb and has had less energy than in the past. Her blood pressure and heart rate are normal. She has no striae, central adiposity, or galactorrhea. Neurologic examination is normal. Her prolactin is measured to be 52 ng/mL (normal 4–30 ng/mL), pregnancy test is negative, and pituitary MRI is normal.  
The most appropriate next step is to order:
- Ovarian ultrasonography
  - CT of the head
  - Serum luteinizing hormone
  - Serum testosterone
  - Serum TSH
9. A 68-year-old woman was found unresponsive at home by her daughter. In the emergency department, her temperature was 103.2°F, oxygen saturation 70% on room air, blood pressure 90/40 mm Hg, and heart rate 115 beats per minute. When given oxygen, she was sleepy but arousable. She was hospitalized and treated with intravenous fluids and antibiotics. On day 2, thyroid function tests (TFTs) were drawn because of persistent sinus tachycardia. TSH was 0.15  $\mu\text{U}/\text{mL}$  (normal 0.5–5.0  $\mu\text{U}/\text{mL}$ ), and free thyroxine was 0.6 ng/dL (normal 0.8–1.6 ng/dL). The best next step is:
- Pituitary MRI
  - Thyroid ultrasound
  - Thyroid  $^{123}\text{I}$  scan and uptake
  - Initiate levothyroxine 100  $\mu\text{g}$  daily.
  - Reevaluate in 4 to 6 weeks.
10. A 75-year-old woman comes for a follow-up visit 2 years after initiating alendronate (Fosamax) for treatment of osteoporosis. She takes calcium 500 mg twice daily and vitamin D 800 units daily. She takes alendronate on Sunday mornings together with the rest of her medications. She walks 1 mile 5 days a week. Her 25(OH)D level is 32 ng/mL (normal). Two years ago, her *T* score in left hip was –2.6. A week ago, follow-up bone densitometry showed a 6% decrease in the left hip (significant). The best next step is:
- Ask her to skip the morning calcium on Sundays.
  - Double her calcium dose.
  - Double her vitamin D dose.
  - Add raloxifene (Evista).
  - Add ibandronate (Boniva).
11. A 62-year-old man comes for follow-up of diabetes. He used to be treated with metformin 1000 mg bid and glipizide 10 mg twice daily, but 2 years ago, glipizide was stopped and glargine (Lantus) insulin started. He now takes 30 units of glargine at night. He wakes up from hypoglycemia 2 to 3 times a week, but his daytime glucose ranges between 150 and 220 mg/dL. His hemoglobin A1c (HbA<sub>1c</sub>) is 7.5%. The best next step is:
- Stop glargine, and restart glipizide.
  - Take glargine in the morning instead of at night.
  - Decrease glargine, and add a rapidly acting insulin before every meal.
  - Stop glargine, and start detemir (Levemir) insulin at night.
  - Ask him to eat a snack before going to bed.
12. A 57-year-old woman is evaluated for severe hypertension resistant to treatment with three antihypertensive medications (angiotensin-converting enzyme inhibitor, calcium channel blocker, and a thiazide diuretic) and hypokalemia. She is found to have serum aldosterone 24 ng/dL and plasma renin activity 0.2 ng/mL/h. Plasma metanephrine and normetanephrine levels are normal. Abdominal CT shows a 2-cm benign-appearing nodule in the right adrenal gland. The best next step is:
- Abdominal MRI
  - Repeat the CT in 6 months.
  - Refer to an experienced surgeon for right adrenalectomy.
  - Adrenal vein sampling
  - 24-hour urine collection for aldosterone and creatinine
13. A 41-year-old man comes to your office complaining of progressive erectile dysfunction over the last several years. Evaluation shows testosterone 1200 pg/mL (normal 1800–6900 pg/mL) and prolactin of 73 ng/mL (normal 4–23 ng/mL), confirmed by dilution. Pituitary MRI shows a 2-cm suprasellar mass consistent with pituitary adenoma. He denies headaches; his neurologic examination is normal, and visual fields are intact. Morning cortisol is 12  $\mu\text{g}/\text{dL}$ . The best next step is:
- Surgical resection of the tumor
  - Start bromocriptine (Parlodel).
  - Start cabergoline (Dostinex).
  - Start testosterone patch.
  - Repeat pituitary MRI in 6 months.

14. A 25-year-old man comes in for a routine physical. He had craniopharyngioma resection at age 12 years and has been taking levothyroxine ever since. His current dose is 112 µg daily. Blood tests show TSH of 0.05 µU/mL (normal 0.5–5.0 µU/mL) and free thyroxine 0.7 ng/dL (normal 0.8–1.6 ng/dL). The best next step is:
- Decrease levothyroxine to 88 µg daily.
  - Increase levothyroxine to 125 µg daily.
  - Radioactive iodine uptake
  - Pituitary MRI
  - Reevaluate in 6 months.
15. A 71-year-old man returns to see you for follow-up of type 2 diabetes. He also has hypercholesterolemia, heart failure, hypertension, remote history of pancreatitis, and osteoarthritis. His current medications include glipizide 10 mg twice daily and simvastatin 20 mg at bedtime. His HbA<sub>1c</sub> is 8.2%, and fasting blood glucose 130–150 mg/dL. The best next step is:
- Start metformin 1000 mg daily.
  - Start liraglutide (Victoza) 0.6 µg subcutaneously (SQ) daily.
  - Start sitagliptin (Januvia) 100 mg daily.
  - Start pioglitazone (Actos) 15 mg daily.
  - Start glargine (Lantus) insulin 15 units SQ at bedtime.

### Answers

- C. This man has primary adrenal insufficiency caused by bilateral adrenal hemorrhage. These hemorrhages are most likely to occur in patients being treated with heparin or warfarin, perhaps augmented by illness-induced stimulation of ACTH secretion and therefore increased adrenal blood flow and hormone production. The key clinical findings are abdominal pain and tenderness, hypotension, hyponatremia, hyperkalemia, and anemia. The diagnosis of acute adrenal insufficiency is best confirmed by measurements of serum cortisol before and 30 and/or 60 minutes after administration of ACTH. Both basal and stimulated serum cortisol values should be low in patients with primary adrenal insufficiency. The patient can be treated with dexamethasone (or another glucocorticoid known not to be detected by the serum cortisol assay in use) immediately after the basal serum sample is collected. Measurements of basal serum cortisol alone (B) are not the best test for diagnosis of adrenal insufficiency because the values may be normally low in the afternoon or at night. Simultaneous measurements of basal serum cortisol and ACTH in the morning, if, respectively, low and high, could also confirm the diagnosis of primary adrenal insufficiency, but this simpler approach is not used widely because it takes up to a week to get the results of ACTH measurements in most hospitals. Decreased production of aldosterone, as manifested by a low serum aldosterone level (which could be detected by A) does not, in and by itself, predict a decreased production of cortisol. Decreased production of cortisol is a more serious condition and should be ruled out first. Urinary cortisol excretion (D) is not a reliable test for diagnosis of adrenal insufficiency. Fluid restriction will not treat hyponatremia due to adrenal insufficiency and is contraindicated for patients with an acute hemorrhage. (Pazderska A, Pearce SHS. Adrenal insufficiency—recognition and management. *Clin Med (Lond)*. 2017;17(3):258–262.)
- D. This woman has an adrenal incidentaloma—a finding common in her age group. Subclinical Cushing syndrome and pheochromocytoma must be ruled out in all patients with adrenal incidentaloma. Cushing syndrome can be diagnosed using low-dose overnight dexamethasone suppression test (C) and pheochromocytoma by measuring free plasma metanephrines (A). Consequently, the best answer is D (combining both of these diagnostic maneuvers). Fine-needle aspiration can only identify metastases to the adrenal glands from other cancers and is unable to distinguish between benign and malignant primary adrenal tumors. Therefore (B) should not be done unless there is a known primary malignancy or an otherwise high suspicion for a metastasis. A repeat CT (E) to ensure the size of the tumor is not increasing with time should be considered as the next step once excess hormone production is ruled out. (Bada M, Castellan P, Tamburro FR, et al. Work up of incidental adrenal mass: state of the art. *Urologia*. 2016;83:179–185.)
- D. This student is surreptitiously taking insulin. Low serum glucose and high serum insulin concentrations suggest insulin-induced hypoglycemia. These findings are compatible with an insulinoma (C), surreptitious injection of insulin (D), and surreptitious ingestion of glyburide (E). The low serum C-peptide concentration is strong evidence that the patient is taking insulin rather than secreting it, because insulin and C-peptide are secreted in equimolar amounts by the beta cells of the pancreatic islets. Hypoglycemia is rare in patients with adrenal insufficiency (A), and a cortisol level of 27 µg/dL rules it out. Some non-islet tumors secrete insulin-like growth factor (IGF-2) (B), which can bind to and activate insulin receptors, thereby causing hypoglycemia. These patients have low serum insulin and C-peptide concentrations. Of note, C-peptide is a single chain of 31 amino acids (molecular weight 3020 kDa), connecting the A and B chains of insulin in the proinsulin molecule. Unlike insulin, C-peptide has no known physiologic function. C-peptide has a longer half-life than insulin (2–5 times longer); thus higher concentrations of C-peptide persist in the peripheral circulation, and these levels fluctuate less than insulin. Plasma C-peptide concentrations may reflect pancreatic insulin secretion more reliably than the level

of insulin itself. (Klein-Schwartz W, Stassinis GL, Isbister GK. Treatment of sulfonylurea and insulin overdose. *Br J Clin Pharmacol.* 2016;81:496–504.)

4. D. This woman probably has mild hypercalcemia caused by primary hyperparathyroidism. Her PTH levels, although normal, are inappropriately high for her mildly elevated calcium. However, the calcium elevation could also be transient or a laboratory error. We only have one measurement and otherwise normal laboratory parameters. Measuring the calcium again would be reasonable. She has some symptoms, but whether they can be attributed to the hypercalcemia is debatable. Given the lack of a convincing constellation of findings, the probability of a spurious calcium elevation is reasonably high. Therefore the most appropriate next step is to confirm it after a period of time (D) before proceeding to more expensive and/or invasive maneuvers. Patients like this with mild hypercalcemia and inappropriately high serum PTH concentrations should be asked if they are taking lithium or hydrochlorothiazide. Lithium may cause parathyroid hyperplasia, whereas thiazide diuretics can increase calcium reabsorption by the kidneys; both can lead to mild hypercalcemia. Parathyroidectomy (C), parathyroid imaging (E), and urine calcium measurement (B) are premature before the diagnosis of primary hyperparathyroidism is definitively established. Bone densitometry screening for osteoporosis (A) is generally indicated in women age  $\geq 65$  years, but the acute concern of elevated calcium level should be addressed first.

5. A. The hypercalcemia is now confirmed, providing further evidence that the patient has primary hyperparathyroidism. The decision to be made now is whether or not the patient needs to be treated surgically. In absence of clear symptoms of hyperparathyroidism, the criteria for surgical intervention developed at the Fourth International Workshop on Asymptomatic Primary Hyperparathyroidism apply. According to these guidelines, asymptomatic patients with primary hyperparathyroidism should be referred for surgery if any of the following are true:

1. Serum calcium concentration is  $\geq 1$  mg/dL above the upper limit of normal
2. Estimated glomerular filtration rate  $< 60$  mL/min
3. Bone mass at the hip, lumbar spine, or distal radius is  $> 2.5$  standard deviations below the peak ( $T$  score  $< -2.5$ ) and/or previous fragility fracture
4. 24-hour urine calcium  $> 400$  mg
5. Presence of nephrolithiasis or nephrocalcinosis by radiograph, ultrasound, or CT
6. Age  $< 50$  years

Bone densitometry (A) would help establish whether the patient meets these criteria. Bone density should also be measured in the distal radius because cortical bone is most vulnerable to hyperparathyroidism.

Sestamibi imaging studies are  $< 100\%$  sensitive, so a negative study does not rule out a parathyroid adenoma or hyperplasia. Treatment with a bisphosphonate (E) is a reasonable option if the patient has low-bone density and is not a surgical candidate or declines surgery. Most patients with primary hyperparathyroidism have normal serum alkaline phosphatase concentrations (B) unless they have severe bone disease. (Bilezikian JP, Bandiera L, Khan A, et al. Hyperparathyroidism. *Lancet.* 2017 Sep 15 [Epub ahead of print]; Stephen AE, Mannstadt M, Hodin RA. Indications for surgical management of hyperparathyroidism. *JAMA Surg.* 2017;152:878–882.)

6. D. Enteral tube feedings have two characteristics important for treatment of hyperglycemia: (1) they provide an even caloric intake over the course of 24 hours, and (2) they can frequently be withdrawn suddenly, as in the case of the patient removing the tube or clinical deterioration. An antihyperglycemic regimen should conform to these constraints. Neither metformin nor glyburide (A) would be appropriate in the setting of an acute renal failure. Both glargine (B) and NPH (C) insulins have long half-lives and present a risk of hypoglycemia if tube feeding is withdrawn. The action of a dose of regular insulin (D) lasts for about 4 to 6 hours and thus presents a reasonable balance between the risk of hypoglycemia and an increased nursing workload if injections (of shorter-acting insulins) were to be administered more frequently. A sliding scale alone without scheduled insulin (E) is unlikely to control hyperglycemia in a patient with known diabetes.

Management of hyperglycemia in a hospitalized patient is important for practical reasons as well as for its potential impact on outcomes. This is reviewed in more detail elsewhere (Clement S, Braithwaite SS, Magee MF, et al. Management of diabetes and hyperglycemia in hospitals. *Diabetes Care.* 2004;27:553–591). The use of oral hypoglycemics in renal disease is discussed by Yale (Yale JF. Oral antihyperglycemic agents and renal disease: new agents, new concepts. *J Am Soc Nephrol.* 2005;16[Suppl 1]:S7–10). Glyburide or glibenclamide is an oral antihyperglycemic drug of the sulfonylurea class. The sulfonylureas (glyburide, glipizide, glibenclamide, tolbutamide, and chlorpropamide) have increased potency as the renal function decreases and are contraindicated in severe renal failure. Furthermore, the long action of sulfonylureas and predisposition to hypoglycemia in patients not consuming their normal nutrition are relative contraindications. Metformin is contraindicated in renal failure because of the associated risk for lactic acidosis. Other risk factors for lactic acidosis in metformin-treated patients are cardiac disease, including heart failure, hypoperfusion, and liver disease.

7. E. This woman has clinical manifestations of hyperthyroidism caused by Graves disease. This diagnosis is confirmed by measurements of serum free thyroxine and TSH and radioiodine imaging. Thyroiditis is unlikely given the prolonged duration of symptoms and is ruled out by the increased radioiodine uptake by the thyroid. Thyroid nodular disease is ruled out by the diffuse uptake of radioiodine by the thyroid. No further diagnostic workup is necessary. Levels of C-reactive protein (A) are usually unchanged in patients with hyperthyroidism and do not have diagnostic value under the circumstances. The next step, therefore, is to consider treatment. In patients with Graves disease, unlike in those with hyperthyroidism caused by hyperactive thyroid nodules, long-term remission can frequently be induced by thionamides without long-term sequelae. On the other hand, radioiodine treatment with  $^{131}\text{I}$  (C) commonly leads to hypothyroidism. It is therefore a second-line choice, particularly in patients with mild hyperthyroidism such as this one. When radioiodine is used for treatment of hyperthyroidism,  $^{131}\text{I}$  isotope is preferred to the  $^{123}\text{I}$  isotope (B) because it emits a significant fraction of its radiation as beta-rays (electrons), which have a very short depth of penetration and will not affect any tissues beyond the thyroid that is taking up the iodine. Of the two thionamides, methimazole (E) is more effective than propylthiouracil (D) and appears to have a lower frequency of some of the serious side effects such as liver failure (the subject of the US Food and Drug Administration's boxed warning for propylthiouracil). (De Leo S, Lee SY, Braverman LE. Hyperthyroidism. *Lancet*. 2016;388(10047):906–918; Franklyn JA, Boelaert K. Thyrotoxicosis. *Lancet*. 2012;379(9821):1155–1166.)
8. E. The most common causes of secondary amenorrhea are pregnancy, hypothalamic amenorrhea, hyperprolactinemia, and ovarian disorders (in particular the polycystic ovary syndrome). Based on her history, the patient may have polycystic ovary syndrome (PCOS) at baseline, but acceleration of the symptoms and elevated prolactin point to the recent development of another condition. Although it is not uncommon for patients with primary hyperprolactinemia to have a normal pituitary MRI, a workup for secondary causes, including primary hypothyroidism (E), is indicated. Other etiologies of elevated prolactin may include dopamine antagonists (e.g., antipsychotic medications), seizures, and stress. Head CT (B) will not provide significant additional information given a normal pituitary MRI. Ovarian ultrasonography (A) may or may not be abnormal even if the patient has PCOS and will not shed light on the secondary causes of hyperprolactinemia. Serum luteinizing hormone (C) will be suppressed in all patients with elevated prolactin, independent of the etiology. None of the secondary causes of hyperprolactinemia leads to abnormal testosterone levels in women (D). (Klein DA, Poth MA. Amenorrhea: an approach to diagnosis and management. *Am Fam Physician*. 2013;87(11):781–788; Roberts-Wilson TK, Spencer JB, Fantz CR. Using an algorithmic approach to secondary amenorrhea: avoiding diagnostic error. *Clin Chim Acta*. 2013;423:56–61.)
9. E. This woman had thyroid hormone levels measured while critically ill. Critical illness commonly results in a profile referred to as “sick euthyroid syndrome” in which TSH, thyroxine, and particularly triiodothyronine are all low. Although a similar profile can result from secondary hypothyroidism, the latter disease is much less common and therefore pituitary MRI (A) to look for pituitary lesions that could cause it is not indicated. There are no data that thyroxine supplementation (D) in the setting of acute illness improves outcomes. Neither thyroid ultrasound (B), which is expected to be normal, nor  $^{123}\text{I}$  scan and uptake (C), which will likely be low/nonfocal, will provide specific information that will help make the diagnosis. (Fliers E, Bianco AC, Langouche L, et al. Thyroid function in critically ill patients. *Lancet Diabetes Endocrinol*. 2015;3(10):816–825.)
10. A. Calcium can decrease the absorption of alendronate and other bisphosphonates and thus their efficacy. Patients should not take calcium for at least several hours after the bisphosphonate (A). A daily calcium dose of 2000 mg (B) is excessive; 1500 mg is recommended for postmenopausal women. Her vitamin D level is adequate, so additional vitamin D supplementation (C) is unlikely to be helpful. Neither raloxifene (D) nor ibandronate (E) has been shown to decrease the incidence of hip fractures and therefore would not be the first choice for treating a patient with a pronounced osteoporosis in the hip. Alendronate is in a class of medications called bisphosphonates. The bisphosphonate class includes etidronate (Didronel), ibandronate (Boniva), pamidronate (Aredia), risedronate (Actonel), tiludronate (Skelid), and zoledronic acid (Reclast or Zometa). Bisphosphonates are used for treating osteoporosis (reduced density of bone that leads to fractures), hypercalcemia, fractures and bone pain from solid malignancies and multiple myeloma with skeletal involvement, and Paget disease. (Khosla S, Hofbauer LC. Osteoporosis treatment: recent developments and ongoing challenges. *Lancet Diabetes Endocrinol*. 2017 Jul 6 [Epub ahead of print].)
11. C. This man takes basal (glargine) but no prandial (premeal) insulin. His nighttime hypoglycemic episodes indicate that his glargine dose is too high. It therefore should be decreased and rapid-acting (e.g., lispro, aspart or glulisine) premeal insulin added to control his postprandial hyperglycemia (C). Given that his  $\text{HbA}_{1c}$  is  $>7\%$  even on this substantial dose of glargine, it is unlikely that replacing glargine with glyburide (A) would improve his glucose control. In

most patients, glargine provides 24-hour coverage, so changing the time of administration (B) will not change insulin levels at night. Although detemir insulin typically provides <24-hour coverage, administration of the same dose of detemir at bedtime (D) is likely to lead to hypoglycemic episodes for the same reason that glargine did. Eating a snack at bedtime (E) may improve the hypoglycemia, but it will not improve the postprandial hyperglycemia and will increase the average glucose levels/A1c, placing the patient at higher risk for complications.

12. D. This patient has findings indicative of primary hyperaldosteronism. If a solitary adenoma is the source of the excess aldosterone, surgical resection is the recommended treatment. However, nonsecretory adrenal adenomas (incidentalomas) are common in this age group. Therefore a finding of an adrenal adenoma in a patient with a biochemical picture of primary hyperaldosteronism is not sufficient to conclude that it is the source of aldosterone production. Referral for surgery (C) is therefore premature at this point. Adrenal vein sampling (D) is used in this situation to confirm that the excess aldosterone is coming from the adrenal vein on the same side as the nodule on CT. Abdominal MRI (A) could be helpful in identifying a pheochromocytoma, which has a bright signal on T2, but is not helpful for diagnostic workup of hyperaldosteronism. Urinary aldosterone excretion (E) has not been validated as a diagnostic test for hyperaldosteronism; if the biochemical diagnosis remains in question, a salt suppression test should be used for confirmation. If adrenal vein sampling does not localize aldosterone production to the side of the adenoma, a follow-up CT in 6 months (B) is reasonable to ensure the adenoma is not increasing in size and thus suspicious for malignancy. However, treatment of hyperaldosteronism should not be postponed until then.

Primary hyperaldosteronism is characterized by increased aldosterone secretion from the adrenal glands, suppressed plasma renin activity (PRA), hypertension, and hypokalemia. Increased aldosterone excretion from the adrenals results primarily from either a unilateral aldosterone-producing adenoma or Conn syndrome (50%–60% of cases) or bilateral adrenal hyperplasia (40%–50% of cases). The plasma aldosterone (PA)/PRA ratio is  $\geq 20$  with a PA  $\geq 15$  ng/dL (this patient has a ratio of 120 and PA level of 24 ng/dL). A 24-hour urine aldosterone level after 3 days of salt loading is indicated as a confirmatory test if the diagnosis of primary hyperaldosteronism remains in doubt (a 24-hour aldosterone excretion rate of  $>14$   $\mu\text{g}$  with a concomitant 24-hour urine sodium  $>200$  mEq is diagnostic of primary hyperaldosteronism). (Vaidya A, Malchoff CD, Auchus RJ, et al. An individualized approach to the evaluation and management of primary aldosteronism. *Endocr Pract.* 2017;23:680–689.)

13. A. This man has a pituitary macroadenoma, elevated prolactin level, and low testosterone. Low testosterone could be caused by the compression of the pituitary by the macroadenoma, suppression of gonadotrophs by elevated prolactin, or both. High prolactin is most likely caused by the tumor's compression of the pituitary stalk leading to decreased flow of dopamine from the hypothalamus. It is unlikely that the tumor itself produces prolactin because in that case prolactin levels would be expected to be much higher (hundreds or thousands of nanograms per milliliter). Consequently, treatment with dopamine agonists such as bromocriptine (B) or cabergoline (C) is not likely to affect the tumor. His macroadenoma is large, placing him at risk for future development of panhypopituitarism, optic chiasm compression, and severe headaches. It is therefore imperative that it be treated. Because dopamine agonists will not work, surgical resection is the only available option (A). Surgical referral should not be postponed (E) because of the nonnegligible risk of development of irreversible complications as this large tumor continues to grow. There is a possibility that his testosterone levels will improve after the tumor is resected and stalk compression has been relieved with consequent drop in prolactin levels, so the decision about testosterone supplementation (D) is best postponed until then.
14. B. This patient has postsurgical secondary hypothyroidism. His TSH level therefore cannot be used to assess his thyroid status. Low TSH is common in these patients and does not indicate that his levothyroxine dose should be lowered (A). Free thyroxine levels should be used to make the decision about thyroid hormone supplementation instead. Based on the low free thyroxine level, his levothyroxine dose should be increased (B). Sufficient information is available to make the decision now, and extended follow-up (E) is unlikely to change it. Imaging studies, including radioactive iodine uptake (C) or pituitary MRI (D), will not be helpful.
- In 20% to 40% of patients with central hypothyroidism (low TSH, low or low normal free thyroxine) from a craniopharyngioma, there is direct compression or destruction of the hypothalamus and pituitary stalk leading to growth hormone deficiency, TSH deficiency, ACTH deficiency, antidiuretic hormone deficiency, and luteinizing hormone or follicle-stimulating hormone deficiency. The correct treatment is to increase the levothyroxine to 125  $\mu\text{g}$  daily. (Beck-Peccoz P, Rodari G, Giavoli C, et al. Central hypothyroidism—a neglected thyroid disorder. *Nat Rev Endocrinol.* 2017;13:588–598.)
15. E. This man has poorly controlled diabetes. Further increase in glipizide dose is unlikely to lower his blood glucose significantly, and a new antihyperglycemic agent should be initiated. Metformin (A) is contraindicated in patients with heart failure because of

increased risk for lactic acidosis. Acute pancreatitis has been reported in patients taking both liraglutide (B) and sitagliptin (C), and these medications are therefore not recommended in patients with history of pancreatitis. Pioglitazone (D) can exacerbate heart failure and is contraindicated in patients with this condition. Therefore initiation of insulin, for example glargine

(E), is the optimal therapeutic intervention for treatment of his hyperglycemia. (Fonarow GC. Diabetes medications and heart failure: recognizing the risk. *Circulation*. 2014;130(18):1565–1567; Dei Cas A, Fonarow GC, Gheorghiade M, et al. Concomitant diabetes mellitus and heart failure. *Curr Probl Cardiol*. 2015;40:7–43.)

## Endocrine Summary

JUAN CARL PALLAIS

In 1905 Starling coined the term *hormone* to describe secretin, a substance secreted by the small intestine into the bloodstream to stimulate pancreatic secretion. Endocrinology derives from *endon* (“within”) + *krinein* (“separate”), a term contrived to describe those glands that store their products within their structure and secrete them to effect a response in separate tissues. The field of endocrinology is concerned with the study of endocrine glands and their secreted hormones.

Intercellular communication is achieved by either the nervous system (electrical and chemical signaling) or the endocrine system (chemical signaling; hormones). Nervous system regulation is rapid and short lived; regulation by hormones tends to be slower and sustained. The endocrine system maintains homeostasis throughout the body, regulating diverse systems including metabolism, respiration, circulation, excretion, and reproduction. It is this diversity of effects that makes endocrine disorders particularly challenging to recognize, diagnose, and treat because they can have protean manifestations.

Classic disorders of the endocrine system are caused by glandular hyperfunction or hypofunction resulting in states of hormone excess or deficiency (Table 57.1). Hypofunction can result from glandular destruction (e.g., tumor, infection, hemorrhage) or hormone biosynthetic problems. Hyperfunction usually results from a tumor or autoimmune stimulation. Selected disorders, along with diagnostic approaches are reviewed in this chapter. Resistance to hormones also plays a major role in disease, particularly in diabetes.

Diagnostically, if an endocrinologist suspects that a hormone is inappropriately low, he or she will try to stimulate it; if high, he or she will try to suppress it (Table 57.2). Failure to rise or fall normally indicates either failure of the gland or unregulated hyperfunction. It is often possible to measure the level of the upstream hormone to determine the location (central [pituitary] or peripheral) of the problem. By going through this process, we capitalize on the presence of feedback loops. Similarly, treatments for endocrine disorders aim to replace the hormone in deficiency states (e.g., hypothyroidism) or to interfere with production in excess states (e.g., prolactinoma).

### Pituitary Tumors

Pituitary tumors account for approximately 15% of all primary intracranial neoplasms. Proliferation of cells within the pituitary can cause hormonal excess syndromes or compress the pituitary, resulting in hormonal deficiency. Pituitary tumors can expand and interfere with local anatomic structures such as the optic chiasm and cavernous sinuses.

#### Prolactinoma

Prolactin-secreting tumors account for the majority of functional pituitary tumors. More than 90% are benign microadenomas (<1 cm) that do not increase in size.

#### Clinical Features

Hyperprolactinemia leads to galactorrhea in approximately 80% of affected women. High levels of prolactin interfere with the secretion of gonadotropin-releasing hormone from the hypothalamus, resulting in amenorrhea/oligomenorrhea and infertility in women and hypogonadism in men. Both men and women can develop osteoporosis if hyperprolactinemia is left chronically untreated. Macroprolactinomas (>1 cm) can enlarge by one-third or more during pregnancy.

#### Evaluation

Dopamine tonically inhibits prolactin release, so medications that interfere with dopamine are often associated with hyperprolactinemia. Phenothiazines, butyrophenones, metoclopramide, risperidone, monoamine oxidase inhibitors, tricyclic antidepressants, verapamil, and serotonin-reuptake inhibitors can all increase prolactin levels. Large pituitary tumors can compress the pituitary stalk and impair normal dopamine signaling, resulting in hyperprolactinemia. Chronic renal failure and severe primary hypothyroidism are also associated with hyperprolactinemia. MRI of the pituitary is recommended when a patient has elevated prolactin levels and other causes of hyperprolactinemia have been excluded.

#### Treatment

Indications for treatment included symptomatic galactorrhea, hypogonadism or infertility, and macroprolactinoma.

**TABLE 57.1 Selected Pathophysiologic Syndromes and Their Hormonal Associations**

Gland	Hormone	Structure	Hyperfunction (Diagnostic Strategy)	Hypofunction (Diagnostic Strategy)
Anterior pituitary lobe	Prolactin	Protein (198) <sup>a</sup>	Prolactinoma (prolactin levels high)	Prolactin deficiency-defective lactation (prolactin levels low)
	GH	Protein (191)	Acromegaly (IGF-1 levels, oral glucose tolerance test)	GH deficiency (Arg-GHRH stimulation test, or insulin tolerance test)
	ACTH	Peptide (39)	Cushing disease (high ACTH and salivary cortisol or 24-h urine free cortisol, failure to suppress on dex-supp test)	Central adrenal insufficiency (failure to respond to ACTH stimulation test, insulin tolerance test)
Posterior pituitary lobe	ADH, vasopressin	Peptide (9)	SIADH (hyponatremia, exclude other causes)	Diabetes insipidus (dehydration with water deprivation test)
Thyroid gland	Thyroxine (T <sub>4</sub> )	Tyrosine derivative	Hyperthyroidism (TSH low, uptake on scan high in Graves, low in thyroiditis) Thyroid nodule (TSH low, hot nodule on scan)	Hypothyroidism (TSH high)
	Calcitonin	Peptide (32)	Medullary carcinoma of the thyroid (aspirate, calcitonin level)	
Parathyroid glands	PTH	Protein (84)	Hyperparathyroidism (calcium high, PTH normal or high)	Hypoparathyroidism (calcium low, PTH normal or low)
Adrenal cortex	Glucocorticoids (e.g., cortisol)	Steroids	Cushing syndrome (morning cortisol high after overnight dex suppression test, ACTH low)	Addison disease (cortisol fails to rise after stimulation with high-dose ACTH)
	Mineralocorticoids (e.g., aldosterone)	Steroids	Conn syndrome/hyperaldosteronism (high aldosterone/renin ratio)	Hypoaldosteronism (high renin, low aldosterone)
Adrenal medulla	Adrenaline/noradrenaline (epinephrine)	Tyrosine derivative	Pheochromocytoma (plasma and 24-h urine metanephrines high)	
Testes/Adrenal	Testosterone	Steroid	Hirsutism or virilization (high androgens, DHEAS)	Male hypogonadism (LH high, testosterone low)
Pancreas (islets of Langerhans)	Insulin	Protein (51)	Insulinoma (insulin, C-peptide, endoscopic ultrasound) Type 2 diabetes (plasma glucose)	Type 1 diabetes (plasma glucose)
Kidney	Erythropoietin	Protein	Paraneoplastic syndrome (Hct high)	Anemia (Hct low)
	Calcitriol	Steroid derivative		Hypovitaminosis D, secondary hyperparathyroidism (high PTH, low calcium)

<sup>a</sup>Numbers in parentheses indicate the number of amino acids in the protein or peptide(s).

ACTH, Adrenocorticotropic hormone; ADH, antidiuretic hormone; DHEAS, dehydroepiandrosterones; GH, growth hormone; GHRH, growth hormone-releasing hormone; Hct, hematocrit; IGF-1, insulin-like growth factor 1; LH, luteinizing hormone; PTH, parathyroid hormone; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TSH, thyroid stimulating hormone.

Both cabergoline (which is typically given twice weekly) and bromocriptine (given twice daily) are effective in decreasing prolactin levels and reducing tumor size in >80% of patients. The goal of treatment is symptomatic relief in patients with galactorrhea, restoration of eugonadism or

fertility, and reduction of macroprolactinoma tumor size. Both microprolactinomas and macroprolactinomas can be managed medically; surgery is only rarely required. Treatment is continued for at least 2 years in patients with microadenomas and may be given indefinitely in patients with

**TABLE 57.2** Cause, Diagnosis, and Treatment of Hypofunction and Hyperfunction

	Suspect Hypofunction	Suspect Hyperfunction
Cause	Gland destruction defective biosynthesis	Tumor/hyperplasia autoimmune stimulation
Diagnose	Try to stimulate production	Try to suppress production
Treat	Replace the hormone	Interfere with the production of the hormone, or remove the gland

macroadenomas. Bromocriptine is preferred over cabergoline in women considering pregnancy. Macroadenomas that do not shrink with dopamine agonist may be debulked surgically before pregnancy is attempted. Some women with macroprolactinomas may require bromocriptine throughout their pregnancy.

### Acromegaly

Acromegaly is rare and develops when somatotropes proliferate and oversecrete growth hormone. These tumors tend to grow slowly and insidiously and are rarely associated with plurihormonal polysecretion (such as coproduction of prolactin and growth hormone). Most of these tumors are >1 cm (macroadenomas) at the time of presentation.

#### Clinical Features

The features of acromegaly are diverse and are generally related to somatic growth (acral enlargement, malocclusion, carpal tunnel syndrome), tissue enlargement (macroglossia, prostatic hypertrophy, left ventricular hypertrophy, sleep apnea, goiter), and metabolic interference (diabetes mellitus, hypertriglyceridemia, hypogonadism).

#### Evaluation

The biochemical diagnosis of acromegaly is made by confirming autonomous secretion of growth hormone during a 2-hour 75-g oral glucose tolerance test. Nadir growth hormone levels in excess of 1 µg/L are consistent with the diagnosis, especially if the patient also has an elevated level of insulin-like growth factor-1 (IGF-1).

#### Treatment

Neurosurgical resection is the treatment of choice for most resectable pituitary tumors associated with acromegaly. Complications such as hypopituitarism and recurrence risk correlate with the size of the tumor. Medical treatments for acromegaly include somatostatin receptor ligands (octreotide, lanreotide, and pasireotide), which suppress pituitary

release of growth hormone; dopamine antagonists (cabergoline is minimally effective); and use of a growth hormone receptor antagonist (pegvisomant). Radiotherapy is used for unresponsive tumors, but it is associated with high risk of panhypopituitarism. Levels of IGF-1 are used to monitor treatment efficacy.

## Other Pituitary Disorders

### Diabetes Insipidus

Central diabetes insipidus is a heterogeneous condition characterized by polyuria and polydipsia resulting from a deficiency of arginine vasopressin. In many patients, it is caused by the destruction or degeneration of the neurons that originate in the supraoptic and paraventricular nuclei of the hypothalamus. The three main causes of diabetes insipidus (trauma/surgery, tumors, and idiopathic) account for approximately equal fractions of cases.

#### Clinical Features

Diminished or absent arginine vasopressin causes polyuria or polydipsia by diminishing the patient's ability to concentrate urine. These patients generally have severe nocturia and consume 3 to 20 L of liquid daily. Nephrogenic diabetes insipidus is characterized by a decrease in the ability to concentrate urine because of a resistance to arginine vasopressin action in the kidney.

#### Evaluation

Diabetes insipidus is diagnosed when urine is inappropriately dilute (urine specific gravity of <1.005 and a urine osmolality <200 mOsm/kg) in a patient with a high serum osmolality (generally >290 mOsm/kg). Because many patients can maintain a normal osmolality with access to water, a water-deprivation test is often necessary to document the abnormality and exclude primary polydipsia. A vasopressin analogue can be given to patients at the end of a water deprivation test to exclude nephrogenic diabetes insipidus. Patients with central diabetes insipidus should undergo pituitary imaging with an MRI.

#### Treatment

Diabetes insipidus is treated with vasopressin analogues, administered subcutaneously, nasally, or orally, coupled with ready access to water.

### Lymphocytic Hypophysitis

Lymphocytic hypophysitis is an uncommon autoimmune disease in which the pituitary gland is infiltrated by lymphocytes, plasma cells, and macrophages, usually causing impaired function. Lymphocytic hypophysitis is mainly associated with late pregnancy or the postpartum period, although it can occur in nonpregnant women (some of whom may be postmenopausal) and in men. This disorder may have an autoimmune origin, and it is associated with

other autoimmune disorders, especially autoimmune thyroiditis. Tests for antinuclear antibodies and rheumatoid factor are often positive, and the erythrocyte sedimentation rate may be elevated. Headache, visual field impairment, and, more rarely, diplopia are caused by extrasellar pituitary enlargement with optic chiasma compression and/or invasion of cavernous sinuses. Deficiency of adrenocorticotropic hormone (ACTH) (resulting in secondary hypoadrenalism) is the earliest and most frequent endocrine manifestation. MRI usually demonstrates extrasellar symmetric pituitary enlargement and loss of the posterior pituitary bright spot. Treatment is symptomatic, with compressive effects reduced through treatment with corticosteroids (20–60 mg/d of prednisone) and/or surgical decompression. The prognosis for hormonal recovery is poor.

## Hypothyroidism

### Presentation of Hypothyroidism

Hypothyroidism affects about 2% of adult women and about 0.2% of adult men; subclinical hypothyroidism is substantially more common. *Primary hypothyroidism* refers to intrinsic thyroid failure and accounts for 99% of cases; *secondary hypothyroidism* refers to hypothyroidism resulting from pituitary dysfunction. The most common cause of primary hypothyroidism in iodine-sufficient areas is chronic autoimmune (Hashimoto) thyroiditis. It is most common among older women and is generally permanent. Thyroidectomy, radioiodine treatment, and external radiation therapy are other frequent causes of hypothyroidism. Both iodine deficiency and excess can cause hypothyroidism. Iodine deficiency is a type of hypothyroidism associated with goiter. It is the most common cause of hypothyroidism worldwide but is quite uncommon in the United States where iodine is added to salt. Acute administration of iodine suppresses thyroxine synthesis (Wolff-Chaikoff effect); however, patients recover their thyroid function after just a few days of treatment. Other drugs that cause hypothyroidism include antithyroid drugs (e.g., methimazole, propylthiouracil), amiodarone, lithium, and interferon- $\alpha$ .

Hypothyroidism can be transient when related to thyroiditis. Inflammation of the thyroid gland can be painful or entirely painless. Hypothyroidism occurring postpartum is one of the most common presentations of thyroiditis. Although the transient hypothyroidism resolves in a significant majority within 3 months, it can last up to 6 months.

### Clinical Features

Patients with hypothyroidism can present with a variety of nonspecific symptoms. Some of the most common features include dry skin, cold intolerance, weight gain, constipation, menorrhagia, and fatigue. The clinical picture of hypothyroidism is now a good deal milder since screening became more common. The most common signs in patients with moderate to severe hypothyroidism include bradycardia,

delayed relaxation phase of deep tendon reflexes, periorbital puffiness, and coarse hair. *Myxedema* refers to the appearance of the skin and subcutaneous tissues in a patient who is severely hypothyroid.

### Evaluation

Patients with primary thyroid failure will have an elevated thyroid-stimulating hormone (TSH) level and low thyroxine concentration. Central hypothyroidism should be suspected if the TSH is normal or low and the thyroxine level is low.

### Treatment

Patients with an elevated TSH level should be treated with replacement thyroxine, with a target TSH of between 1 and 2. Levothyroxine has a long half-life, and once-daily treatment results in a nearly constant serum thyroxine level. As a result of variations in the thyroxine content of individual formulations, reassessment of the adequacy of replacement is indicated if the formulation is changed. The mean replacement dose of thyroxine is 1.6  $\mu\text{g}/\text{kg}$  (generally 75–112  $\mu\text{g}/\text{d}$  in women and 125–200  $\mu\text{g}/\text{d}$  in men). A lower dose (such as 50  $\mu\text{g}$  daily) should be initiated in the elderly and titrated upward as needed. Obese patients require doses that are approximately 20% higher. Drugs that interfere with the absorption of levothyroxine include cholestyramine, calcium carbonate, and ferrous sulfate. Patients receiving estrogen replacement also require a higher dose of levothyroxine because of increased levels of thyroxine binding globulin.

Combination replacement of liothyronine and levothyroxine is requested by some patients, but it is not supported by the balance of clinical trial data. If instituted, 25  $\mu\text{g}$  of levothyroxine can be replaced with 5  $\mu\text{g}$  of liothyronine. Desiccated thyroid, liothyronine alone, and other thyroid preparations are not recommended.

Transient hypothyroidism can be difficult to distinguish from Hashimoto thyroiditis. It is reasonable to attempt to reduce the dose of levothyroxine by 50% after approximately 3 months in patients who are suspected to have had transient hypothyroidism. If the TSH measured 6 weeks later rises, then the initial dose is reinstated; if the TSH is stable, then thyroxine can be withdrawn, and the TSH checked again.

Patients with an elevated TSH and a normal thyroxine level are most likely to have subclinical hypothyroidism. Testing for the presence of thyroid peroxidase antibody can be helpful in such patients because it predicts the progression to permanent hypothyroidism. These patients should be monitored for the development of more severe hypothyroidism, or levothyroxine can be initiated at the outset.

Patients with central hypothyroidism should have their thyroxine dose titrated to the level of free thyroxine.

### Hypothyroidism During Pregnancy

Levothyroxine requirements increase as early as the fifth week of gestation. Given the importance of maternal euthyroidism

for normal fetal cognitive development, women with hypothyroidism should have their levothyroxine dose increased by approximately 30% as soon as pregnancy is confirmed. Thereafter serum thyrotropin levels should be monitored and the levothyroxine dose adjusted accordingly. The goal of thyroxine replacement is to maintain the TSH in the trimester-specific reference range (below 2.5 mU/L in the first trimester and below 3 mU/L in the second and third trimesters) using measurements drawn every 4 to 6 weeks.

## Hyperthyroidism

Hyperthyroidism can be caused by an increased production of thyroid hormone (as in Graves disease or an autonomous nodule) or increased release of preformed thyroid hormone (as in thyroiditis). Hyperthyroidism can also be caused by overreplacement with exogenous thyroid hormone, ectopic hyperthyroidism, or unregulated stimulation of the TSH receptor (as in trophoblastic disease or a TSH-secreting pituitary adenoma).

### Clinical Features

The presentation of hyperthyroidism can be highly variable, especially in older people. Characteristic symptoms include anxiety, tremor, palpitations, heat intolerance, insomnia, oligomenorrhea, and weight loss despite an increased appetite. Typical signs include tachycardia, systolic hypertension, tremor, lid retraction, lid lag, warm skin, and hyperreflexia. The presence of a goiter will depend on the cause of the hyperthyroidism. A single palpable nodule or multiple nodules may indicate an autonomous thyroid adenoma or a multinodular goiter as the source, respectively; a painful tender thyroid gland suggests granulomatous thyroiditis. Signs that are suggestive of Graves disease include goiter, thyroid bruit, exophthalmos, periorbital edema, and pretibial myxedema.

### Evaluation

The diagnosis of hyperthyroidism is confirmed using biochemical testing of the thyroxine and TSH levels. An increased thyroxine level with a suppressed TSH characterizes overt hyperthyroidism. Patients with subclinical hyperthyroidism may have a normal thyroxine level and a suppressed TSH. Occasional patients demonstrate triiodothyronine toxicosis with a normal thyroxine level and an elevated level of triiodothyronine. Activating autoantibody titers directed against the thyrotropin receptor are present in Graves disease. TSH-induced hyperthyroidism and thyroid hormone resistance, each characterized by elevated total and free thyroxine levels and an inappropriately increased level of TSH, are very rare. An elevated total thyroxine level with a normal free thyroxine and TSH level is usually attributed to abnormalities in thyroid binding proteins in patients who are clinically euthyroid.

When the etiology of the hyperthyroidism is unclear, a thyroid radioiodine uptake study can be performed. Graves disease is characterized by a high uptake, whereas thyroiditis is associated with a low uptake.

### Treatment

Methimazole is the preferred antithyroid drug in the United States. Use of propylthiouracil is limited to pregnant women. These agents are actively concentrated by the thyroid gland, and their primary effect is to inhibit thyroid hormone synthesis by interfering with thyroid peroxidase-mediated iodination of tyrosine residues in thyroglobulin, a critical step in the synthesis of thyroxine and triiodothyronine. Propylthiouracil also blocks the conversion of thyroxine to triiodothyronine within the thyroid and peripheral tissues, although the clinical importance of this function is uncertain. No dose adjustment is needed in patients with renal or liver failure, among children, or the elderly.

The usual starting dose of methimazole is 20 mg/d as a single daily dose, and the usual starting dose of propylthiouracil is 100 mg given three times a day. Following initial dosing, follow-up testing of thyroid function is suggested approximately every 6 weeks until the thyroid function tests normalize. Many patients can ultimately be controlled at a low dose. Testing frequency can be reduced to every 6 months over time. Following a discussion about the risk of relapse, antithyroid drugs can be withdrawn after 12 to 18 months to determine if ongoing treatment is required.

Cutaneous reactions to antithyroid drugs are quite common and usually mild. The drug should be discontinued in patients complaining of arthralgias because this may be a presentation of a transient migratory polyarthritis associated with antithyroid drug use. The most feared side effects of antithyroid drugs are agranulocytosis (especially with methimazole, seen in 1 of every 270 treated patients) and liver failure (especially with propylthiouracil). The drug should be discontinued if the granulocyte count is  $<1000/\text{mm}^3$ .

Current treatments for Graves disease include antithyroid drugs, radioiodine, and surgery. Initial treatment usually includes an antithyroid drug such as methimazole 20 mg taken once daily. Beta-blockers may provide symptomatic relief. For patients with more severe hyperthyroidism, iodine treatment can provide rapid relief of symptoms by preventing thyroxine release from the thyroid. A typical approach would be to prescribe three drops of saturated solution of potassium iodide three times daily for up to 10 days. Radioiodine can be given as primary treatment for patients with Graves hyperthyroidism, although many clinicians will wait until the first relapse before offering this approach. Hyperthyroidism can be exacerbated for a short time by radioiodine treatment. In patients with cardiac disease or in the elderly in whom such an exacerbation would be risky, pretreatment with antithyroid drugs can be useful. Surgery is usually reserved for patients with an obstructing goiter.

Hyperthyroidism associated with toxic thyroid adenomas can be treated with antithyroid drugs and a beta-blocker. These autonomous nodules do not resolve spontaneously; therefore more definitive treatment is usually indicated after the initial symptoms have been controlled. Radioiodine is preferred over surgery for most patients (because it tends to target only the overactive tissue, resulting in low long-term

risk of hypothyroidism), but this is less likely to be effective in patients with large or multiple nodules.

### Hyperthyroidism During Pregnancy

Women who develop hyperthyroidism while pregnant are at increased risk of spontaneous abortion, premature labor, stillbirth, and preeclampsia. Changes in thyroid hormone-binding globulin (usually doubles), levels of human chorionic gonadotropin (that can mimic the actions of TSH), and endogenous physiology (altered TSH responsiveness) can complicate the biochemical assessment of thyroid function in pregnancy. Because radioiodine is absolutely contraindicated during pregnancy, antithyroid drugs are the preferred treatment for pregnant women with hyperthyroidism. The doses should be minimized to prevent fetal hypothyroidism because both propylthiouracil and methimazole can cross the placenta. Methimazole may be associated with congenital anomalies including aplasia cutis and choanal or esophageal atresia. Propylthiouracil has been associated with severe liver failure. In general, treatment is given to a point where mild hyperthyroidism is allowed to persist. Low thyroid function at birth is found in approximately half of neonates whose mothers received an antithyroid drug; ultimate intelligence appears to be normal. Both methimazole and propylthiouracil are approved for nursing mothers by the American Academy of Pediatrics, although they do appear in breast milk in minute quantities. Because of the potential for propylthiouracil-associated hepatotoxicity, methimazole may be preferred for nursing mothers.

## Thyroid Nodules

In the United States, between 1% and 5% of the adult population have a palpable thyroid nodule, but between 20% and 70% have nodules detectable on ultrasound. Approximately 5% to 15% of these are malignant, but generally, microcarcinomas <1 cm are not likely to be clinically significant. Other causes of nodules include thyroid cyst, a colloid nodule, a focal area of thyroiditis, and benign follicular neoplasms. Nodules can be solitary or multiple. The risk of cancer is not lower when nodules are multiple.

### Evaluation

The history can provide useful prognostic information. Rapid growth, or the presence of a family history of thyroid carcinoma, or multiple endocrine neoplasia (MEN) increases the risk that a nodule is cancerous. Risk increases more moderately if age is <30 years or >60 years, if the patient is male, if there is a history of head and neck irradiation, if the nodule is >4 cm or has increased uptake on positron emission tomography (PET) scan, or if there are local symptoms such as dysphagia, hoarseness, or cough. High-risk signs include a hard nodule, the presence of regional lymphadenopathy, or hoarseness.

A suppressed TSH level suggests a benign hyperfunctioning nodule. Radionuclide scanning uses  $^{123}\text{I}$ iodine,  $^{131}\text{I}$ iodine, or  $^{99\text{m}}\text{Tc}$ technetium-pertechnetate to detect whether

or not a nodule is functioning. A scan cannot accurately determine the size of a thyroid nodule. Hyperfunctioning nodules are so rarely malignant that if the TSH is suppressed, fine-needle aspiration (FNA) can be deferred.

A normal or high TSH level does not obviate the need for further investigation. Ultrasonography can be performed in the office and increases the sensitivity and specificity of the FNA result. Ultrasonography can detect high-risk features such as solid composition, hypoechogenicity, microcalcifications, irregular margins, shape taller than wide, and evidence of local lymphadenopathy.

FNA is recommended for nodules  $\geq 1$  cm and any of the high-risk sonographic features. If none of these features is present, FNA is recommended for nodules  $\geq 1.5$  cm in size. Biopsy is not necessary for purely cystic nodules. Patients undergoing FNA do not typically need to stop aspirin or anticoagulants. The procedure is safe and well tolerated.

Cystic nodules can be drained after any solid portion has been aspirated, although most recur; use of sclerosants such as ethanol and tetracycline has been disappointing.

### Treatment

Benign nodules can remain in situ. Repeat ultrasonography is suggested after 12 to 24 months to evaluate for significant growth or development of new suspicious sonographic features. Levothyroxine suppression is rarely recommended because the potential for harm (bone loss and atrial fibrillation) outweighs the modest benefit in growth suppression.

Nodules with indeterminate cytology or follicular neoplasm that are cold on thyroid scintigraphy may be benign or malignant. Molecular testing can be considered to guide surgical options. Malignant nodules should generally be excised. The extent of surgery and need for postoperative thyroid ablation with  $^{131}\text{I}$ iodine will depend on multiple clinical factors. Disease recurrence following thyroidectomy can be screened for using thyroglobulin measurements.

Nondiagnostic aspirates occur about 10% of the time. If a second sample is again nondiagnostic, then referral for surgical excision is appropriate.

## Thyroid Cancer

Papillary and follicular thyroid cancers account for approximately 80% and 10% of all cancers in the thyroid gland, respectively. Metastases, lymphomas, and medullary and anaplastic cancers make up the balance of cases. The 10-year survivals are very different for these tumors, ranging from 98% for papillary, 92% for follicular, and <10% for anaplastic carcinoma.

### Clinical Features

Most tumors are detected incidentally, or a nodule is palpated. High-risk features of a nodule include rapid growth, a family history of thyroid carcinoma or multiple endocrine neoplasia, age <30 years or >60 years, male gender, and if there is a history of head and neck irradiation. Local symptoms such as dysphagia, hoarseness, or cough are worrisome.

## Evaluation

Thyroid cancers are almost always diagnosed by FNA. Differentiated cancers are staged according to the TNM classification to estimate mortality. In this classification, all patients aged <45 years are stage 1 unless they have distant metastases (stage 2). For older patients, stage depends on size, presence and laterality of lymph node involvement, and whether distant metastases have been detected. A different stratification system relying on clinicopathologic findings (histology, molecular markers, degree of invasion, residual disease, lymph node involvement) is used to estimate the risk of disease recurrence.

## Treatment

Total thyroidectomy is recommended for differentiated thyroid cancers  $\geq 4$  cm in size, with extrathyroidal extension, or with metastases to lymph nodes or distant sites. Unilateral lobectomy can be considered for smaller intrathyroidal tumors. Regional neck dissection is indicated if a preoperative neck ultrasound shows evidence of adenopathy. Following surgery, levothyroxine therapy is frequently required to prevent symptomatic hypothyroidism and reduce potential thyrotropin stimulation of tumor growth. The target thyrotropin level is generally below or in the bottom half of the normal range; lower targets are used for advanced disease. Radioiodine ablation is reserved for high-risk and some intermediate-risk patients after total thyroidectomy. Response to therapy is determined primarily by neck ultrasound and serum thyroglobulin measurements to identify residual disease. Adjuvant external-beam radiotherapy and some chemotherapy are occasionally used for refractory cases.

Anaplastic thyroid cancer is almost always fatal. The cancer is generally treated surgically. If unresectable, some of these tumors respond to doxorubicin and external beam radiotherapy for local control.

## Osteoporosis

Osteoporosis is a common problem ultimately afflicting half of all postmenopausal women and about a quarter of men. It is characterized by low bone mass and an increased risk of fracture. Fractures occur because of qualitative and quantitative deterioration in the trabecular and cortical skeleton. Bone quality cannot be measured clinically, but bone mineral density can be measured easily using bone densitometry.

### Clinical Features

Osteoporosis is asymptomatic until fracture occurs. Vertebral fracture is the most common, and the majority are asymptomatic. Hip fracture and radial fractures are common.

### Evaluation

Most fractures of the hip, wrist, and vertebral body with no occurrence of trauma are indicative of osteoporosis.

On densitometry, osteopenia is defined as bone mass that is between 1 and 2.5 standard deviations below the mean peak bone mass of control population, also known as the *T-score*. Osteoporosis is defined as a bone mass value >2.5 standard deviations below the peak bone mass of a control population. In general, the hip and spine are imaged. In postmenopausal white women, the relative risk of fracture is increased by a factor of 1.5 to 3 for each decrease of 1 in the T-score. Densitometry also provides the deviation of bone mass from age-matched controls and reports this as a Z-score. The Z-score determines whether any bone loss is substantially greater than expected for age. A basic evaluation with low bone density comprises a biochemical profile, liver enzymes, alkaline phosphatase, 25-hydroxyvitamin D, and a complete blood count. Patients with low Z-scores should have evaluation for secondary causes of bone loss such as hyperparathyroidism, hyperthyroidism, myeloma, and malabsorption. Markers of bone turnover (such as urinary N-terminal telopeptide or serum C-terminal telopeptide) can be useful in determining the need for treatment in equivocal cases.

### Treatment

An optimal initial strategy for patients with low bone mass includes supplemental calcium (1000–1200 mg elemental) and vitamin D (400–800 IU daily) when appropriate, weight-bearing physical activity (30 minutes at least three times per week), and smoking cessation counseling if needed. Patients with any of the following four criteria qualify for pharmacologic intervention: (1) history of hip or vertebral fracture; (2) osteoporosis by densitometry; (3) any fragility fracture and osteopenia by densitometry; (4) osteopenia by densitometry with a 10-year risk of a major osteoporotic fracture that is more than 20% or of hip fracture more than 3% (risk calculator at <http://www.shef.ac.uk/FRAX/>).

Bisphosphonates are the recommended first-line treatment for patients with osteoporosis. Alendronate (70 mg orally once weekly) and risedronate (35 mg once weekly or 150 mg once a month) are given orally. Zoledronate 5 mg is given intravenously once a year. All have been shown to reduce hip and spine fracture risk. Ibandronate (150 mg once monthly by mouth or 3 mg intravenously every 3 months) has more limited data regarding its efficacy.

Gastrointestinal adverse effects of oral bisphosphonates are rare if administration instructions are followed. Intravenous bisphosphonates lead to short-term flu-like symptoms. Hypocalcemia can complicate bisphosphonate treatment if vitamin D levels are not sufficient. Osteonecrosis of the jaw is a rare complication of bisphosphonate use, occurring once per 10,000 to 100,000 patient-years. Although most cases have been in cancer patients or in patients with cancers treated with intravenous bisphosphonates, rare cases have been noted in patients with postmenopausal osteoporosis taking oral bisphosphonates.

Synthetic parathyroid hormone (PTH: teriparatide) is available for daily subcutaneous use and increases bone mineral density and reduces fracture risk. It is generally

reserved for patients with severe osteoporosis; treatment is limited to 24 months. Denosumab is an injectable medication used to manage patients who cannot tolerate or be treated with bisphosphonates or who have severe osteoporosis or renal dysfunction. Monitoring densitometry should generally be performed no more frequently than every 2 years.

## Hypercalcemia

### Clinical Features

Patients with mild hypercalcemia (10.5–12 mg/dL) are often asymptomatic. Patients with more severe hypercalcemia can present with nonspecific symptoms that include nausea, anorexia, constipation, abdominal pain, bone pain, fatigue, polydipsia, and confusion. Calcium levels higher than 14 mg/dL are dangerous and can be lethal. Signs of hypercalcemia include dysrhythmias, hypertension, and a shortened QT-interval on an electrocardiogram.

### Evaluation

The two most common causes of hypercalcemia are primary hyperparathyroidism and neoplastic disease, accounting for more than 90% of cases, and these can be discriminated based on the serum PTH level. Primary hyperparathyroidism has a relatively benign course. Osteoporosis and renal impairment are two important long-term consequences that drive early intervention. Parathyroidectomy is recommended for patients with an elevated PTH and hypercalcemia who are aged <50 years or if the calcium is >11.5 mg/dL. Additional indications for surgery include the presence of renal stones, evidence of renal insufficiency, vertebral fractures on imaging studies, a T-score on bone densitometry of <-2.5, and hypercalciuria with urine biochemical analysis suggesting high risk of kidney stones. A preoperative parathyroid sestamibi scan or ultrasound can assist the endocrine surgeon and limit the extent of surgery. Intraoperative PTH levels allow the surgeon to be confident of the procedure's success before surgical closure. The calcimimetic, cinacalcet, can be used to lower calcium levels in hypercalcemic patients who cannot undergo surgery. Bisphosphonates are an option for patients who cannot undergo surgery but have evidence of bone loss.

Chronic renal failure generally increases phosphate levels and decreases the activation of vitamin D. If untreated, prolonged high phosphate and low vitamin D levels can lead to increased PTH secretion and subsequent hypercalcemia. This is termed *tertiary hyperparathyroidism* and can be managed surgically or medically.

Hypercalcemia of malignancy is usually symptomatic and can be severe. Solid tumors induce hypercalcemia by releasing PTH-related protein, which mimics the action of endogenous PTH. Bone destruction by metastatic disease or myeloma can also induce hypercalcemia, often in association with an elevated alkaline phosphatase level.

Vitamin D can induce hypercalcemia if taken in overdose or if there is excessive action of the 1-alpha hydroxylase

that creates the active form of vitamin D. This enzyme is hyperactive in patients with granulomatous disease such as sarcoidosis and responds well to treatment with glucocorticoids while the underlying disease is being treated. Consumption of large amounts of calcium or vitamin A can rarely lead to hypercalcemia.

Familial hypocalciuric hypercalcemia is an autosomal dominant condition caused by a mutation in the gene for the calcium-sensing receptor. Patients have an innocuous course characterized by mild-to-moderate hypercalcemia, normal or slightly elevated PTH levels, and low urinary calcium excretion. These patients do not benefit from parathyroidectomy.

### Treatment

Treatment of severe hypercalcemia includes emergent fluid repletion with saline and intravenous administration of bisphosphonates. Initially saline is given at 200 to 300 mL per hour and adjusted to maintain the urine output to 100 to 150 mL per hour. A loop diuretic can be added but is not always necessary and can lead to hypokalemia and hypomagnesemia. In the United States, pamidronate and zoledronate are bisphosphonates licensed for use in this indication. Zoledronate is preferred because it can be given over a shorter time (15 minutes as compared with 2 hours for pamidronate) and is more potent. Hypocalcemia can occur in patients treated with intravenous bisphosphonates for hypercalcemia of malignancy, although symptomatic hypocalcemia is rare. Calcitonin is characterized by good tolerability but poor efficacy in normalizing the serum calcium level. However, a major advantage of calcitonin is the acute onset of the hypocalcemic effect (reduction of 1–2 mg/dL within 6 hours), which contrasts with the delayed (approximately 2–4 days) but more pronounced effect of bisphosphonates. It is administered intramuscularly or subcutaneously every 12 hours at a dose of 4 IU/kg (nasal calcitonin is not effective for this purpose). Denosumab may be considered in patients with renal failure.

## Hypoparathyroidism

Hypocalcemia results from inadequate PTH, an insufficient supply of vitamin D, abnormal magnesium levels, or during metabolic circumstances such as sepsis or pancreatitis. Hypoparathyroidism is diagnosed when the PTH level is inappropriately low in a patient with hypocalcemia and a normal magnesium level.

### Clinical Features

Neuromuscular symptoms such as muscle cramping, circumoral numbness and tingling, and muscle twitching are the most typical presenting features of hypocalcemia. As calcium levels drop further, seizures, heart failure, bronchospasm, and laryngospasm can occur. Chronic hypocalcemia can lead to cataracts and, basal ganglial calcification and has been associated with pseudotumor cerebri.

Hypoparathyroidism typically results from surgical intervention in the neck and occurs in up to 5% of total thyroidectomy surgeries. Parathyroid sufficiency generally requires a single remaining parathyroid gland. Parathyroid failure may also occur if the parathyroids accumulate iron (e.g., hemochromatosis) or copper (Wilson disease). Autoimmune destruction of the parathyroid glands is generally associated with the autoimmune polyendocrine syndrome type 1 (which incorporates at least two of the triad of Addison disease, hypoparathyroidism, and chronic mucocutaneous candidiasis). Early-onset hypoparathyroidism accompanying immunodeficiency characterizes the DiGeorge syndrome or activating mutations of the calcium-sensing receptor gene. Magnesium is essential for PTH secretion, and both hypermagnesemia and hypomagnesemia can lead to hypocalcemia.

### Evaluation

The corrected total calcium should be calculated (measured total calcium in mg/dL + 0.8 [4 – serum albumin in g/dL]) or ionized calcium measured. The laboratory evaluation should include measures of intact PTH, 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D, phosphate, and magnesium.

### Treatment

Patients with severe symptoms of hypocalcemia should be treated with intravenous calcium gluconate. Long-term management requires patients to receive calcium salts and a vitamin D metabolite such as calcitriol. Each is titrated to obtain normal levels. Thiazides can be used to reduce hypercalciuria and prevent nephrolithiasis, particularly if the 24-hour urinary calcium level exceeds 250 mg. PTH repletion recently gained limited approval for the treatment of hypoparathyroidism.

## Adrenal Failure

*Addison disease* refers to chronic adrenocortical insufficiency caused by dysfunction of the entire adrenal cortex (incorporating glucocorticoid, mineralocorticoid, and sex steroid deficiency). Acute adrenal failure can also result from surgery, hemorrhage, tumor invasion, antifungal medications, acquired immunodeficiency syndrome, or infections affecting both adrenal glands. Adrenal failure becomes symptomatic when approximately 90% of adrenal function has been lost.

### Clinical Features

Patients in acute adrenal crisis present with nausea, vomiting, and hypotension. Abdominal or flank pain and fever may be present. Chronic adrenal failure presents insidiously with weakness, fatigue, arthralgia, anorexia, nausea, and weight loss. Examination may reveal both hyperpigmentation (resulting from the stimulant effect of adrenocorticotropin on melanocytes), and vitiligo (autoimmune destruction of melanocytes). Other examination features

include decreased body hair owing to loss of adrenal androgens, a feature that is especially apparent in women.

### Evaluation

Patients with acute adrenal failure will generally be hypotensive and may have hyponatremia. Hyperkalemia is an indicator of mineralocorticoid deficiency. Eosinophilia and hypoglycemia may accompany adrenal crisis.

An adrenocorticotropin-stimulation test generally comprises measurement of cortisol at baseline, intravenous injection of 250 µg of adrenocorticotropin, with cortisol levels drawn at 60 minutes. The cortisol level should rise to more than 18 µg/dL to establish normal glucocorticoid function. A very low morning cortisol level can also be suggestive of adrenal insufficiency. Corticotropin measurement helps differentiate between peripheral and central etiologies. Concurrent aldosterone and renin measurements can determine the presence of mineralocorticoid deficiency. Thyrotropin and thyroxine levels should be measured. Adrenal autoantibodies can be helpful to establish risk of other autoimmune conditions.

### Treatment

Acute treatment comprises 50 to 100 mg of hydrocortisone administered intravenously. Clinical improvement should follow within 6 hours. Glucocorticoid repletion generally comprises hydrocortisone 15 to 25 mg daily in two to three divided doses, titrated to symptoms. Mineralocorticoid repletion should be initiated with fludrocortisone for patients with primary adrenal insufficiency. Doses are generally 0.05 to 0.2 mg/d titrated to blood pressure, potassium, and morning plasma renin activity. Patients should be provided with injectable glucocorticoids for emergency use such as during vomiting, diarrhea, and trauma; they should also wear an emergency identification bracelet or necklace.

## Adrenal Nodules and Tumors

Adrenal masses are detected in approximately 5% of all abdominal imaging scans and autopsies. When evaluating adrenal masses, the clinician should consider whether the mass is malignant and whether it is hormonally active. The adrenal cortex can produce a variety of hormones and syndromes including cortisol (Cushing syndrome), aldosterone (Conn syndrome), androgens (virilization), and estrogens (feminization); the adrenal medulla generates catecholamines (pheochromocytoma).

### Evaluation

Imaging features can help to determine the malignancy risk. High-risk features include irregular shape, diameter >4 cm, high CT attenuation value (>10 Hounsfield units [HU]), and inhomogeneous enhancement with slow washout after intravenous contrast. Metastatic disease from another source tends to cause bilateral disease and have a similar attenuation as the liver on T1 imaging and a high T2-signal intensity. Benign nodules (that may be functional) tend to

be round, homogeneous, and smaller (<4 cm) with low CT attenuation (<10 HU), fast washout of intravenous contrast, and isointense with the liver on T1- and T2-weighted MRI imaging. Adrenal cysts, myelolipoma, and adrenal hemorrhage are usually readily distinguishable by their unique imaging characteristics.

### Clinical Features

Pheochromocytoma can be suggested by the presence of hypertension (can be chronic or paroxysmal), a history of “spells,” headache, palpitations, or pallor. Even in the absence of any symptoms, pheochromocytoma should always be excluded before proceeding to surgery because intraoperative risks of an unrecognized pheochromocytoma are high. Serum metanephrines are highly sensitive but not as specific. Two consecutive 24-hour urinary collections for total metanephrines and catecholamines provide confirmatory evidence.

Primary aldosteronism is suggested by refractory hypertension and occasionally hypokalemia. An aldosterone to renin ratio of >30 is suggestive. To obtain an interpretable result, patients must not be taking aldosterone receptor antagonists (such as spironolactone, eplerenone). A suppressed renin in a patient taking an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker is highly suggestive of hyperaldosteronism.

Measures of androgens and estrogens are not routinely performed in the absence of suggestive symptoms or signs. Virilization is suggested by male-pattern baldness, deepening of the voice, and clitoromegaly in women. Feminization in men is suggested by gynecomastia, decreased libido, and loss of muscle strength.

### Primary Aldosteronism

Primary aldosteronism resulting from an adrenal adenoma is a reversible cause of hypertension; it accounts for at least 10% of causes of resistant hypertension. These tumors are usually <2 cm in size and are benign; most adenomas are unilateral.

### Clinical Features

Most patients are asymptomatic or have minimal symptoms. Headache may accompany severe hypertension. Polyuria, nocturia, and muscle cramps may accompany hypokalemia.

### Evaluation

Spontaneous hypokalemia with metabolic alkalosis and a serum sodium level at the high end of the normal range or hyponatremia is common. Plasma renin activity is suppressed in almost all patients with untreated primary aldosteronism, and plasma aldosterone levels are elevated. A plasma aldosterone to plasma renin ratio of >30 with a plasma aldosterone of >10 ng/dL usually indicates primary aldosteronism. Aldosterone concentrations are uninterpretable in a patient on spironolactone. Diuretics, ACE inhibitors, and angiotensin

receptor blockers can falsely elevate the plasma renin activity, leading to a lower aldosterone to plasma renin activity ratio; therefore the presence of suppressed plasma renin activity in a patient treated with a diuretic or, especially, an ACE inhibitor or angiotensin receptor blocker, is a strong predictor for primary hyperaldosteronism. The most definitive test in diagnosing primary aldosteronism is a nonsuppressed 24-hour urinary aldosterone excretion rate during a salt load (of at least 1 teaspoon of salt daily for 3 days). Patients over the age of 40 generally require adrenal vein sampling to avoid resecting an innocuous cortical adenoma.

### Treatment

Patients with confirmed unilateral aldosterone-producing adenoma can proceed to unilateral adrenalectomy. Patients with bilateral adrenal hyperplasia, and patients who either refuse or are not surgical candidates, can be managed with spironolactone or eplerenone with a program of salt restriction and regular aerobic activity.

### Pheochromocytoma

Catecholamine-secreting tumors can result in a dramatic and life-threatening clinical syndrome. Most of these tumors arise from the adrenal medulla. Tumors arising outside of the adrenal gland are termed *paragangliomas*. These tumors are rare, accounting for fewer than 1 per 1000 cases of hypertension.

### Clinical Features

The classic triad includes episodic headache, palpitation, and diaphoresis. Spells may occur as infrequently as monthly or multiple times daily. Anxiety, nausea, tremor, chest and epigastric pain, and weight loss are other reported features. Patients with pheochromocytoma are typically hypertensive; approximately half of the patients will have episodic hypertension.

### Evaluation

Because pheochromocytomas and paragangliomas can occur in association with the multiple endocrine neoplasia type 2 syndrome, in neurofibromatosis 1, in von Hippel Lindau syndrome, and in patients with succinate dehydrogenase mutations, indications of these diagnoses should be sought.

Patients at low risk for pheochromocytoma can have the diagnosis excluded by measuring catecholamines and metanephrines in a 24-hour urine collection, a test with high specificity. High-risk patients can be screened with plasma metanephrines. Most patients with pheochromocytomas have urinary or plasma metanephrine levels that are at least three to four times the upper limit of normal. Tricyclic antidepressants, levodopa, labetalol, ethanol, sotalol, amphetamines, buspirone, benzodiazepines, methyl dopa, and chlorpromazine all increase catecholamines and should be avoided.

If the diagnosis is biochemically confirmed, imaging of the adrenals with MRI is recommended; these lesions are

usually at least 3 cm in size, and pheochromocytomas are uniquely hyperintense on T2-weighted images. Nuclear medicine scanning with  $^{123}\text{I}$ -metaiodobenzylguanidine or PET can be performed if MR/CT imaging is equivocal.

### Treatment

Patients with pheochromocytoma should be managed by experienced hypertension specialists. Surgery is the treatment of choice and can be a high-risk procedure. Preoperative preparation generally combines alpha-blockade (such as phenoxybenzamine, titrated to postural hypotension) with calcium channel or beta-blockers as needed. Some clinicians recommend metyrosine, but there is limited experience with this inhibitor of catecholamine synthesis. Perioperative crises are managed with nitroprusside. Surgical resection is prudent for malignant pheochromocytomas, although long-term survival is poor.

## Cushing Syndrome

Chronically elevated glucocorticoid levels result in protean symptoms and signs that are common (such as obesity, hyperglycemia, and hypertension) and nonspecific (weakness, acne, edema, striae, headache, plethora). These features make the diagnosis of Cushing syndrome challenging. The hypercortisolemia of Cushing syndrome can originate in the adrenal or result from a pituitary adenoma or other tumors secreting ACTH.

### Clinical Features

The most common presenting feature is obesity of the face, neck, and abdomen that spares the extremities. Facial fat deposition can result in a rounded face, exacerbated by deposition of fat in the supraclavicular fat pads, which makes the neck appear shortened. These patients develop skin thinning, atrophy, and easy bruising. Striae typical of Cushing syndrome are typically purple in color, wide, and multiple, factors that help distinguish them from stretch marks associated with obesity. Women with Cushing disease may have signs of hyperandrogenism such as hirsutism. Proximal myopathy (usually described as difficulty rising from a seated position), psychiatric change (emotional lability, depression, and mild paranoia are common), and hypertension are often present at presentation. Other features associated with more long-standing or more severe hypercortisolemia include glucose intolerance, glaucoma, and osteopenia.

### Evaluation

The first step in evaluating whether a patient may have Cushing syndrome is to elucidate any history of exposure to corticosteroids, including potent inhaled, injected, or topical steroids, or medroxyprogesterone acetate (a progestin with intrinsic steroid activity). Factitious Cushing syndrome accounts for <1% of all cases and is suggested by erratic and inconsistent results. In such cases, synthetic glucocorticoids can be assayed directly in the urine.

To establish hypercortisolemia, at least two 24-hour urine samples for free cortisol (and creatinine) should be obtained. Patients whose levels are greater than three times higher than the upper reference range can be assumed to have Cushing syndrome. Patients with equivocal values should be retested after a few weeks or be evaluated with further testing according to the clinical suspicion.

An overnight dexamethasone suppression test is also used as a screening test to diagnose hypercortisolemia. In this test, an 8 AM serum cortisol level is drawn after a 1-mg dexamethasone dose at 11 PM to midnight. Most normal patients should suppress their endogenous cortisol level to <2  $\mu\text{g}/\text{dL}$ . A screening strategy that uses three consecutive late-evening salivary cortisols may ultimately replace these aforementioned tests. These can be performed by an ambulatory patient with minimal instruction. Reference ranges are laboratory specific.

Once the diagnosis of Cushing syndrome is secure, a source for the hypercortisolemia should be sought. Determining whether Cushing syndrome is ACTH dependent or adrenal in origin requires accurate measurement of ACTH levels. Cortisol secretion can be deemed to be ACTH independent if the ACTH is <5 pg/mL when the cortisol level is >15  $\mu\text{g}/\text{dL}$ . Under the same circumstances, the syndrome is very likely to be ACTH-dependent if the ACTH level is >15 pg/mL when the cortisol is at least 15  $\mu\text{g}/\text{dL}$ ; ACTH levels of between 5 and 15 pg/mL are less specific but usually indicate ACTH dependency. Patients with equivocal values should be reinvestigated.

Patients with ACTH-independent hypercortisolemia should undergo thin-slice CT of the adrenal glands to identify the responsible adenoma, carcinoma, or nodules.

Patients with ACTH-dependent hypercortisolemia should undergo further testing to discriminate between Cushing disease related to a pituitary adenoma and that related to ectopic ACTH secretion. Tumors recognized to secrete ACTH include small cell cancer of the lung and bronchial and thymic carcinoids. Clinicians should resist the temptation to image the pituitary because 10% of the population have a structurally abnormal pituitary. Patients should instead undergo a high-dose dexamethasone-suppression test, with either 2 mg of dexamethasone given every 6 hours for 2 days or 8 mg of dexamethasone given between 11 PM and midnight, before morning cortisol measurement. This test capitalizes on the fact that ACTH-secreting pituitary adenomas retain some feedback responsiveness and often suppress their ACTH production when ambient glucocorticoid levels are high. Cortisol levels are reduced by >90% among 70% of those with Cushing disease. In the same study, by contradistinction, no patients with ectopically derived ACTH-suppressed cortisol below 90% in response to this high-dose suppression test.

Petrosal sinus sampling using corticotropin-releasing hormone (CRH) stimulation is a final approach to confirming that ACTH is derived from the pituitary. Criteria for confirming the pituitary as the source of the ACTH include

a ratio of ACTH between one side of the petrosal sinus and the peripheral plasma of  $>2$  or a ratio  $>3$  during infusion of CRH as compared with the level before infusion is begun. If one side has an ACTH level that is a multiple of 1.4 times or more the level on the opposite side, then the adenoma is highly likely to reside on that side. Patients with suspected ectopic ACTH should have an octreotide imaging performed with chest plain and tomographic images obtained as indicated.

### Treatment

The goal of treatment of Cushing syndrome is the eradication of any tumor, suppression of cortisol levels to as low as possible, and avoidance of permanent hormone dependency. The treatment of choice for Cushing disease is transphenoidal pituitary resection, irrespective of the size of the pituitary tumor. The more extensive the resection, the greater is the risk of permanent hypopituitarism. This may have particular implications for younger patients who have yet to start a family. Pituitary radiation can be provided to patients with unresectable or residual tumors, although this is associated with a high rate of hypopituitarism. Steroidogenesis inhibitors, glucocorticoid receptor antagonist, or pituitary-directed medical therapies are additional options for patients with persistent hypercortisolemia.

Adrenal tumors causing hypercortisolemia are best resected. Medical management of unresectable tumors or patients with metastatic hormonally active adrenal cancer is challenging because these malignancies are poorly responsive to adjuvant therapies. Patients may benefit from the use of mitotane, an adrenal poison. These patients must be given supplemental glucocorticoids in replacement doses to ensure they do not develop adrenal insufficiency during treatment. Patients with uncontrollable hypercortisolemia can benefit from adrenal steroid enzyme inhibitors such as ketoconazole or metyrapone. Experimental chemoradiotherapy or additional agents may be available as part of a clinical trial.

### Hirsutism

*Hirsutism* refers to the appearance of excessive terminal hair that appears in a male pattern in women. Approximately 5% of women are hirsute. Hirsutism results from an interaction between the androgen level and the sensitivity of the hair follicle to androgen; as a result, androgen levels do not correlate well with the degree of hirsutism. Approximately one-half of women with hirsutism have the idiopathic condition.

### Clinical Features

Clinical features that suggest one of the rare or more serious causes of hirsutism include abrupt onset, a presentation later in life, and progressive worsening. Symptoms and signs of virilization include frontal balding, acne, clitoromegaly, and deepening of the voice. Hair growth on the upper lip, chin, chest, abdomen, back, pubis, and legs should be assessed.

Hirsutism should be distinguished from hypertrichosis, the appearance of generalized excessive hair growth that is genetically determined or follows treatment with glucocorticoids, phenytoin, or cyclosporine.

### Evaluation

If hirsutism is moderate or severe, the plasma testosterone and free testosterone should be measured in the early morning (ideally on days 4–10 of the menstrual cycle in premenopausal women).

Hyperandrogenism is most frequently related to the polycystic ovary syndrome, one of the most common hormonal disorders affecting women. The syndrome is diagnosed when the patient has at least two of chronic hyperandrogenism, oligoovulation or anovulation, and polycystic ovaries, and other diagnoses are excluded. These patients often have menstrual irregularity, obesity, and evidence of insulin resistance (e.g., acanthosis nigricans). A pelvic ultrasound is not required for diagnosis. Additional testing may include a pregnancy test if the patient has amenorrhea. These patients should be evaluated for glucose intolerance and sleep apnea and often respond well to insulin sensitizers such as metformin or a thiazolidinedione. Spironolactone and oral contraceptives are frequently used to manage hirsutism in these patients.

Other causes of hyperandrogenism are unusual. Virilizing congenital adrenal hyperplasia is suggested by the premature growth of pubic hair and clitoromegaly and can be excluded by measuring the morning 17- $\alpha$ -hydroxyprogesterone level.

Cushing syndrome is suggested by the development of truncal obesity, moon face, buffalo hump, purple striae, or proximal muscle weakness (see [Chapter 51](#)). Hyperprolactinemia is suggested by the presence of galactorrhea and an elevated prolactin level. Acromegaly is suggested by the coarsening of facial features or by hand enlargement and confirmed by an elevated IGF-1 level.

Androgen-secreting tumors are very rare, but they should be considered among women with an acute presentation or who have very high levels of testosterone ( $>200$  ng/dL). Such women should be evaluated with a level of dehydroepiandrosterone sulfate and an abdominal and pelvic imaging.

Idiopathic hirsutism is the most common diagnosis after these other disorders have been excluded by clinical or laboratory features.

### Treatment

Hirsutism can be managed with cosmetic and hormonal therapy. It is useful to complete an objective assessment of the degree of hirsutism in advance of initiating treatment. The Ferriman-Gallwey score is one such scoring system.

Cosmetic approaches include bleaching, shaving, waxing, electrolysis, laser treatment, and the use of depilatory agents. Eflornithine hydrochloride cream can be used for facial hirsutism but must be used approximately 8 weeks before its efficacy can be determined.

Estrogen-progestin contraceptives reduce circulating androgen levels and can reduce the need for shaving and slow the progression of hirsutism. Contraceptives with non-androgenic progestins are preferred. Antiandrogens can be offered when hirsutism is moderate to severe. Spironolactone at high dose (50–100 mg twice a day) is effective in reducing hirsutism. Patients must be informed that spironolactone may be teratogenic and is generally not prescribed to women who are sexually active without concomitant use of an oral contraceptive. Hyperkalemia is rarely associated with spironolactone among women with normal renal function. Flutamide is an antiandrogen that is associated with hepatotoxicity and is not generally recommended for managing hirsutism. Cyproterone acetate is an antiandrogen that is available in Canada, Mexico, and Europe but not in the United States.

## Male Hypogonadism

Testosterone deficiency can result from disease of the testes or from pituitary or hypothalamic dysfunction. These causes can be distinguished by measuring the gonadotropins, luteinizing hormone, and follicle-stimulating hormone.

### Clinical Features

Intrauterine testosterone deficiency can result in micropenis and cryptorchidism, and, when it occurs before puberty, testosterone deficiency will result in incomplete maturation, a eunuchoid habitus, and reduced peak bone mass. When testosterone deficiency occurs after puberty, a decrease in libido and erectile function occurs, with loss of sexual hair, muscle mass, and bone mineral density. Gynecomastia can be present.

### Evaluation

Causes of low testosterone should be sought from the history, including indications of opiate use, sleep apnea, hemochromatosis, testicular trauma, orchitis, and obesity. The normal adult testis is approximately 3.5 to 5.5 cm in length or 15 to 30 mL in volume. Arm span should normally be no more than 5 cm longer than height. Breast enlargement, small testes, and behavioral abnormalities suggest Klinefelter syndrome. Anosmia suggests Kallmann syndrome.

Total testosterone and sex-hormone binding globulin concentrations should be measured in a morning sample with luteinizing hormone and follicle-stimulating hormone. Free testosterone measurements are generally unreliable. Semen analysis is appropriate if infertility is a primary concern.

### Treatment

Testosterone treatment should be reserved for men with clinical symptoms and signs of hypogonadism accompanied by a subnormal testosterone concentration who have a normal prostate specific antigen level. Testosterone esters can be given by intramuscular injection weekly or biweekly. Transdermal testosterone gels are available in sachets and a metered-dose pump and are administered daily after

showering; patients should be cautious about skin-to-skin transmission to a bed partner. Testosterone patches are available but cause local irritation. The dose is titrated to a morning total testosterone level, drawn before the next dose. Clinicians should monitor for symptoms of benign prostatic hypertrophy, sleep apnea, and acne, and monitor prostate specific antigen and hematocrit for erythrocytosis.

## Diabetes Mellitus

The prevalence of diabetes mellitus is increasing exponentially around the globe. The disease affects approximately 20 million Americans, with many more yet to be diagnosed. Type 2 diabetes accounts for approximately 95% of all cases and is characterized by insulin resistance and hyperglycemia. Hyperinsulinemia occurs early in the disease but is not maintained indefinitely. Many patients ultimately require insulin to maintain glucose in the normal range. Because almost 80% of all patients with diabetes will die from cardiovascular complications, cardiovascular risk reduction is the primary target.

### Clinical Features

Diabetes is diagnosed if there are symptoms of diabetes (polyuria, polydipsia, unexplained weight loss), and a random glucose of  $\geq 200$  mg/dL. A fasting glucose  $\geq 126$  mg/dL or a glucose of  $\geq 200$  mg/dL 2 hours after a 75-g glucose load is also diagnostic. A hemoglobin A1c (HbA<sub>1c</sub>) of at least 6.5% is also diagnostic. Screening every 3 years for diabetes is recommended for all patients who are overweight with risk factors and in everyone beginning at age 45.

Prediabetes is indicated by an HbA<sub>1c</sub> between 5.7% and 6.5%, impaired fasting glucose (fasting glucose 100–125 mg/dL), or impaired glucose tolerance (glucose 140–199 mg/dL 2 hours after a 75-g glucose load). The incidence of diabetes can be reduced by over 50% in patients with prediabetes if patients lose weight and embark on an exercise program comprising at least 30 minutes of exercise five times weekly. Metformin reduces the incidence of diabetes in these high-risk patients by approximately 25%.

### Evaluation

Secondary causes of diabetes should be considered when evaluating any patient with newly diagnosed hyperglycemia. Drugs that are associated with hyperglycemia such as glucocorticoids, antipsychotics, and some antiretrovirals should be reevaluated to determine if an alternative agent can be substituted safely. Genetic causes of diabetes should be excluded if a strong family history of diabetes is present or a typical phenotype (e.g., Down syndrome, Turner syndrome, or Klinefelter syndrome) is noted. Endocrinopathies such as Cushing syndrome, acromegaly, pheochromocytoma, hyperthyroidism, and others should be sought from the history and examination. Patients with diseases that affect the exocrine pancreas such as hemochromatosis, chronic pancreatitis, pancreatic malignancy, or cystic fibrosis are at high risk for diabetes; treatment of

the underlying disease is often critical to reduce the rate of progression to insulin deficiency and to manage the hyperglycemia.

### Treatment

Patients who are newly diagnosed with type 2 diabetes should be provided with a glucometer and testing instructions and referred for diabetes education and medical nutrition therapy. The optimal frequency of fingerstick glucose testing has not been determined. Smoking cessation and the benefits of exercise and weight loss should be emphasized. Targets of treatment are listed in [Table 57.3](#).

For patients with type 2 diabetes requiring treatment, metformin remains the first-line agent of choice. Patients should be warned that early gastrointestinal side effects are not uncommon and should be tolerated if possible; these usually abate within 2 weeks. Metformin use is associated with cardiovascular risk reduction but must be used cautiously in patients whose creatinine >1.5 mg/dL or among those who have severe chronic illnesses.

Sulfonylureas are generally recommended as second-line agents because of high efficacy and low cost. Short-acting sulfonylureas such as glipizide are preferred for their shorter half-life, especially among older patients. The related meglitinides are less potent and more costly.

More recent approaches to glycemic management include the use of glucagon-like peptide (GLP)-1 analogues and inhibitors of dipeptidyl-peptidase-4 (DPP-4). GLP-1 analogues such as exenatide, liraglutide, and dulaglutide

provide modest improvements in HbA<sub>1c</sub> and can contribute to weight loss in some patients; they are often used in the place of insulin in those who are close to their HbA<sub>1c</sub> goal and who may benefit from weight loss.

DPP-4 inhibitors such as sitagliptin, linagliptin, alogliptin, and saxagliptin appear to be safe and well tolerated, but their efficacy is limited to an HbA<sub>1c</sub> drop of <0.7 percentage points.

Sodium-glucose transport inhibitors, such as canagliflozin, dapagliflozin, and empagliflozin, increase glycosuria and appear to lower glucose and blood pressure in a glucose-dependent manner, reducing the risk of hypoglycemia. They are associated with an increase in minor pelvic infections.

Despite its association with lower blood pressure and the absence of hypoglycemia, the thiazolidinedione pioglitazone is rarely recommended because it causes fluid retention, weight gain, and premature bone loss.

For patients with type 2 diabetes who remain hyperglycemic despite two hypoglycemic agents, insulin is a suitable choice. A typical starting dose of insulin is 10 to 20 U. Insulin management should include a basal insulin (such as insulin glargine, detemir, or isophane [NPH]) initially titrated to a fasting glucose of approximately 100 mg/dL. If the HbA<sub>1c</sub> remains elevated, a short-acting insulin (such as insulin aspart, glulisine, or lispro) can be added incrementally, starting with a dose before the largest meal and then before other meals. The short-acting insulin dose can be titrated to a postprandial glucose level taken approximately 2 to 3 hours after a test meal. Patients in need of insulin treatment should be advised to check their glucose levels before driving.

Patients with type 1 diabetes require lifelong insulin treatment. Typically, basal insulin is used with ultrashort-acting insulins given before each meal or snack. Patients with type 1 diabetes can be taught to count carbohydrates and how to calculate both correction and prandial insulin dosing. These patients should work with a diabetes team and can benefit from the convenience of insulin-pump therapy, especially when combined with continuous glucose monitor. Blood pressure, lipid, and renal, eye, and foot care guidelines are similar to those for patients with type 2 diabetes.

### Preventing Complications

Blood pressure control is at least as important as glycemic control in reducing long-term cardiovascular disease incidence in patients with diabetes. Treatment with an ACE inhibitor or angiotensin-receptor blocker is typically used first line, with thiazide diuretics or calcium channel blockers added as necessary.

Urinary microalbumin levels should be assessed yearly. The presence of >30 mg of microalbumin per gram of creatinine is a risk factor for nephropathy and cardiovascular disease. Either ACE inhibitors or angiotensin receptor blockers should be started in patients with diabetes and microalbuminuria to decrease the risk of progressive renal disease.

**TABLE 57.3 Treatment Goals for Patients With Diabetes**

#### Targets for Patients With Diabetes

HbA <sub>1c</sub>	<7% <sup>a</sup>
Fasting glucose	80–130 mg/dL
Peak postprandial glucose	<180 mg/dL
Blood pressure	<140/90 mm Hg
Urine microalbumin	<30 mg/dL creatinine
Lipids	
ASCVD or age 40–75 with ASCVD risk factors	High-intensity statin
Age >75 or age <40 with ASCVD risk factors	Moderate-intensity or high-intensity statin
Age 40–75 without ASCVD risk factors	Moderate-intensity statin
Daily low-dose aspirin therapy (age ≥50 with additional risk factors)	
Annual foot examination	
Dilated eye examination by an ophthalmologist every 1–2 years.	

<sup>a</sup>More or less stringent targets may be appropriate for individual patients depending on age, duration of diabetes, presence of complications or comorbidities, risk of hypoglycemia, and so on.  
ASCVD, Atherosclerotic cardiovascular disease; HbA<sub>1c</sub>, hemoglobin A<sub>1c</sub>.

Statins should be offered to patients with diabetes and >40 years of age. High-intensity statin therapy is recommended for patients with atherosclerotic cardiovascular disease (ASCVD) or those between 40 and 75 years of age with additional cardiovascular risk factors. Adding moderate-intensity statins should be considered for patients between 40 and 75 years of age and no ASCVD risk factors. Either moderate-intensity or high-intensity statin therapy can be considered in patients >75 years of age or those <40 years with additional ASCVD risk factors. Adding ezetimibe to moderate-intensity statin therapy may provide incremental cardiovascular benefit to those unable to tolerate high-intensity statins. Hyperlipidemia in diabetes typically features hypertriglyceridemia and low levels of high-density lipoprotein. Although the latter can be treated with fibrates or niacin, there is little evidence that this treatment reduces cardiovascular risk.

### Gestational Diabetes

The prevalence of diabetes in pregnancy has been rising because of increases in both gestational diabetes (GDM) and pregestational diabetes. Pregestational diabetes confers greater risk of maternal and fetal complications than GDM. The exponential increase in insulin resistance during the second and third trimesters is a significant driver of GDM. Women with risk factors for diabetes should undergo diabetes screening before conception or during the first prenatal visit using standard diagnostic criteria. Women with diabetes in the first trimester have overt diabetes, not GDM. Screening for GDM is optimally performed at 24 to 28 weeks of gestation.

The diagnosis of gestational diabetes during pregnancy can be made in women who have a fasting plasma glucose of at least 92 mg/dL or a glucose that is higher than 180 mg/dL at 1 hour or higher than 153 mg/dL at 2 hours after a 75-g glucose load. There are different criteria for the diagnosis using a two-step approach with a 50-g followed by a 100-g glucose load.

Patients with gestational diabetes should be provided with nutritional counseling and a glucometer. Fasting glucose readings should be kept  $\leq 95$  mg/dL, and postprandial levels should be  $\leq 140$  mg/dL at 1 hour and  $\leq 120$  mg/dL at 2 hours. HbA<sup>1c</sup> goal should be <6% to 6.5%. A minority of women with GDM will require insulin therapy; usually insulin NPH and ultrashort-acting insulins (lispro or aspart) are used. Metformin may be used to manage gestational diabetes, but patients should be informed that long-term effects are unknown.

### Hyperglycemia in the Hospital

Hyperglycemia during hospitalization is associated with significant increases in morbidity and mortality. In intensive-care settings, intravenous insulin infusions are often recommended if glucose is >180 mg/dL and titrated thereafter to a glucose target of 140 to 180 mg/dL. Lower targets may be appropriate for select patients. The patient can be transitioned to subcutaneous insulin when stable (e.g.,

extubated, off pressors) whether or not they are eating. If glucose control has been on target, many clinicians start with an insulin dose that is 80% of the previous day's total daily insulin use. Prescriptions should be written for basal, prandial, and correction doses.

## Endocrine Syndromes

### Multiple Endocrine Neoplasia

MEN types 1, 2A, and 2B are rare genetic syndromes comprising multiple hormonally active tumors and some cancers (Table 57.4).

#### Multiple Endocrine Neoplasia 1

Hyperparathyroidism is the most common manifestation of MEN-1, caused by hyperplasia of multiple parathyroid glands. Penetrance is almost 100% by age 50 years. The second most common tumors are pancreatic-polypeptide producing pancreatic tumors. Gastrinomas occur in approximately 60% of patients with MEN-1 and are often metastatic at the time of diagnosis. Glucagonomas are rare. Prolactinomas are the most common of the pituitary tumors in patients with MEN-1, but acromegaly occurs in some 25% of patients. Other tumors that are reported to occur in patients with the MEN-1 syndrome include carcinoid tumors of the foregut, angiofibromas, lipomas, and benign adrenal adenomas.

TABLE 57.4

Components of the Multiple Endocrine Neoplasia and Autoimmune Polyendocrine Syndromes

Syndrome	Mutation	Components
<b>Multiple Endocrine Neoplasia</b>		
Type 1	MENIN	Primary hyperparathyroidism Pituitary tumors Enteropancreatic tumors
Type 2A	RET	Medullary thyroid cancer Pheochromocytoma Parathyroid hyperplasia Cutaneous lichen amyloidosis
Type 2B	RET	Medullary thyroid cancer Pheochromocytoma Mucosal neuromas Intestinal ganglioneuromas Marfanoid habitus
<b>Autoimmune Polyendocrine Syndrome</b>		
Type 1	AIRE	Primary adrenal insufficiency Hypoparathyroidism Mucocutaneous candidiasis
Type 2	Polygenic, HLA DR3	Primary adrenal insufficiency Autoimmune thyroid disease type 1 diabetes mellitus

## Multiple Endocrine Neoplasia 2

Type 2A MEN accounts for almost 95% of cases of type 2 MEN. C-cell hyperplasia is a precursor for medullary thyroid cancer that arises multifocally and bilaterally. Pheochromocytomas occur in the third to fourth decade and are typically bilateral. Frank hyperparathyroidism is unusual. Patients suspected of MEN-2 should have testing for the *RET* germline mutation and annual screening with plasma metanephrines. Prophylactic thyroidectomy with lymph node dissection is recommended in children younger than 5 years who have a *RET* germline mutation in exon 16.

## Autoimmune Polyendocrine Syndrome

Polyglandular autoimmune syndromes are constellations of multiple endocrine gland insufficiencies. These are

extremely rare disorders and are usually apparent by early adolescence.

The order of appearance of components in autoimmune polyendocrine syndrome type 1 is generally candidiasis, hypoparathyroidism, and then adrenal insufficiency. The screening antibody panel can include autoantibodies to 21-hydroxylase, 17-hydroxylase, thyroid peroxidase, and thyroid-stimulating immunoglobulins, glutamic acid decarboxylase and islet cell antibodies, and parietal cell enzyme antibodies.

Autoimmune polyendocrine syndrome type 2 is more common than type 1. Primary adrenal insufficiency is an obligatory component. Primary hypogonadism, celiac sprue, and myasthenia gravis can also complicate the presentation. The onset is generally in the fourth decade or later, with a female predominance.

## SECTION 6

# Nephrology and Hypertension

# 58

## Acute Kidney Injury

BRADLEY M. DENKER

Acute renal failure, now referred to as acute kidney injury (AKI), is common in general hospital admissions and is associated with increased morbidity and mortality and prolonged hospitalizations. A systematic review of over 300 studies of AKI indicates a worldwide estimated incidence of ~22%. The definition of AKI varies, but it is usually defined as an increase in serum creatinine concentration of 25% to 50% above the baseline, a decline in estimated glomerular filtration rate (eGFR) of 25% to 50%, or the need for renal replacement therapy. It is now recognized that changes in GFR are delayed manifestations of renal injury, and the development of urinary biomarkers may help to identify AKI earlier in the course of injury. The major causes of AKI in hospitalized patients include prerenal causes (~40%), postrenal causes (~5%–10%), and intrinsic diseases affecting blood vessels, glomeruli, or tubules. Of the intrinsic causes, tubular disorders (acute tubular necrosis [ATN] and acute interstitial nephritis) are the most common etiologies, accounting for 40% to 50% of all causes of AKI. Acute glomerulonephritis and vascular disorders are rare etiologies of AKI in hospitalized patients (<5%).

### Regulation of Glomerular Filtration

To understand the mechanisms of renal injury, it is helpful to review renal anatomy and the regulation of glomerular filtration. The major structures comprising the normal kidney include the blood supply, glomeruli, tubules, and collecting system. Fig. 58.1A shows the arrangement of glomerular perfusion with afferent (inflow) and efferent (outflow) movement of blood to and from a single glomerulus. Glomerular filtration through each glomerulus is determined by the pressure gradient across the glomerular basement membrane ( $P_{GC}$ ), and total GFR is the sum of filtration from all individual glomeruli (~800,000/kidney). As shown in Fig. 58.1A, GFR is regulated by hormonal control of vascular tone in the afferent and efferent arterioles to maintain pressure across the glomerular basement membrane. Normally, GFR is maintained over a wide range of mean arterial pressures (MAPs) (Fig. 58.1B). GFR is preserved as mean systemic blood pressure (BP) falls by afferent vasodilation (more inflow, mediated by prostaglandins) and by efferent

vasoconstriction (increased resistance, thereby maintaining transglomerular capillary pressure to maintain GFR; mediated by angiotensin II). Fig. 58.1B shows the changes in GFR with falling MAP in control conditions (*circles*). GFR is maintained over a wide range of MAPs and does not significantly fall until MAP <80 mm Hg.

However, in the setting of angiotensin II inhibition (angiotensin-converting enzyme [ACE] inhibitor or angiotensin receptor blocker [ARB]), GFR begins to fall at higher MAPs (120 vs. 80 mm Hg) and falls much more significantly (see Fig. 58.1B, *squares*). Fig. 58.1A shows the loss of efferent vasoconstriction with angiotensin II inhibition leading to lower GFR.

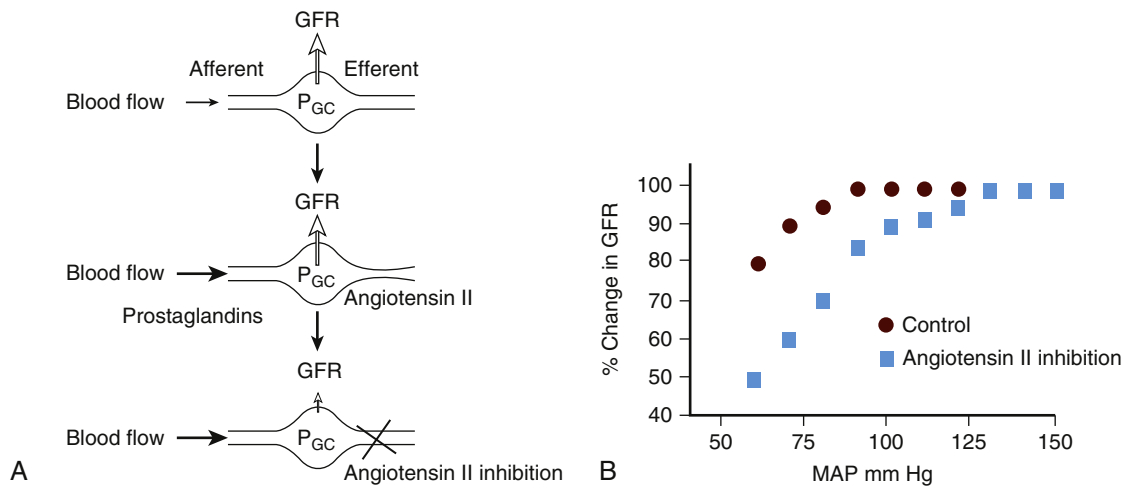

### Mechanisms of Reduced Glomerular Filtration

#### Postrenal

Urinary outflow obstruction is a reversible cause of AKI that must be excluded early in the evaluation of AKI. Finding an obstruction by ultrasound not only identifies the cause of AKI, it also may reveal the anatomic etiology for the obstruction. This allows the management of the patient to be directed toward relief of the obstruction. However, the renal ultrasound may not reveal a dilated collecting system early in the course of obstruction, and with bulky pelvic tumors the compression of the ureters may prevent dilation. Therefore it is important to have a high index of suspicion for obstruction in these clinical scenarios even in the absence of hydronephrosis on ultrasound. In addition, obstruction in a single kidney (such as from a kidney stone) will not result in a significant change in GFR because of compensation from the remaining kidney. The finding of a severe reduction in GFR from obstruction must involve the outflow tract (such as prostate hypertrophy) or a bilateral process.

#### Prerenal

The definition of prerenal AKI is any etiology of reduced renal perfusion resulting in a decreased GFR without intrinsic renal damage. By definition, prerenal AKI will

• **Fig. 58.1** Autoregulation of glomerular filtration. (A) The glomerular filtration rate (*GFR*) for each glomerulus is determined by glomerular capillary pressure ( $P_{GC}$ ) and is represented by the *open arrow*. Total *GFR* is the sum of all individual glomeruli. The magnitude of blood entering the glomerulus through the afferent arteriole is shown by size of the *solid black arrows*. With a drop in renal blood flow, *GFR* is preserved by afferent vasodilation (augments in-flow; mediated by prostaglandins) and efferent vasoconstriction (maintains  $P_{GC}$ ; mediated by angiotensin II). In the presence of angiotensin blockade, efferent vasoconstriction is inhibited, and *GFR* falls due to the decrease in  $P_{GC}$ . (B) The changes in *GFR* from baseline as a function of mean arterial pressure (*MAP*). *Circles* are control conditions. *Squares* are in the presence of an angiotensin-converting enzyme inhibitor.

resolve when adequate renal perfusion has been restored. The etiologies of prerenal AKI can be broadly divided into volume depletion, peripheral vasodilation, decreased cardiac output, intrarenal vasoconstriction, and impaired autoregulatory responses (material summarized in [Box 58.1](#)). In clinical practice, there are often multiple prerenal mechanisms contributing to the decreased *GFR*. For example, volume depletion in addition to decreased cardiac output or impaired autoregulatory response caused by medications is a common combination of factors. In all causes of prerenal AKI, the renal compensatory mechanisms discussed earlier (afferent vasodilation and efferent vasoconstriction) are preserved, and *GFR* will be protected until compensatory mechanisms are overwhelmed.

Volume depletion is a common cause of prerenal AKI and can be seen with any fluid loss. These include blood loss from any site or protracted vomiting or diarrhea. Bleeding from the gastrointestinal tract or other locations can lead to prerenal AKI after approximately 5% of blood volume loss or after *MAP* falls <80 mm Hg. Other causes of volume depletion include severe insensible losses that occur with systemic skin reactions or burns and renal etiologies from the overuse of diuretics, uncontrolled hyperglycemia (osmotic diuresis), or with adrenal insufficiency.

Peripheral vasodilation leads to shunting of blood away from the renal circulation and contributes to decreased renal perfusion. This commonly occurs with certain medications (anesthetics, vasodilators) and is also a major feature of both the hepatorenal and sepsis syndromes. Early sepsis can lead to decreased *GFR* before there is a demonstrable drop in *BP*. Other mechanisms of decreased renal perfusion can be seen with intrinsic

### • BOX 58.1 Prerenal Mechanisms of Acute Kidney Injury

#### Intravascular Volume Depletion

Bleeding, poor oral intake, insensible losses (burns, exfoliative skin reactions)

Gastrointestinal: vomiting, diarrhea

Renal osmotic diuresis (hyperglycemia), overuse of diuretics, adrenal insufficiency

#### Peripheral Vasodilation

Antihypertension medications, pain medications, anesthetics, sepsis, anaphylaxis, hepatorenal syndrome

#### Decreased Cardiac Output

Myocardial: acute infarction, cardiomyopathy, decompensated congestive heart failure, pericardial effusion with tamponade, arrhythmias

Pulmonary: acute pulmonary embolism, pulmonary hypertension

#### Intrarenal Vasoconstriction

Drugs (e.g., cyclosporine, amphotericin), hypercalcemia, vasopressors (norepinephrine, epinephrine), ionic contrast, sepsis, hepatorenal syndrome

#### Impaired Autoregulatory Responses

Inhibition of afferent vasodilation: prostaglandin inhibitors (NSAIDs)

Inhibition of efferent vasodilation: ACE inhibitors, ARBs

*ACE*, Angiotensin-converting enzyme; *ARBs*, angiotensin receptor blocker; *NSAIDs*, nonsteroidal antiinflammatory drugs.

cardiac disease (acute myocardial infarction, decompensated congestive heart failure, valvular abnormalities, arrhythmias), pulmonary processes (pulmonary emboli or pulmonary hypertension), or from renal artery stenosis (either when bilateral or occurring in a single kidney).

Intrarenal vasoconstriction, especially on the afferent arteriole (increased catecholamines), also contributes to decreased perfusion and GFR in the sepsis and hepatorenal syndromes. Intrarenal vasoconstriction is also seen with the use of certain medications and hypercalcemia (see [Box 58.1](#)).

Finally, hemodynamic AKI (also called *normotensive ischemic renal failure*) can result from impairment of the autoregulatory mechanisms. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit prostaglandins and prevent compensatory vasodilation of the afferent arteriole (see [Fig. 58.1](#)). ACE inhibitors and ARBs prevent angiotensin II actions on the efferent arteriole and block compensatory vasoconstriction necessary for maintaining GFR with reduced perfusion (see [Fig. 58.1](#)). These are commonly used medications and are often taken simultaneously. Nevertheless, most patients will not suffer hemodynamic AKI until there is another perturbation of the system (i.e., mild volume depletion from a gastrointestinal source or more aggressive diuresis). As discussed previously, inhibiting either the afferent or efferent compensation will make patients more susceptible to hemodynamic mechanisms of AKI, and inhibiting both afferent and efferent mechanisms further increases the risk.

## Intrinsic Causes of Acute Kidney Injury

The three anatomic structures that can be injured with intrinsic kidney injury are the renal tubules, the glomeruli, and blood vessels ([Box 58.2](#)). Of these, the renal tubules are the most susceptible to acute injury. Although kidneys receive 25% of cardiac output, the enormous metabolic activity within the tubules renders the environment quite hypoxic. In the renal cortex, arterial oxygen tension is approximately 50 mm Hg, but it rapidly falls to 10 mm Hg in the medulla. This normally hypoxic environment renders the renal tubules uniquely susceptible to any disruption in oxygen delivery.

## Tubular Etiologies of Acute Kidney Injury

Any etiology of prerenal AKI can lead to acute tubular injury, commonly referred to as ATN. The factors that determine whether the reduced GFR is prerenal or has produced tubular damage relate to the severity and duration of the injury. As discussed earlier, the restoration of perfusion will restore GFR in patients with prerenal AKI and is a diagnosis made retrospectively. Volume-depleted patients must receive adequate volume resuscitation, but knowing whether intrinsic damage has occurred is important for anticipating the clinical course and prognosis of patients with acute renal failure. Numerous criteria can be used to help distinguish prerenal AKI from ATN, and these are summarized in [Table 58.1](#). Each of these parameters reveals whether tubular function is intact (i.e., without injury). The appropriate renal response to volume depletion is to preserve sodium (by catecholamine and angiotensin II

## • BOX 58.2 Intrarenal Mechanisms of Acute Kidney Injury

### Glomerular

#### Nephrotic Syndrome and Acute Kidney Injury

Minimal change disease with acute injury  
Collapsing glomerulopathy  
NSAIDs (acute interstitial nephritis plus membranous or minimal change disease)

#### Rapidly Progressive Glomerulonephritis

Antiglomerular basement membrane disease  
Pauci-immune GN (often ANCA associated)  
Immune complex GN  
Low complement levels; lupus, postinfectious, cryoglobulinemia, poststreptococcal GN  
Normal complement levels; IgA nephropathy, Henoch-Schönlein purpura, fibrillary (immunotactoid GN)

### Tubular

#### Acute Tubular Necrosis

All etiologies in [Box 58.1](#)  
Toxic injury: ionic contrast, drugs (gentamicin), pigments (myoglobin)

#### Acute Interstitial Nephritis

Medications, herbs, supplements  
Infectious: pyelonephritis, viral (cytomegalovirus)  
Infiltrative: lymphoma, leukemia, sarcoidosis, Sjögren syndrome

#### Intratubular Obstruction

Drugs: acyclovir, sulfonamides, indinavir  
Crystals: oxalate, uric acid  
Protein: Bence-Jones protein with multiple myeloma

### Vascular

#### Thrombotic Microangiopathy

TTP, HUS, antiphospholipid antibody syndrome  
Malignant hypertension, scleroderma, DIC

#### Vasculitis

Small vessels: pauci-immune GN (Churg-Strauss, Wegener granulomatosis/microscopic polyarteritis, hypersensitivity, and cryoglobulinemia)  
Medium vessels: polyarteritis nodosa

ANCA, Antineutrophil cytoplasmic antibody; DIC, disseminated intravascular coagulation; GN, glomerulonephritis; HUS, hemolytic uremic syndrome; IgA, immunoglobulin A; NSAIDs, nonsteroidal antiinflammatory drugs; TTP, thrombotic thrombocytopenic purpura.

stimulation of sodium reabsorption in the proximal tubule) leading to concentrated urine with very low sodium (see [Table 58.1](#)). In addition, filtered urea nitrogen is reabsorbed in the proximal tubule along with sodium. As a result, blood urea nitrogen (BUN) rises disproportionately to the rise in serum creatinine (creatinine is not reabsorbed but, rather, secreted), and the BUN/creatinine ratio often exceeds 20:1 with volume depletion. Although the BUN/creatinine ratio and the urine findings in [Table 58.1](#) are helpful for distinguishing prerenal AKI from ATN, they are often indeterminate, especially in a volume depleted patient who has suffered some tubular injury.

**TABLE 58.1** Laboratory Parameters Used to Distinguish Prerenal Azotemia From Acute Tubular Necrosis

Laboratory Parameter	Prerenal Azotemia	Acute Tubular Damage
BUN/creatinine ratio	>20:1	10–15:1
Urine sodium ( $U_{Na}$ ), mEq/L	<20	>40
Fractional excretion of Na: $FE_{Na} = \frac{U_{Na} \times P_{Cr} \times 100}{P_{Na} \times U_{Cr}}$	<1%	>2%
Urine osmolality (mOsm/L $H_2O$ )	>500	<350
Urine/plasma creatinine ( $U_{Cr}/P_{Cr}$ )	>40	

*BUN*, Blood urea nitrogen; *Cr*, creatinine; *Fe*, iron; *Na*, sodium; *P*, plasma; *U*, urea.

Finally, the urinalysis can be helpful. With prerenal AKI, the urinary sediment is bland and may only reveal hyaline casts characteristic of concentrated urine, whereas ATN (tubular injury) is often associated with muddy brown casts (~85% of ATN presentations) and renal tubular epithelial cells reflecting dead/necrotic cells shed into the urine.

In addition to hemodynamic insults resulting in ATN, the renal tubules are also susceptible to toxic injuries (see [Box 58.2](#)). Again, this reflects the hypoxic metabolic environment and renal clearance for many of these compounds. Many etiologies of toxic ATN result from administered agents, but endogenous compounds liberated into the circulation, such as myoglobin with rhabdomyolysis and free hemoglobin, can also cause tubular injury. The clinical presentation and biochemical findings of toxin tubular injury are similar to what is described previously for hemodynamic etiologies. However, a urinalysis showing strongly positive blood by dipstick and only a few red blood cells (RBCs) should prompt an investigation for myoglobin or free hemoglobin in the blood and urine (as seen with rhabdomyolysis and hemolysis, respectively).

Two other mechanisms of tubular injury are important causes of AKI. Interstitial nephritis (common) and intratubular obstruction (less common) must be considered in the evaluation of patients with AKI (see [Box 58.2](#)). Interstitial nephritis is most commonly allergic in origin, has been reported with virtually every category of medication, and may not be associated with systemic manifestations (rash, eosinophilia). The kidneys can also be affected by interstitial infiltrates in infectious disorders, malignancy (lymphoma, leukemia), and autoimmune disorders (sarcoid, rheumatologic diseases). With allergic interstitial nephritis, the cellular infiltrate is often mononuclear and not eosinophilic. As a result, a negative urine eosinophil count does not exclude drug-induced interstitial nephritis. With all etiologies of interstitial nephritis, the urinalysis will often have white blood cells (WBCs), RBCs, and may have WBC and RBC casts. Even in the absence of systemic manifestations, the clinical scenario will often suggest the diagnosis of interstitial nephritis (e.g., initiation of a new medication with development of AKI and abnormal urinalysis).

Another important mechanism of AKI results when crystals, drugs, or proteins precipitate within the renal tubules resulting in intratubular obstruction. Often the patients at risk develop this complication in the setting of volume depletion and a concentrated urine. The hemodynamic consequences on GFR are identical to those of urinary obstruction at more distal sites, but intratubular obstruction will not be associated with hydronephrosis. Uric acid and oxalates are the most common crystals that precipitate within the tubules. Uric acid may precipitate in the tumor lysis syndrome, and likewise oxalates may precipitate with primary hyperoxalosis or ethylene glycol ingestion. Certain drugs (e.g., acyclovir, indinavir, methotrexate, sulfonamides) may precipitate if overdosed or administered to a volume-depleted patient, especially in the setting of pre-existing renal insufficiency. Occasionally the drug crystals can be identified on the urinalysis. Finally, paraproteins can precipitate within renal tubules, and this is most commonly seen in patients with multiple myeloma and Bence-Jones proteinuria.

## Glomerular Etiologies of Acute Kidney Injury

Acute glomerulonephritis is a rare cause of AKI (see [Box 58.2](#)) and requires a renal biopsy for diagnosis. Rapid diagnosis and treatment can prevent the destruction of glomeruli and may delay or prevent the development of end-stage renal disease. An overview of glomerular disease can be found in [Chapter 63](#), and here the focus will be on disorders associated with AKI. Glomerular disease can be broadly divided into the nephrotic syndrome (>3.5 g of proteinuria/d, hypoalbuminemia, edema, hypercholesterolemia) and nephritic syndrome (hypertension, edema, azotemia, active urinary sediment with RBCs, WBCs, and cellular casts). Nephrotic syndrome is not usually associated with acute reductions in GFR. However, there are three clinical syndromes to consider in patients presenting with nephrotic syndrome and AKI. First, minimal change disease (normal glomeruli but podocyte foot process effacement on renal biopsy) in elderly or volume-depleted patients can have coexisting ATN.

Second, collapsing glomerulopathy (focal and segmental glomerulosclerosis with collapsed glomeruli on kidney biopsy) is associated with rapid declines in GFR and can lead to end-stage disease within months. This syndrome is often seen in HIV-positive patients, but it can also be seen in the absence of HIV disease. Finally, allergic reactions to NSAIDs are commonly associated with minimal change or membranous patterns of injury in addition to classical findings of allergic interstitial nephritis. As a result, these patients will often have AKI and a picture of allergic interstitial nephritis and nephrotic syndrome.

Acute glomerulonephritis or rapidly progressive glomerulonephritis (RPGN) can present as part of a systemic disease or may be renal limited. The presentation usually includes hypertension, AKI, and active urinary sediment. The hallmark of an active urinary sediment in acute glomerulonephritis is the presence of dysmorphic RBCs and RBC casts. RBC casts are not always visualized, but hematuria of renal origin (dysmorphic RBCs) is nearly universal. Other cells and casts, especially those of WBCs, can also be present. RPGN can develop through three major mechanisms:

1. Antiglomerular basement membrane antibody disease, also known as Goodpasture syndrome, may be associated with pulmonary hemorrhage. Rapid diagnosis and treatment with plasmapheresis and cytotoxic agents are imperative, because renal recovery is rare when the creatinine reaches 5.8 mg/dL.
2. Pauci-immune etiologies of glomerulonephritis do not reveal immune complex staining or deposits on kidney biopsy and are often associated with antineutrophil cytoplasmic antibodies (ANCA). These disorders typically include granulomatosis with polyangiitis, Churg-eosinophilic granulomatosis with polyangiitis (Churg-Strauss), and microscopic polyarteritis.
3. Immune complex diseases are typically divided into those with normal complement levels and those with hypocomplementemia. Systemic lupus erythematosus, postinfectious causes (streptococcal [group A] pharyngitis and subacute bacterial endocarditis are most common), and cryoglobulinemia are the most common etiologies of acute glomerulonephritis associated with low complement levels. These disorders are discussed in more detail in [Chapter 63](#). Other glomerular diseases that can present with AKI and do not include complement deposition are IgA nephropathy, the most common etiology of glomerulonephritis worldwide; Henoch-Schönlein purpura (HSP; IgA nephropathy with vasculitic rash and abdominal pain); and a less common deposition disease known as fibrillary or immunotactoid glomerulonephritis. [Box 58.2](#) summarizes these disorders.

### Vascular Etiologies of Acute Kidney Injury

Damage to the renal microcirculation can mimic acute glomerulonephritis, although the pathologic pattern is distinct from other etiologies of acute glomerulonephritis. The glomerular capillary is uniquely susceptible to injury

and is frequently a target of pathology even when other capillary beds are spared. Glomerular endothelial cells are disproportionately affected in systemic microangiopathies such as thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS). In addition to systemic thrombocytopenia and evidence for intravascular hemolysis, these disorders are characterized by platelet microthrombi in glomerular capillary loops and thickened glomerular basement membranes. The occlusion of blood flow in the renal microcirculation leads to shearing of RBCs and loss of GFR. Both TTP and HUS can present as primary diseases (such as diarrhea-associated *Escherichia coli* O157 toxin-mediated), as a paraneoplastic syndrome in malignancy, or as complications of therapy with medications including cyclosporine, chemotherapy agents, or radiation therapy. Endothelial damage with a thrombotic microangiopathy is also seen in malignant hypertension, scleroderma crisis, and disseminated intravascular coagulation. Thrombotic microangiopathy can also be seen with antiphospholipid antibody syndrome associated with systemic lupus and as a complication of pregnancy. In all of these conditions the underlying renal pathophysiology is identical and therefore not distinguishable by kidney biopsy.

Vasculitis (see [Box 58.2](#)) of small arterioles can result in acute glomerulonephritis as described earlier. These are often ANCA associated and usually associated with Churg-Strauss syndrome (asthma, eosinophilia), granulomatosis with polyangiitis (pulmonary or ear, nose, and throat involvement common), microscopic polyarteritis (similar to polyarteritis nodosa [PAN]), hypersensitivity (drug related), cryoglobulinemia (often seen with hepatitis B or C or paraprotein disease), or HSP. Vasculitis of medium-sized arteries as seen with PAN can result in AKI, but vasculitis of large arteries (giant cell and Takayasu arteritis) rarely results in renal failure.

### Common Scenarios of Acute Kidney Injury in Hospitalized Patients

AKI in hospitalized patients is often associated with complications of procedures performed in the course of evaluation and treatment of other disease processes. AKI that develops during a hospital course can often be anticipated. The two most common scenarios are postoperative AKI and radiologic imaging/intervention injuries.

#### Postoperative Acute Kidney Injury

There are numerous variables that increase the risk for AKI in patients undergoing surgical procedures. Any patient with preexisting chronic renal disease is at higher risk, and the more severe the chronic kidney disease the greater the risk for procedure-related AKI. Virtually all patients will have anesthesia-induced drops in BP because of the vasodilatory action of anesthetic agents. This alone will not cause AKI in most settings, but if there is significant blood loss or

larger drops in BP for a prolonged interval, this can result in AKI. Certain medications taken before surgery including NSAIDs and ACE inhibitors or ARBs may interfere with normal renal autoregulatory mechanisms (as described previously) and, when combined with anesthesia-induced drop in BP, may lead to AKI. Other risk factors include the length of the procedure and the type of operation. Vascular and cardiac surgeries pose a higher risk, and large blood loss or the use of cardiopulmonary bypass also increases the risk of AKI. Finally, identify additional potential nephrotoxins administered during the surgery including antibiotics or irrigants (many of which are highly nephrotoxic if absorbed).

### Postintravenous Contrast and Angiographic Procedure Acute Kidney Injury

There are two common mechanisms of AKI in the setting of intravenous contrast (Table 58.2). One results from renal toxicity related to contrast exposure (contrast nephropathy), and the other is atheroembolic syndrome resulting from mechanical disruption of cholesterol plaque during an angiographic procedure. Atheroemboli to the renal arteries can occur spontaneously, but they are usually associated with angiographic procedures through the femoral artery. The atheroembolic syndrome is often associated with a diffuse systemic reaction that can mimic an acute autoimmune disease and may include livedo reticularis, fever, eosinophilia, hypocomplementemia, and AKI. On renal biopsy, cholesterol emboli may be visualized in the small intrarenal arteries. The course and prognosis of

renal atheroembolic disease are variable. Some patients will recover, but others will progress to end-stage disease requiring renal replacement over the course of days to weeks because many of these patients had existing chronic kidney disease before the procedure. Some patients exhibit a waxing and waning course in which GFR will worsen and improve over several weeks to months before stabilizing with reduced GFR.

Contrast nephropathy (see Table 58.2) is associated with increased creatinine 24 to 48 hours postcontrast exposure, and the usual course is for the creatinine to peak at 3 to 5 days and then begin to recover. Most patients will return to baseline creatinine, but there is likely a subclinical loss of GFR not reflected in the postprocedure baseline creatinine. Several studies have shown that developing contrast nephropathy is associated with increased morbidity and mortality in addition to longer hospital stays. The risk factors for developing contrast nephropathy are preexisting renal disease, volume depletion at the time of exposure, dose and osmolality of the contrast agent, coexisting diabetes, coexisting congestive heart failure, and recent use of NSAIDs (see Table 58.2). Unlike atheroembolic disease that may not be preventable, the risk of contrast nephropathy can be reduced with periprocedure interventions. Several studies have confirmed the benefit of intravenous hydration. Although exact regimens differ, the use of normal saline or sodium bicarbonate-based fluids is associated with a lower incidence of contrast nephropathy. Other medications such as the use of diuretics and mannitol have not been shown to be of benefit. The use of *N*-acetylcysteine is controversial, and there are conflicting recommendations from professional societies.

**TABLE 58.2** Summary of Contrast Nephropathy and Atheroembolic Renal Disease

	Contrast Nephropathy	Atheroembolic Disease
Can occur spontaneously	No	Yes
Associated with angiography	Yes	Yes
Signs/symptoms	None	Fever, eosinophilia, livedo reticularis, stigmata of emboli, low complements
Urinalysis/urine chemistry	Low $FE_{Na}$ , bland sediment	Hematuria
Mechanism of injury	Afferent vasoconstriction (acute), tubular toxicity	Embolization of cholesterol crystals to small renal arterioles—acute inflammation
Course	Creatinine peaks at 3–5 days; returns to baseline	Variable; often waxes and wanes
Risk factors	CKD, volume depletion, dose and osmolality of contrast, diabetes, CHF, NSAIDs	Known vascular disease, procedure (renal angiography highest risk but can be seen with any intervention)
Prevention	Intravenous fluids, <i>N</i> -acetylcysteine	None

*CHF*, Chronic heart failure; *CKD*, chronic kidney disease; *FE*, iron; *Na*, sodium; *NSAIDs*, nonsteroidal antiinflammatory drugs.

## Management of Acute Kidney Injury

Treatment of AKI depends on the etiology, but in most circumstances it is supportive (Box 58.3). As described previously, detecting hydronephrosis and urinary obstruction on ultrasound provides an etiology and therapeutic plan.

Acute glomerulonephritis is often treated with immunosuppressive medications to reduce inflammation and lower the risk for scarring but requires a kidney biopsy for diagnosis. Most causes of AKI are either prerenal or tubular in origin. In straightforward prerenal AKI resulting from volume depletion, GFR will begin to improve within hours of restoring adequate circulatory volume. If there is a medication component contributing to hemodynamically mediated decreased GFR, then it may take longer for the pharmacologic effects to dissipate. In acute interstitial nephritis, stopping the offending medication will usually lead to resolution of the allergic reaction. However, in some circumstances treatment with steroids may be indicated, because they may shorten the duration of the renal injury. In ATN, there are no effective remedies once injury is established. Numerous interventions have been tried including atrial natriuretic peptide, diuretics, dopamine, and calcium channel blockers, but none of these has proven effective in human disease. Therefore prevention of ATN, when possible, is the mainstay of

### • BOX 58.3 Management of Acute Kidney Injury

#### Prevention

- Avoid volume depletion, nephrotoxins, and hypotension in risk situations
- Use intravenous fluids, and consider *N*-acetylcysteine in high-risk patients receiving contrast (CKD, diabetics)

#### Support Care Once Acute Kidney Injury Established

- Volume expansion: restrict Na, diuretics
- Hyponatremia: free-water restriction
- Hyperkalemia: restrict intake, diuretics, Kayexalate
- Metabolic acidosis: bicarbonate administration
- Hyperphosphatemia: oral phosphate binders if possible, otherwise observe
- Hypocalcemia: replace calcium, consider vitamin D
- Nutrition: TPN or external feeds dosed at 35 kcal/kg
- Anemia: GI prophylaxis, transfusions, DDAVP, estrogens
- Dose all medications for GFR <10 mL/min
- Avoid ACE inhibitors, ARBs, NSAIDs, and other nephrotoxic medications if possible (aminoglycosides)

#### Indications for Renal Replacement Therapy

- Pericarditis
- Encephalopathy
- Refractory volume overload
- Hyperkalemia
- Refractory acidosis

*ACE*, Angiotensin-converting enzyme; *ARBs*, angiotensin receptor blocker; *CKD*, chronic kidney disease; *DDAVP*, desmopressin; *GFR*, glomerular filtration rate; *GI*, gastrointestinal; *NSAIDs*, nonsteroidal antiinflammatory drugs; *TPN*, total parenteral nutrition.

therapy in high-risk situations. Surgical and radiographic procedures, in addition to new medications, are the main threats to renal function in hospitalized patients. Identifying patients at risk and using preventive measures (such as avoiding nephrotoxins, use of hydration) will reduce but not eliminate the risk of AKI.

Once AKI with tubular injury is established, the primary goal is to prevent additional renal injury and manage the complications of severely reduced GFR. Avoidance of volume depletion, hypotension, and exposure to nephrotoxins constitute the hallmarks of support. The natural history of ATN is to enter a maintenance phase that can persist for weeks to months depending on the severity of the injury. During this interval, the GFR is usually <10 mL/min, and renal replacement therapy may be required. It is essential that all renally excreted medications be appropriately dosed for the low GFR to avoid additional injury. In most patients, tubular regeneration will occur and GFR will improve but often not back to baseline levels. Once ATN is established, there is no proven role for dopamine, diuretics, calcium channel blockers, or atrial natriuretic peptide in altering the natural history of the injury. Oliguric ATN (urine output <400 mL/d) is associated with a poorer prognosis than nonoliguric ATN, and nonoliguric patients are easier to manage. The use of diuretics may increase urine output in oliguric ATN, but it does not alter the prognosis and is not generally recommended.

The medical management of patients with AKI is focused on correcting the resulting metabolic disturbances. Volume overload may be managed with diuretics, but high doses of loop diuretics, often in combination with thiazide diuretics, are required to achieve an effective diuresis. The major metabolic disturbances are hyperkalemia and metabolic acidosis. If urine output is established with diuretics, potassium may be easier to manage. If hyperkalemia is acute and severe, then short-term interventions should be used (insulin/glucose, sodium bicarbonate, beta-agonists, and calcium). Kayexalate is effective with repeated doses, but acute dialysis may be required to manage life-threatening hyperkalemia. Metabolic acidosis may be managed with sodium bicarbonate, but the sodium load can contribute to volume expansion. Other electrolyte disturbances such as hyponatremia, hyperphosphatemia, hypocalcemia, and hypermagnesemia can usually be managed with conservative measures. In the intensive care unit (ICU) setting, nutritional requirements are high, and often this is provided through the use of total parenteral nutrition (TPN). Patients on TPN have large obligate fluid intake and with oliguria intake may be limited. Platelet dysfunction and bleeding may be treated with desmopressin (DDAVP) (increases release of von Willebrand factor) and/or estrogens, and patients should be protected from gastrointestinal bleeding with the use of proton-pump inhibitors.

Failure to control any of these factors may necessitate renal replacement therapy. The most common indications for dialysis are volume management, hyperkalemia,

and acidosis. Uremic encephalopathy and pericarditis are two other important indications for dialysis. Although acute peritoneal dialysis has been used in the past, nearly all patients today are treated with intermittent hemodialysis or a continuous dialysis modality such as continuous venovenous hemofiltration. Continuous modalities require specialized equipment, specially trained staff, and must be performed in an ICU setting. Although they are better tolerated than intermittent hemodialysis in hemodynamically unstable patients, to date there are no data showing better outcomes with continuous modalities.

## Summary

Acute kidney injury is common in hospitalized patients and is associated with increased morbidity, mortality, and length of stay. The initial approach should be to rule out obstruction with an imaging study and look for other reversible causes of AKI. In addition, medications that

interfere with autoregulation of GFR should be avoided in the acute setting. Although specific therapies for reversing acute tubular injury are currently lacking, the situations that place patients at high risk for ATN are well known and can be minimized by optimizing hemodynamics and medications. The most common high-risk scenario for AKI in hospitalized patients is in the setting of intravenous contrast for imaging studies. Intravenous hydration, using low volumes of isoosmolar contrast agents, can reduce the risk for AKI in this setting. Recognition and discontinuation of medications causing acute interstitial nephritis will help shorten the course of AKI. In those patients who have suffered acute tubular injury, the cornerstone of management is supportive: maintenance of hemodynamic stability and avoidance of nephrotoxins. Renal replacement therapy, usually by intermittent hemodialysis or a continuous therapy, is indicated when medical management is unable to address metabolic and/or volume complications.

## Chapter Review

### Questions

- A 22-year-old male is seen in the emergency department (ED) for evaluation of acute renal failure. He explains that he has just finished running the Boston marathon. He complains of severe leg cramps. He tells you that his urine is light pink. He has no significant medical history. He is not taking any medications. He denies recent alcohol consumption. His physical examination shows a BP of 100/60 mm Hg with a 15 mm Hg drop in his systolic pressure on standing, a heart rate of 110 beats per minute, and a temperature of 99.3°F. His jugular venous pressure is 2 to 3 cm. He has clear lungs and a normal cardiovascular and abdominal examination. He has no edema. His skin turgor is reduced. Urinalysis reveals specific gravity of 1020, pH 5.0, 4+ blood, rest negative. His urine sediment shows 0 to 2 hyaline casts per high-power field (HPF) but is otherwise negative. The next step in management would be:

  - Obtain intravenous access, and begin treatment with D5W.
  - Obtain intravenous access, and begin treatment with isotonic saline.
  - Arrange for an urgent renal ultrasound to investigate his hematuria.
  - Administer *N*-acetylcysteine for his acute kidney injury.
  - Arrange for an urgent renal biopsy.
- A 67-year-old man presents with a 1-week history of anorexia, nausea, lassitude, and pedal edema. He has history of long-standing hypertension, well controlled with hydrochlorothiazide and amlodipine. He has been taking fenoprofen for osteoarthritis of the hip for the past 3 months. Physical examination is notable for BP 157/93 mm Hg with 2+ pitting edema. His urinalysis reveals protein 4+, 1+ blood, 2 to 4 RBCs and 15 to 20 WBCs per HPF, and occasional granular casts. Laboratories notable for BUN 93 mg/dL; creatinine 7.8 mg/dL; albumin 2.9 g/dL; hematocrit 29%. ANCA is negative, antinuclear positive at a 1:40 titer, anti-double-stranded DNA antibody level 0 IU/mL, 24-hour protein excretion 7.7 g. Renal ultrasound showed normal-sized kidneys bilaterally without obstruction. Three months previously his serum creatinine was 1.7 mg/dL. The nephrotic-range proteinuria and renal failure are most likely the result of:

  - Lupus nephritis
  - Multiple myeloma
  - Systemic small vessel vasculitis
  - Fenoprofen-induced nephrotic syndrome and interstitial nephritis
  - Renal vein thrombosis secondary to membranous nephropathy
- A 52-year-old female presents to the ED with unstable angina. She is noted to have a medical history of mild chronic renal insufficiency (creatinine of 1.8 mg/dL). She is transferred to the coronary care unit, and therapy for her unstable angina is initiated. A cardiac catheterization is planned for the next day. The best strategy for reducing her risk of contrast-induced nephropathy is:

  - Intravenous isotonic saline or bicarbonate preprocedure and postprocedure
  - Administer *N*-acetylcysteine the day before and the day of the procedure.
  - Renal dose dopamine
  - Intravenous half normal saline preprocedure and postprocedure
  - Administer 40 mg of intravenous furosemide precontrast infusion.

4. A 57-year-old female with a history of mild hypertension presents with headache and a BP of 240/140 mm Hg. She is alert and fully oriented and has no history of fever, chills, diarrhea, joint pains, dysphagia, skin changes, or Raynaud phenomenon. She has grade 4 papilledema on her funduscopic examination. The rest of the examination is unremarkable. Her laboratory data are notable for a hematocrit of 22%, WBC count is 6000/ $\mu$ L, platelet count  $95 \times 10^3/\text{mm}^3$ , sodium 138 mEq/L, potassium 4.3 mEq/L, chloride 102 mEq/L, bicarbonate 22 mEq/L, BUN 84 mg/dL, a serum creatinine of 4.5 mg/dL, calcium 11.2 mg/dL, phosphate 4.2 mg/dL, albumin 4.9 g/dL. Prothrombin time and partial thromboplastin time are normal. Her urinalysis shows 1+ blood, 1+ protein. Her urine sediment shows few RBCs/HPF and no casts. She is admitted to ICU for treatment. Her peripheral smear is shown in Fig. 58.2.

What is the most likely diagnosis (more than one may be correct)?

- A. Acute kidney injury from hypertensive urgency
- B. TTP/HUS
- C. Scleroderma renal crisis
- D. Acute kidney injury from malignant hypertension
- E. Disseminated intravascular coagulation

• Fig. 58.2 Peripheral blood smear of patient in Question 4.

### Answers

- 1. B
- 2. D
- 3. A
- 4. All correct

## Electrolyte Disorders

DAVID B. MOUNT

Disorders of electrolyte balance are common especially in hospitalized patients. Abnormalities in electrolyte levels and potentially their correction may be associated with significant morbidity and mortality, and care needs to be taken in both diagnosis and treatment. In this chapter, the focus will be on disorders of sodium ( $\text{Na}^+$ ) and potassium ( $\text{K}^+$ ) metabolism.

### Sodium Disorders

Disorders of serum sodium concentration ( $[\text{Na}^+]$ ) are caused by abnormalities in water homeostasis leading to changes in the relative ratio of  $\text{Na}^+$  to body water. Water intake and circulating arginine vasopressin (AVP) are the dominant mediators in the defense of serum osmolality (Table 59.1); defects in one or both of these defense mechanisms cause most cases of hyponatremia and hypernatremia. AVP secretion and thirst are both induced by increases in serum osmolality, via the activation of central osmoreceptors. Circulating vasopressin acts on V2-type vasopressin receptors in the thick ascending limb of Henle and principal cells of the collecting duct, increasing cyclic-adenosine monophosphate (AMP) and activating protein kinase A (PKA)-dependent phosphorylation of multiple transport proteins. The PKA-dependent activation of salt transport by the thick ascending limb is thus a key determinant of the countercurrent mechanism, which ultimately increases the interstitial osmolality in the inner medulla of the kidney and generates an osmotic gradient that drives water absorption across the renal collecting duct. PKA-dependent phosphorylation of the aquaporin-2 water channel in principal cells increases the insertion of active water channels into the lumen of the collecting duct, resulting in transepithelial water absorption down this osmotic gradient (Fig. 59.1). Abnormalities in this “final common pathway” cause most disorders of serum  $[\text{Na}^+]$ , with, for example, an exaggerated insertion of aquaporin-2 water channels into the membrane of principal cells in hyponatremic conditions.

Volume status also modulates the release of AVP by the posterior pituitary, such that hypovolemia is associated with higher circulating levels of the hormone at each level of serum osmolality; hypovolemia can thus be associated with hyponatremia caused by retention of ingested

free water in response to increased AVP. Similarly, in the setting of impaired arterial circulatory integrity, as seen in cirrhosis and heart failure, the associated neurohumoral activation leads to an increase in circulating AVP, predisposing to hyponatremia. These interactions between volume status, AVP release, and water homeostasis can lead to diagnostic confusion, which can be lessened by considering the relevant physiology (see Table 59.1). A key concept in this regard is that the absolute serum  $[\text{Na}^+]$  conveys no diagnostic information as to the volume status of a given patient, with hyponatremia, in particular, occurring at all extremes of whole-body water and  $\text{Na}^+\text{-Cl}^-$  content.

### Hyponatremia

#### Diagnostic Approach

Hyponatremia, defined as a serum  $[\text{Na}^+] < 135$  mEq/L, is a very common disorder, occurring in up to 22% of hospitalized patients. This disorder is almost always the result of an increase in circulating AVP and/or increased renal sensitivity to AVP, combined with an intake of free water. A notable

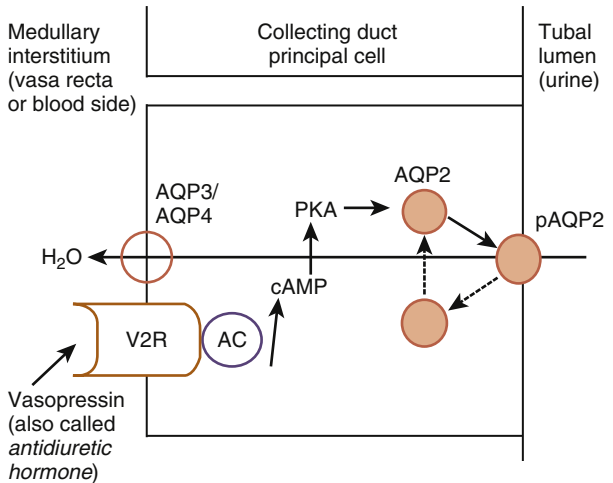

**TABLE 59.1 Osmoregulation Versus Volume Regulation**

	Osmoregulation	Volume Regulation
What is sensed	Plasma osmolality	Arterial circulatory integrity
Sensors	Hypothalamic osmoreceptors	Carotid sinus Afferent arteriole Atria
Effectors	AVP Thirst	Sympathetic nervous system Renin-angiotensin-aldosterone system ANP/BNP AVP
What is affected	Urine osmolality Water intake	Urinary sodium excretion Vascular tone

ANP, Atrial natriuretic peptide; AVP, arginine vasopressin; BNP, brain natriuretic peptide.

Modified from Rose BD, Black RM. *Manual of Clinical Problems in Nephrology*, New York: Little Brown & Co.; 1988:4.

exception is hyponatremia caused by low solute intake, as can occur with extreme vegan diets or “beer potomania,” wherein urinary solute concentrations are inadequate to support the excretion of ingested free water; the reduced capacity for renal water excretion is easily overwhelmed in these patients, leading to water retention and hyponatremia.

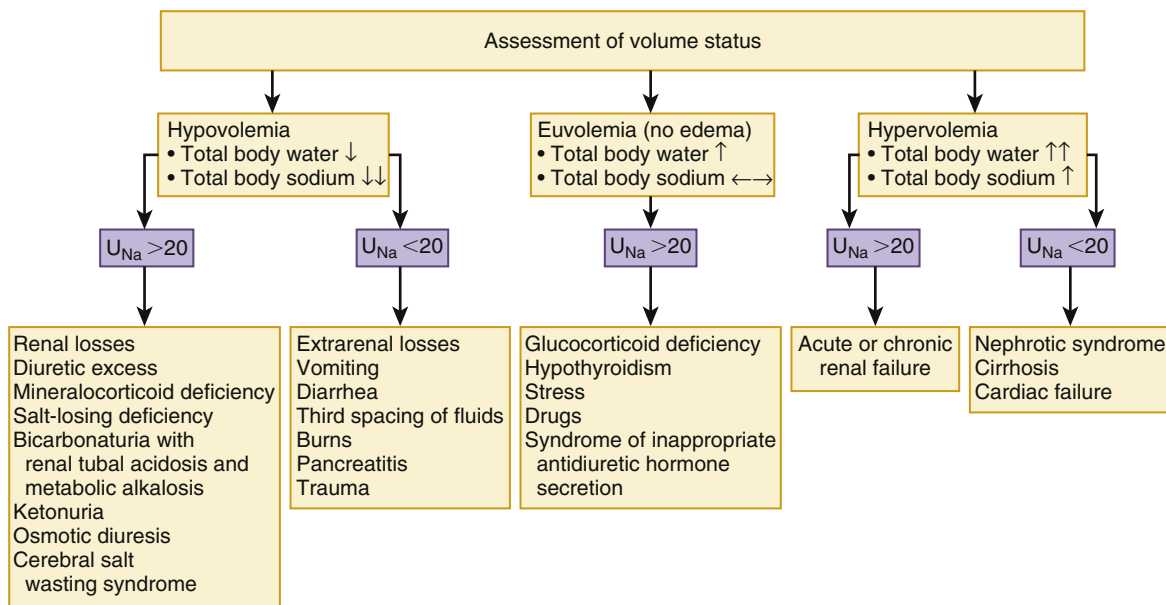

• **Fig. 59.1** Vasopressin and the regulation of water permeability in the renal collecting duct. Vasopressin binds to the type 2 vasopressin receptor (*V2R*) on the basolateral membrane of principal cells, activates adenylyl cyclase (*AC*), increases intracellular cyclic adenosine monophosphate (*cAMP*), and stimulates protein kinase A (*PKA*) activity. Cytoplasmic vesicles carrying aquaporin-2 (*AQP*) water channel proteins are inserted into the luminal membrane in response to vasopressin, thereby increasing the water permeability of this membrane. When vasopressin stimulation ends, water channels are retrieved by an endocytic process, and water permeability returns to its low basal rate. The *AQP3* and *AQP4* water channels are expressed on the basolateral membrane and complete the transcellular pathway for water reabsorption. *pAQP2*, Phosphorylated aquaporin-2. (From Sands JM, Bichet DG. Nephrogenic diabetes insipidus. *Ann Int Med.* 2006;144:186–194.)

The underlying pathophysiology for the typical exaggerated or inappropriate vasopressin response differs in patients with hyponatremia as a function of their extracellular fluid volume. Hyponatremia is thus subdivided diagnostically into three groups, depending on clinical history and volume status: hypovolemic, euvolemic, and hypervolemic hyponatremia (Fig. 59.2). Notably, hyponatremia is frequently multifactorial, particularly when severe; clinical evaluation should examine all the possible causes for increased AVP including nausea, pain, and drugs.

Laboratory investigation of a patient with hyponatremia should always include a measurement of serum osmolality to exclude pseudohyponatremia, that is, hyponatremia with a normal or increased plasma tonicity. Most clinical laboratories measure serum  $[Na^+]$  by testing diluted samples with automated ion-sensitive electrodes, correcting for this dilution by assuming that plasma is 93% water. This correction factor can be inaccurate in patients with pseudohyponatremia caused by extreme hyperlipidemia and/or hyperproteinemia, in whom serum lipid or protein makes up a greater percentage of plasma volume. The measured osmolality should also be converted to the effective osmolality (tonicity) by subtracting the measured concentration of urea (divided by 2.8 if in mg/dL); patients with hyponatremia have an effective osmolality of  $<275$  mOsm/kg. Serum glucose should also be measured; serum  $[Na^+]$  falls by  $\sim 1.4$  mEq/L for every 100 mg/dL increase in glucose, because of glucose-induced water efflux from cells; this form of hyponatremia resolves with normalization of serum glucose.

Urine electrolytes and osmolality are particularly critical tests in the initial evaluation of hyponatremia. A urine  $[Na^+] < 20$  mEq is consistent with hypovolemic hyponatremia, in the clinical absence of a hypervolemic  $Na^+$ -avid syndrome such as congestive heart failure (CHF) or cirrhosis (see Fig. 59.2). Urine osmolality  $< 100$  mOsm/kg is in turn

• **Fig. 59.2** The diagnostic approach to hyponatremia. See text for details. (From Kumar S, Berl T. Diseases of water metabolism. In: Schrier RW, ed. *Atlas of Diseases of the Kidney*. Vol. 1. New York: Wiley; 1999.)

suggestive of polydipsia. A urine osmolality  $>400$  mOsm/kg indicates that AVP excess is playing a more dominant role, whereas intermediate values are more consistent with multifactorial pathophysiology (e.g., AVP excess with a component of polydipsia). Patients with hyponatremia caused by decreased solute intake, as in beer potomania, typically have urines with  $[\text{Na}^+] <20$  mEq and urine osmolality in the range of  $<100$  to the low 200s. Urine electrolytes and osmolality should always be interpreted in the context of the available clinical data.

Measurement of serum uric acid should also be performed; whereas patients with syndrome of inappropriate antidiuresis (SIADH)-type physiology will typically be hypouricemic (serum uric acid  $<4$  mg/dL), volume-depleted patients will often be hyperuricemic. Finally, in the right clinical setting, thyroid, adrenal, and pituitary function should also be tested. Hypothyroidism and secondary adrenal failure caused by pituitary insufficiency are important causes of euvolemic hyponatremia, whereas primary adrenal failure causes hypovolemic hyponatremia. Radiologic imaging should also be considered, looking for a pulmonary or central nervous system (CNS) cause for inappropriate AVP secretion and hyponatremia; patients with a history of smoking should undergo chest CT to rule out SIADH-associated small cell lung carcinoma, which can sometimes be missed on routine chest radiographs.

### Hypovolemic Hyponatremia

Hypovolemia causes marked neurohumoral activation, activating systems such as the renin-angiotensin-aldosterone axis (RAA), the sympathetic nervous system, and circulating AVP (see Table 59.1). The increase in circulating AVP helps preserve blood pressure via vascular and baroreceptor V1A receptors, and increases water and  $\text{Na}^+\text{-Cl}^-$  reabsorption via renal V2 receptors; the latter effect can lead to hyponatremia, in the setting of increased free water intake. Nonrenal causes of hypovolemic hyponatremia include gastrointestinal (GI) (vomiting, diarrhea, tube drainage, etc.) and insensible loss of  $\text{Na}^+\text{-Cl}^-$  (sweating, burns, respiratory tract); urine  $[\text{Na}^+]$  is typically  $<20$  mEq in these cases. These patients may be clinically classified as euvolemic, with only the reduced urine  $[\text{Na}^+]$  to indicate the cause of their associated hyponatremia.

The renal causes of hypovolemic hyponatremia share an inappropriate loss of  $\text{Na}^+\text{-Cl}^-$  in the urine leading to volume depletion; urine  $[\text{Na}^+]$  is typically  $>20$  mEq (see Fig. 59.2). The associated deficiency in circulating aldosterone can lead to hyponatremia in primary adrenal insufficiency and other causes of hypoaldosteronism; hyperkalemia and hyponatremia in a hypotensive and/or hypovolemic patient with high urine  $[\text{Na}^+]$  should strongly suggest this diagnosis. Salt-losing nephropathies are characterized by impaired renal tubular function and thus a reduced ability to reabsorb filtered  $\text{Na}^+\text{-Cl}^-$ , leading to hypovolemia and neurohumoral activation. Typical causes include reflux nephropathy, interstitial nephropathies, cisplatin-associated kidney injury, postobstructive uropathy, medullary cystic disease, and the recovery phase of acute tubular necrosis. Diuretic therapy,

particularly with thiazides, causes hyponatremia via a number of mechanisms. Increased excretion of an osmotically active nonreabsorbable or poorly reabsorbable solute can also lead to volume depletion and hyponatremia; important causes include glycosuria, ketonuria, and bicarbonaturia (e.g., in proximal renal tubular acidosis, where the associated bicarbonaturia leads to loss of  $\text{Na}^+$ ). Finally, the syndrome “cerebral salt wasting” is a rare cause of hypovolemic hyponatremia caused by inappropriate natriuresis in association with intracranial disease; causative disorders include subarachnoid hemorrhage, traumatic brain injury, craniotomy, encephalitis, and meningitis. Distinction from the SIADH is difficult but critical for successful management, because cerebral salt wasting will typically respond to aggressive  $\text{Na}^+\text{-Cl}^-$  repletion.

### Hypervolemic Hyponatremia

Patients with hypervolemic hyponatremia develop an increase in total body  $\text{Na}^+\text{-Cl}^-$  that is accompanied by a proportionately greater increase in total body water, leading to a reduced serum  $[\text{Na}^+]$ . Again, the causative disorders can be separated by the effect on urine  $[\text{Na}^+]$ , with acute or chronic renal failure uniquely associated with an increase in urine  $[\text{Na}^+]$  (see Fig. 59.2); advanced renal insufficiency can reduce the ability to excrete free water, leading to hyponatremia. The pathophysiology of hyponatremia in the  $\text{Na}^+$ -avid edematous disorders (CHF, cirrhosis, and nephrotic syndrome) is similar to that in hypovolemic hyponatremia except that the arterial perfusion pressure is decreased because of the specific etiologic factors, such as cardiac dysfunction in CHF. Urine  $[\text{Na}^+]$  is typically very low (i.e.,  $<10$  mEq); this  $\text{Na}^+$ -avid state may be obscured by diuretic therapy depending on the timing of sample collection, schedule and choice of diuretics, and so forth. The degree of hyponatremia is an indirect index of the associated neurohumoral activation (see Table 59.1) and thus an important prognostic indicator in hypervolemic hyponatremia. Management consists of treating the underlying disorder (e.g., angiotensin-converting enzyme [ACE]-inhibition in heart failure),  $\text{Na}^+$  restriction, diuretic therapy, and, when appropriate, water restriction. Vasopressin antagonists (vaptans) are effective in normalizing hyponatremia associated with both cirrhosis and CHF. However, tolvaptan is contraindicated in cirrhosis because of drug-associated liver toxicity and should not be used for  $>30$  days in patients with CHF. Conivaptan, a mixed V1a/V2 receptor antagonist, must also be used with caution in cirrhosis given the potential for hypotension and/or renal insufficiency caused by blockade of V1a vasopressin receptors.

### Euvolemic Hyponatremia

SIADH is the most common cause of euvolemic hyponatremia (Table 59.2). Other causes include hypothyroidism and secondary adrenal insufficiency caused by pituitary disease; whereas the deficit in circulating aldosterone in primary adrenal insufficiency causes hypovolemic hyponatremia, the predominant glucocorticoid deficiency in secondary adrenal failure leads to euvolemic hyponatremia. Common

**TABLE 59.2** Causes of the Syndrome of Inappropriate Antidiuresis

Malignant Diseases	Pulmonary Disorders	Disorders of the CNS	Drugs	Other Causes
Carcinoma	Infections	Infection	Drugs that stimulate release of AVP or enhance its action	Hereditary (gain of function mutations in the vasopressin V2, receptor)
Lung	Bacterial pneumonia	Encephalitis	Chlorpropamide	Idiopathic
Small cell	Viral pneumonia	Meningitis	SSRIs	Transient
Mesothelioma	Pulmonary abscess	Brain abscess	Tricyclic antidepressants	Endurance exercise
Oropharynx	Tuberculosis	Rocky Mountain spotted fever	Clofibrate (Atromid-S, Wyeth-Ayerst)	General anesthesia
GI tract	Aspergillosis	AIDS	Carbamazepine (Epitol, Lemnon; Tegretol, and Ciba-Geigy)	Nausea
Stomach	Asthma	Bleeding and masses	Vincristine (Oncovin, Vincasar, Pharmacia and Upjohn)	Pain
Duodenum	Cystic fibrosis	Subdural hematoma	Nicotine	Stress
Pancreas	Respiratory failure associated with positive-pressure breathing	Subarachnoid hemorrhage	Narcotics	
GU tract		Cerebrovascular accident	Antipsychotic drugs	
Ureter		Brain tumors	Ifosfamide (Ifex, Bristol-Myers Squibb; Neosar, Pharmacia and Upjohn)	
Bladder		Head trauma	NSAIDs	
Prostate		Hydrocephalus	MDMA	
Endometrium		Cavernous sinus thrombosis	AVP analogues	
Endocrine thymoma		Other	Desmopressin (DDAVP, Rhone-Poulenc Rorer; Stimat, Centeon)	
Lymphomas		Multiple sclerosis	Oxytocin (Pitocin, Parke-Davis; Syntocinon, Novartis)	
Sarcomas		Guillain-Barré syndrome	Vasopressin	
Ewing sarcoma		Shy-Drager syndrome		
		Delirium tremens		
		Acute intermittent porphyria		

*AVP*, Arginine vasopressin; *CNS*, central nervous system; *GI*, gastrointestinal; *GU*, genitourinary; *MDMA*, 3,4-methylenedioxymethamphetamine ("Ecstasy"); *NSAIDs*, nonsteroidal antiinflammatory drugs; *SSRI*, selective serotonin reuptake inhibitor.

From Ellison DH, Berl T. Syndrome of inappropriate antidiuresis. *N Engl J Med*.2007;356:2064–2072.

causes of SIADH include pulmonary disease (e.g., pneumonia, tuberculosis, pleural effusion) and CNS diseases (e.g., tumor, subarachnoid hemorrhage, meningitis); SIADH also occurs with malignancies, primarily small cell lung carcinoma, and drugs; most commonly the selective serotonin reuptake inhibitors (SSRIs; see [Table 59.2](#)).

The initial treatment of euvolemic hyponatremia should include treatment or withdrawal of the underlying cause if feasible and appropriate. Water restriction to <1 L per

day is a cornerstone of therapy but may be ineffective or poorly tolerated; thirst is also stimulated in these patients at lower than the usual "physiologic" osmolalities. Patients who fail to respond to water restriction can be treated with loop diuretics to inhibit the countercurrent mechanism and reduce urinary concentration, combined with oral salt tablets to replace diuretic-induced salt loss. Historically, oral demeclocycline has been used to treat SIADH that fails water restriction or furosemide (Lasix)/salt tablets; this

agent can, however, cause acute kidney injury and necessitates close follow-up of renal function. Vaptans are highly effective at normalizing serum  $[Na^+]$  in almost all patients with SIADH. Conivaptan, the only available intravenous vaptan in the United States, can be used as an alternative to hypertonic saline for maintaining eunatremia in critically ill patients with SIADH. However, oral tolvaptan (currently the only available oral vaptan in the United States) should not be used for more than 30 days and should not be used in patients with liver disease given the risk of liver toxicity. Given these limitations, therapy with tolvaptan should be reserved for SIADH patients who have serum  $[Na^+]$  that remains  $<120$  mEq or who have persistent neurologic symptoms attributed to hyponatremia.

### Treatment of Hyponatremia

Three primary considerations guide the therapy of hyponatremia. First, the presence and/or severity of symptoms determine the urgency of therapy. Patients with acute hyponatremia (Box 59.1) present with symptoms that can include headache, nausea and/or vomiting, altered mental status, seizures, obtundation, and/or death. Patients with chronic hyponatremia (present for  $>48$  hours) are less likely to be symptomatic but may demonstrate subtle deficits in neuropsychologic function including gait abnormalities and an increased risk of falls. Chronic hyponatremia also increases the risk of bony fractures caused by the increased risk of falls and to a hyponatremia-associated reduction in bone density. Second, patients with chronic hyponatremia are at risk for osmotic demyelination syndrome, typically central pontine myelinolysis, if serum  $[Na^+]$  is corrected by  $>10$  to  $12$  mEq within the first 24 hours and/or by  $>18$  mEq within the first 48 hours. Brain cells in chronic hyponatremia reduce the intracellular concentration of organic osmolytes (creatine, betaine, glutamate, and taurine) to cope with hypoosmolality. The intracellular reaccumulation of these solutes is attenuated and delayed after reestablishment of normal tonicity, leading to osmotic demyelination in the setting of overly rapid correction of hyponatremia. Third, the response of the serum  $[Na^+]$  to interventions such as hypertonic saline or vasopressin antagonists can

#### • BOX 59.1 Causes of Acute Hyponatremia

Iatrogenic

- Postoperative; premenopausal women
- Hypotonic fluids with cause of ↑ vasopressin

- Colonoscopy preparation
- Recent institution of thiazides

Polydipsia

MDMA (“Ecstasy” or “Molly”) ingestion

Exercise induced

Multifactorial, such as thiazide and polydipsia

MDMA, 3,4-Methylenedioxymethamphetamine (“Ecstasy”); TURP, transurethral resection of the prostate.

be highly unpredictable, such that frequent monitoring of serum  $[Na^+]$  (every 2–4 hours) is required during therapy with these measures.

Acute symptomatic hyponatremia can occur in several clinical settings (see Box 59.1). This syndrome is a medical emergency; a sudden drop in serum  $[Na^+]$  can overwhelm the capacity of the brain to regulate cell volume, leading to massive cerebral edema. Notably, this may occur after relatively modest acute reductions in serum  $[Na^+]$ . Premenopausal women are particularly prone to severe symptoms of acute hyponatremia; neurologic consequences are comparatively rare in male patients. A critical and often overlooked complication is respiratory failure, which may be hypercapnic because of CNS depression or normocapnic because of neurogenic, noncardiogenic pulmonary edema; the associated hypoxia amplifies the impact of hyponatremic encephalopathy. Many of these patients develop hyponatremia from iatrogenic causes, including hypotonic fluids in the postoperative period, prescription of a thiazide diuretic, colonoscopy preparation, or intraoperative use of glycine irrigants. Polydipsia occurring with a cause of increased AVP may also cause acute hyponatremia, as with increased water intake in the setting of strenuous exercise (e.g., marathon-associated hyponatremia). The recreational drug Ecstasy (3,4-methylenedioxymethamphetamine) can also cause acute hyponatremia, rapidly inducing both AVP release and increased thirst.

Treatment of acute symptomatic hyponatremia should include hypertonic saline to acutely increase serum  $[Na^+]$  by 1 to 2 mEq/h to a total increase of 4 to 6 mEq; this increase is typically sufficient to alleviate acute symptoms, after which corrective guidelines for chronic hyponatremia are appropriate (see later). A number of equations have been developed to estimate the required rate of hypertonic solution; one popular approach is to calculate a “ $Na^+$  deficit,” where the  $Na^+$  deficit =  $0.6 \times$  body weight  $\times$  (target  $[Na^+] -$  starting  $[Na^+]$ ). However, a major caveat is that the increase in serum  $[Na^+]$  can be highly unpredictable during treatment with hypertonic saline, caused by rapid changes in the underlying physiology; serum  $[Na^+]$  should be monitored every 2 to 4 hours with appropriate adjustments in the rate of administered saline. In hypokalemic patients,  $K^+-Cl^-$  replacement can also lead to an increase in serum  $[Na^+]$ , given that serum  $[Na^+]$  is a function of exchangeable  $Na^+$  and  $K^+$ , divided by whole body water; this phenomenon can also lead to an overly rapid correction in serum  $[Na^+]$  in chronic hyponatremia (see later).

The administration of supplemental oxygen and ventilatory support can also be critical in acute hyponatremia in the event that patients develop acute pulmonary edema or hypercapnic respiratory failure. Intravenous loop diuretics will help treat acute pulmonary edema and will also increase free water excretion, by interfering with the renal counter-current multiplication mechanism. It should be emphasized that vaptans do not have a role in the management of acute symptomatic hyponatremia.

The management of chronic hyponatremia is complicated significantly by the asymmetry of the cellular response

to correction of serum  $[Na^+]$ . Specifically, the reaccumulation of protective organic osmolytes by brain cells is attenuated and delayed as osmolality increases after correction of hyponatremia, sometimes resulting in degenerative loss of oligodendrocytes and the “osmotic demyelination syndrome” (ODS). Overly rapid correction of hyponatremia is also associated with a disruption in integrity of the blood-brain barrier, allowing the entry of immune mediators that may contribute to demyelination in ODS. The lesions of ODS classically affect the pons; clinically, patients with “central pontine myelinolysis” can present one or more days after overcorrection of hyponatremia with paraparesis or quadraparesis, dysphagia, dysarthria, diplopia, a “locked-in syndrome,” and/or loss of consciousness. Other regions of the brain can also be involved; clinical presentation of ODS varies as a function of the extent and localization of this extrapontine myelinolysis, with the reported development of ataxia, mutism, parkinsonism, dystonia, and catatonia. “Relowering” of serum  $[Na^+]$  after overly rapid correction can prevent or attenuate ODS. However, even appropriately “slow” correction can be associated with ODS, particularly in patients with additional risk factors; these include alcoholism, malnutrition, hypokalemia, and liver transplantation.

To reduce the risk of ODS, the rate of correction should be comparatively slow in chronic hyponatremia, no greater than 10 to 12 mEq in the first 24 hours and no greater than 18 mEq in the first 48 hours but preferably much less of an increase. Should patients overcorrect serum  $[Na^+]$  in response to vasopressin antagonists, hypertonic saline, or isotonic saline (in chronic hypovolemic hyponatremia), hyponatremia can be safely reinduced or stabilized by the administration of the vasopressin agonist desmopressin acetate (DDAVP) and the administration of free water, typically intravenous 5% dextrose in water (D5W). In patients with marked initial hyponatremia, a more linear, controlled increase in serum  $[Na^+]$  can be achieved by using high-dose DDAVP to “clamp” vasopressin activity, in combination with a slow infusion of hypertonic saline.

## Hypernatremia

Hypernatremia is usually the result of a combined water and volume deficit, with losses of water in excess of  $Na^+$ . Elderly individuals with reduced thirst and/or diminished access to fluids are at the highest risk of developing hypernatremia. Patients with hypernatremia may rarely have a central defect in hypothalamic osmoreceptor function, with a mixture of both decreased thirst and reduced AVP secretion; causes include primary or metastatic tumor, occlusion or ligation of the anterior communicating artery, trauma, hydrocephalus, and inflammation. More commonly, hypernatremia develops following the loss of water via renal or nonrenal routes, combined with a reduced intake of water. “Insensible losses” of water caused by evaporation from the skin or respiratory tract may increase in the setting of fever, exercise, heat exposure, severe burns, or mechanical ventilation. Diarrhea is in turn the most common gastrointestinal cause

## • BOX 59.2 Causes of Diabetes Insipidus

### Central Diabetes Insipidus

- Pituitary surgery
- Head trauma
- Tumors
- Cerebrovascular event or hypoxic encephalopathy
- Infections
- Idiopathic—? autoimmune
- Granulomatous disease—sarcoid, histiocytosis X
- Hereditary—autosomal dominant mutations in preprovasopressin/neurophysin, Wolfram syndrome

### Nephrogenic Diabetes Insipidus

- Genetic
  - X-linked— $V_2$  vasopressin receptor
  - Autosomal recessive/dominant—aquaporin-2
  - Autosomal recessive—aquaporin-1 (proximal tubule and thin limb)
- Drug-induced (e.g., lithium, cisplatin, demeclocycline, ifosfamide, foscarnet)
- Hypokalemia
- Hypercalcemia
- Infiltrating lesions (e.g., sarcoidosis, amyloidosis)
- Cellular defect (e.g., after acute tubular necrosis)

### Gestational Diabetes Insipidus (DI)

- Preexisting DI
- Transient DI during pregnancy
- DI after delivery

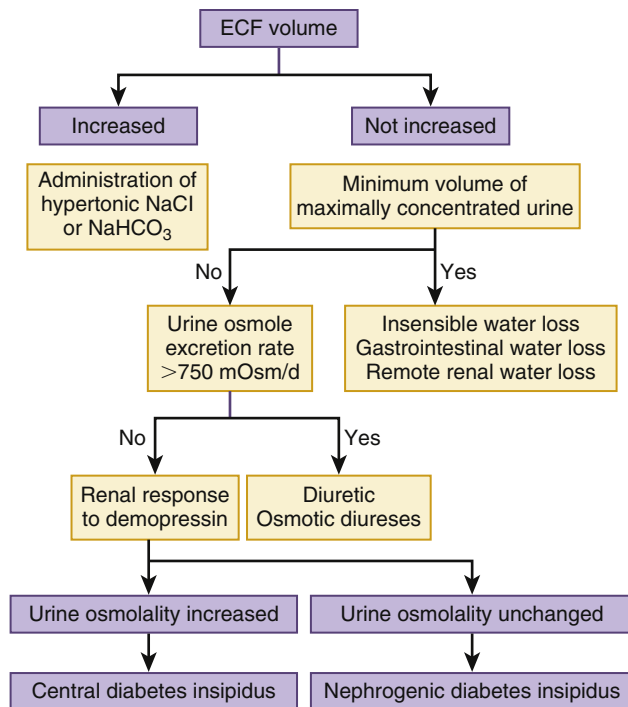

of hypernatremia. Osmotic diarrhea and viral gastroenteritis typically generate stools with  $Na^+$  and  $K^+ < 100$  mEq, thus leading to water loss and hypernatremia; secretory diarrheas typically result in isotonic stool and hypovolemia  $\pm$  hypovolemic hyponatremia.

Common causes of renal water loss include osmotic diuresis secondary to hyperglycemia, postobstructive diuresis, or drugs (e.g., mannitol). Water diuresis per se occurs in central or nephrogenic diabetes insipidus (DI). The various causes of central and nephrogenic DI are listed in [Box 59.2](#). Nephrogenic DI is most commonly caused by therapy with lithium, which inhibits the renal response to AVP and can cause chronic distal tubular injury. Gestational DI is a rare complication of pregnancy wherein increased activity of a placental protease with vasopressinase activity leads to reduced circulating AVP; DDAVP is an effective therapy, given its resistance to the enzyme. Finally, the ingestion or iatrogenic administration of excess  $Na^+$  is a rare cause of hypernatremia, typically occurring with the intravenous (IV) administration of excess hypertonic  $Na^+-Cl^-$  or sodium bicarbonate ( $Na^+-HCO_3^-$ ).

### Diagnostic Approach

The history should focus on the presence or absence of thirst, polyuria, and/or an extrarenal source for water loss such as diarrhea. The physical examination should include a detailed neurologic examination and assessment of the extracellular fluid volume; accurate documentation of daily fluid intake and daily urine output is also required.

• **Fig. 59.3** The diagnostic approach to hypernatremia. See text for details. *ECF*, Extracellular fluid; *NaCl*, sodium chloride; *NaHCO<sub>3</sub>*, sodium bicarbonate. (From Singer GG, Brenner BM. Fluid and electrolyte disturbances. In: Fauci AS, Braunwald E, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008:274–284.)

Laboratory investigation should include a measurement of serum and urine osmolality in addition to urine electrolytes. The appropriate response to hypernatremia and a serum osmolality  $>295$  mOsm/kg is the excretion of low volumes ( $<500$  mL/d) of maximally concentrated urine,  $>800$  mOsm/kg; should this be the case, then an extrarenal source of water loss is primarily responsible. Patients with hypernatremia often exhibit polyuria; should an osmotic diuresis be responsible, with excessive excretion of  $\text{Na}^+\text{-Cl}^-$ , glucose, and/or urea, then daily solute excretion will be  $>750\text{--}1,000$  mOsm per day ( $>15$  mOsm/kg body water per day; Fig. 59.3). More typically, patients with hypernatremia and polyuria will have a predominant water diuresis with excessive urination of hypotonic urine. Adequate differentiation between nephrogenic and central causes of DI, if not apparent from the clinical scenario, requires an assessment of the response in urinary osmolality to DDAVP combined with measurement of circulating AVP; patients with nephrogenic DI will fail to respond to DDAVP, with a high circulating AVP level. Notably, water deprivation testing is inappropriate in hypernatremic patients, because they are already hypertonic (with adequate stimulus for AVP release). For patients with hypernatremia caused by renal loss of water it is critical to quantify ongoing daily losses using the formula for electrolyte-free water clearance in addition to calculation of the baseline water deficit (the relevant formulas are discussed in Box 59.3).

### • BOX 59.3 Management of Hypernatremia

#### Water Deficit

1. Estimate total-body water (TBW): 50%–60% body weight (kg) depending on body composition
2. Calculate free-water deficit:  $[(\text{Na}^+ - 140)/140] \times \text{TBW}$
3. Administer deficit over 48–72 h

#### Ongoing Water Losses

4. Calculate free-water clearance,  $C_{\text{eH}_2\text{O}}$ :

$$C_{\text{eH}_2\text{O}} = V(1 - [U_{\text{Na}} + U_{\text{K}}/S_{\text{Na}}])$$

where  $V$  is urinary volume,  $U_{\text{Na}}$  is urinary  $[\text{Na}^+]$ ,  $U_{\text{K}}$  is urinary  $[\text{K}^+]$ , and  $S_{\text{Na}}$  is serum  $[\text{Na}^+]$

#### Insensible Losses

5.  $\sim 10$  mL/kg/d: less if ventilated, more if febrile

#### Total

6. Add components to determine water deficit and ongoing water loss; correct the water deficit over 48–72 h, and replace daily water loss

From Mount DB. Electrolytes/acid-base. In: Fauci A, Braunwald E, Kasper D, et al., eds. *Harrison's Manual of Medicine*. 17th ed. New York: McGraw-Hill; 2009:3–21.

### Treatment of Hypernatremia

The approach to the management of hypernatremia is outlined in Box 59.3. As with hyponatremia, it is advisable to correct the water deficit slowly to avoid neurologic compromise, decreasing serum  $[\text{Na}^+]$  over 48 to 72 hours. Depending on the blood pressure or clinical volume status, it may be appropriate to initially treat with hypotonic saline solutions (1/4 or 1/2 normal saline). Blood glucose should be monitored in patients treated with large volumes of D5W should hyperglycemia occur. Calculation of urinary electrolyte-free water clearance is helpful to estimate daily, ongoing loss of free water in patients with nephrogenic or central DI (see Box 59.3). Other forms of therapy may be helpful in selected cases of hypernatremia after the normalization of the serum  $[\text{Na}^+]$  has been accomplished with free water repletion. Patients with central DI may respond to the administration of intranasal desmopressin (DDAVP). Patients with nephrogenic DI caused by lithium may reduce their polyuria with amiloride (2.5–10 mg/d) or hydrochlorothiazide (12.5–50 mg/d). These diuretics are thought to increase proximal water reabsorption and decrease distal solute delivery, thus reducing polyuria. Amiloride also decreases entry of lithium into principal cells in the distal nephron by inhibiting the amiloride-sensitive epithelial sodium channel (ENaC), thus reducing the effect of lithium within principal cells. In practice, however, most patients with lithium-associated DI are able to compensate for their polyuria by simply increasing their water intake. Occasionally nonsteroidal antiinflammatory drugs (NSAIDs) have also been used to treat polyuria associated with nephrogenic DI, reducing the negative effect of local prostaglandins on

urinary concentration; however, the nephrotoxic potential of NSAIDs typically limits their utility in this setting.

## Potassium Disorders

$K^+$  is the major intracellular cation, and extracellular  $K^+$  constitutes <2% of total-body  $K^+$  content. In consequence, changes in the exchange and distribution of intracellular and extracellular  $K^+$  can lead to marked hypokalemia or hyperkalemia. Insulin,  $\beta_2$ -adrenergic agonists, thyroid hormone, and alkalosis tend to promote  $K^+$  uptake by cells, leading to hypokalemia. For example, hyperthyroid patients can present with hypokalemic periodic paralysis with intermittent weakness accompanied by hypokalemia, hypomagnesemia, and hypophosphatemia; more common in males of Asian or Latin American origin, this disorder responds dramatically to the nonselective beta-blocker propranolol, followed by treatment of the underlying thyroid disease. In contrast, acidosis, insulinopenia, or acute hyperosmolality (e.g., after treatment with mannitol) promotes the efflux of  $K^+$  from tissues, leading to hyperkalemia. A corollary is that massive necrosis and the attendant release of tissue  $K^+$  can cause severe hyperkalemia, particularly in the setting of acute kidney injury and reduced excretion of  $K^+$ . Hyperkalemia caused by rhabdomyolysis is thus particularly common, because of the enormous store of  $K^+$  in muscle.

Changes in body  $K^+$  content are primarily mediated by the kidney, which reabsorbs filtered  $K^+$  in hypokalemic,  $K^+$ -deficient states and secretes  $K^+$  in hyperkalemic,  $K^+$ -replete states. Although  $K^+$  is transported along the entire nephron, it is the principal cells of the connecting segment and cortical collecting duct that play a dominant role in renal  $K^+$  excretion. Apical  $Na^+$  entry into principal cells via the amiloride-sensitive epithelial sodium channel (ENaC) generates a lumen-negative potential difference, which drives passive  $K^+$  exit through apical  $K^+$  channels (Fig. 59.4). Knowledge of this relationship is critical for the bedside understanding of  $K^+$  disorders. For example, decreased distal delivery of  $Na^+$  in prerenal states reduces the lumen-negative potential difference and blunts the ability to excrete  $K^+$ , leading to hyperkalemia. Hyperkalemia is also a predictable consequence of drugs that directly inhibit ENaC, such as amiloride, triamterene, trimethoprim (in trimethoprim/sulfamethoxazole), and pentamidine. Aldosterone has a major influence on  $K^+$  excretion, increasing the activity of ENaC channels and thus amplifying the driving force for  $K^+$  secretion across the luminal membrane of principal cells; abnormalities in the renin-angiotensin-aldosterone system can cause both hypokalemia and hyperkalemia.

## Hypokalemia

Hypokalemia, defined as a serum  $[K^+]$  of <3.6 mEq, occurs in up to 20% of hospitalized patients. Major causes of hypokalemia are outlined in Box 59.4. The severity of the manifestations of hypokalemia tends to be proportionate to the degree and duration of the reduction in serum

• **Fig. 59.4** Potassium ( $K^+$ ) secretory pathways in principal cells of the connecting segment and cortical collecting duct. The absorption of sodium ( $Na^+$ ) via the amiloride-sensitive epithelial sodium channel (ENaC) generates a lumen-negative potential difference, which drives  $K^+$  excretion through the apical secretory  $K^+$  channel ROMK/SK (renal outer medullary  $K^+$  channel/secretory  $K^+$  channel). Flow-dependent  $K^+$  secretion is mediated by an apical voltage-gated, calcium-sensitive BK (big potassium) channel. *Aqp4*, Aquaporin 4; *ATP*, adenosine triphosphate. (From Mount DB, Zandi-Nejad K. Disorders of potassium balance. In: Brenner BM, ed. *Brenner and Rector's the Kidney*. 9th ed. Philadelphia: Saunders; 2012:640–688.)

$[K^+]$ . Symptoms generally do not become manifest until the serum  $[K^+]$  is <3 mEq/L, unless the serum  $[K^+]$  falls rapidly or the patient has a potentiating factor such as a predisposition to arrhythmia caused by the use of digitalis. Atrial and ventricular arrhythmias are the most serious consequences. Hypokalemia also prolongs the QT interval and can synergize in provoking arrhythmia in patients with other causes of a prolonged QT, such as genetic long QT syndrome. Other clinical manifestations include muscle weakness, which may be profound at serum  $[K^+] < 2.5$  Eq/L. If hypokalemia is sustained, patients may develop hypertension, polyuria, renal cysts, and renal failure.

The cause of hypokalemia is usually obvious from history, physical examination, and/or basic laboratory tests. However, persistent hypokalemia may require a more thorough evaluation (Fig. 59.5). The history should focus on medications (e.g., laxatives, diuretics, antibiotics), diet and dietary habits (e.g., licorice), and symptoms that suggest a particular cause (e.g., periodic weakness, diarrhea). The physical examination should pay particular attention to blood pressure, volume status, and signs suggestive of specific hypokalemic disorders such as hyperthyroidism and Cushing syndrome. Initial laboratory evaluation should include electrolytes, blood urea nitrogen (BUN), creatinine, serum osmolality, magnesium ( $Mg^{2+}$ ), and  $Ca^{2+}$ , a complete

blood count, and urinary pH, osmolality, creatinine, and electrolytes. The presence of a nonanion-gap acidosis suggests a distal, hypokalemic renal tubular acidosis or diarrhea; calculation of the urinary anion gap can help differentiate these two diagnoses. The urine anion gap is calculated as urine  $[Na^+]$  plus urine  $[K^+]$  minus urine  $[Cl^-]$ . The ammonium ion  $NH_4^+$  should be the major “unmeasured cation” in acidemic patients, such that the physiologically appropriate urinary anion gap (as in diarrhea with normal renal function) should be a negative value; patients with renal tubular acidosis will have a positive value for the urine anion gap. Measurement of a spot urine  $[K^+]$  is not particularly helpful, given the effect of variations in urine volume. To correct for changes in urine volume, the serum and urine osmolality can be used for calculation of the transtubular  $K^+$  gradient (TTKG), which should be  $<3$  in the presence of hypokalemia (see also Hyperkalemia); urine from patients with “redistributive” hypokalemia (e.g., in thyrotoxic paralysis) will have a TTKG of  $<2$  to  $3$ , whereas urine from patients with renal  $K^+$  wasting will typically have a TTKG of  $>4$ . Measurement of the urine  $K^+$ -to-creatinine ratio can also correct for variations in urine volume. The urine  $K^+$ -to-creatinine ratio is usually  $<13$  mEq/g creatinine (1.5 mEq/mmol creatinine) when hypokalemia is caused by poor dietary intake, transcellular  $K^+$  shifts, gastrointestinal losses, that is, “nonrenal” causes. Further tests such as urinary  $Mg^{2+}$  and  $Ca^{2+}$ , urine diuretic screens, and/or plasma renin and aldosterone levels may be necessary in specific cases. The most common causes of chronic, diagnosis-resistant hypokalemia are Gitelman syndrome (hereditary hypokalemic alkalosis with hypomagnesemia and hypocalciuria), surreptitious vomiting, and diuretic abuse; each has specific

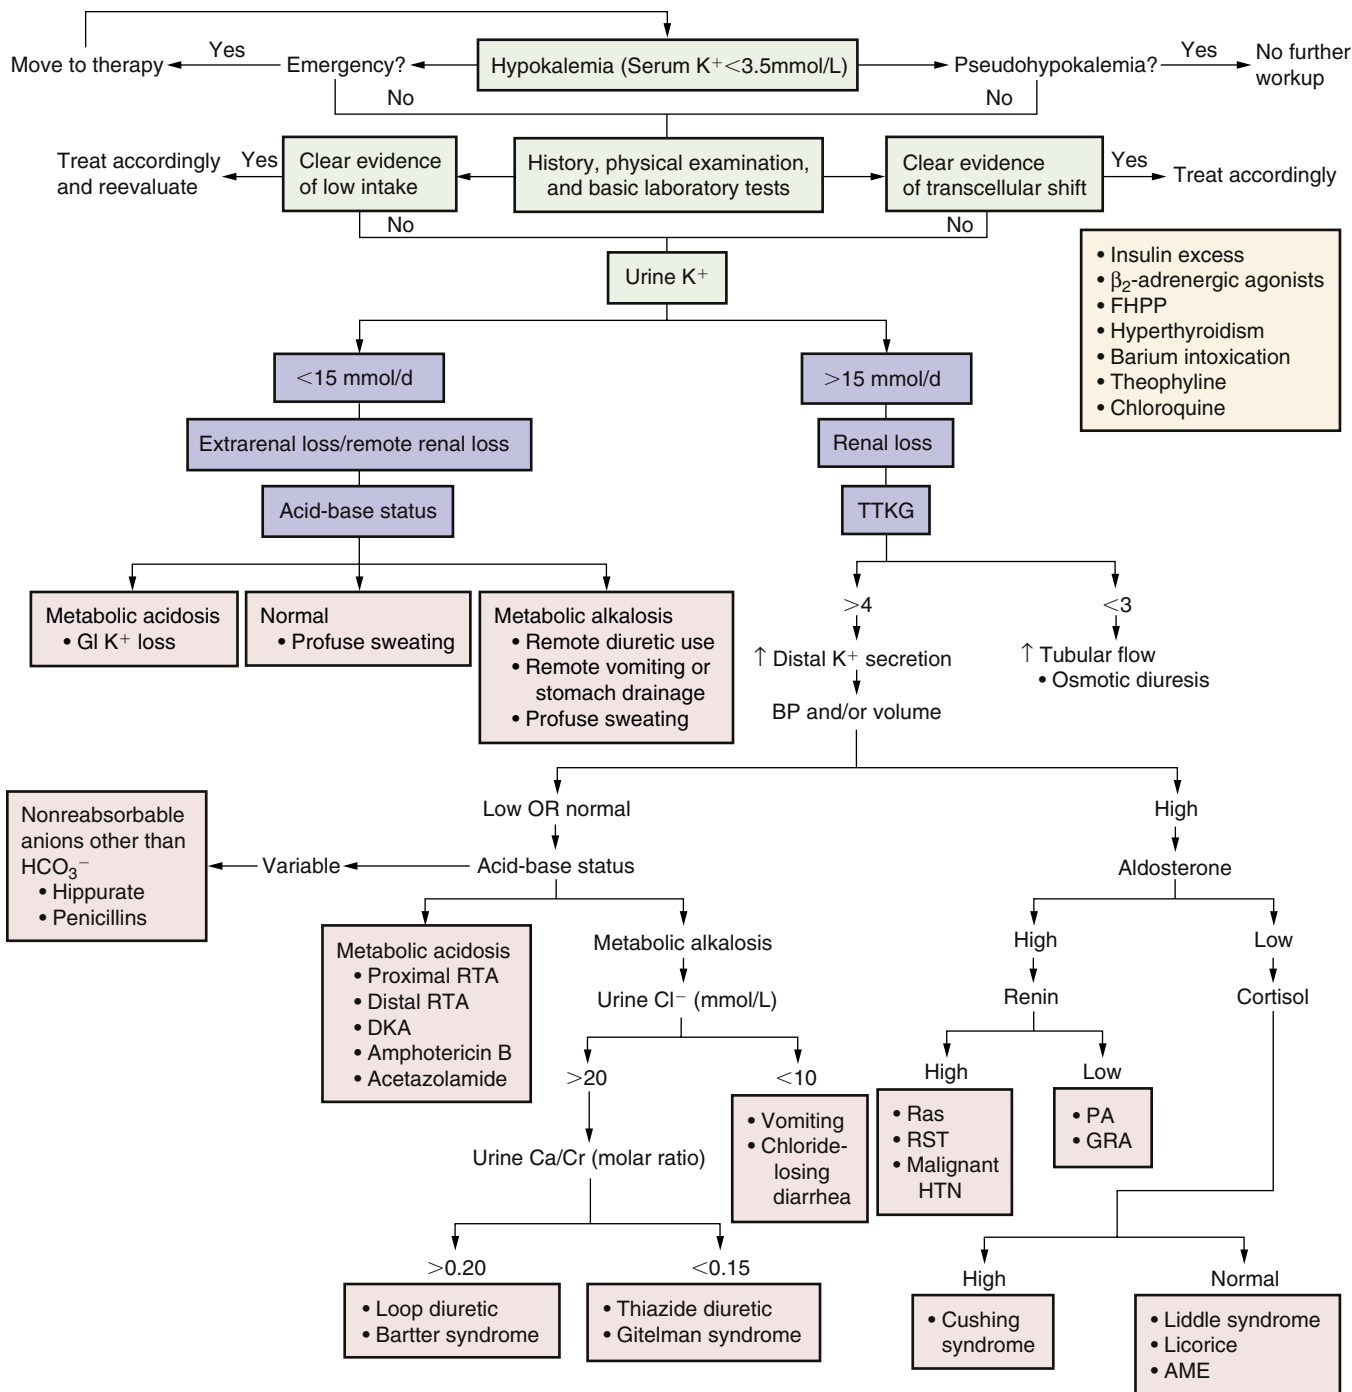

patterns of urine electrolytes. Urinary testing for diuretics may be positive in patients with diuretic abuse.

### Treatment of Hypokalemia

The assessment of the hypokalemic patient begins with evaluation of muscle strength and obtaining an electrocardiogram (EKG), with particular attention to the QT interval. At serum  $[K^+] <2.5$  mEq/L, severe muscle weakness and/or marked electrocardiographic changes may be present that require immediate treatment. Telemetry or continuous EKG monitoring is indicated for hypokalemic patients with a prolonged QT, other EKG changes associated with hypokalemia, and/or underlying cardiac issues that predispose to arrhythmia in the setting of hypokalemia (digoxin toxicity, hypomagnesemia, myocardial infarction, underlying long QT syndrome, etc.).

The underlying cause of hypokalemia should be identified as quickly as possible, particularly the presence of hypomagnesemia or redistributive hypokalemia. Hypokalemia is refractory to correction in the presence of  $Mg^{2+}$  deficiency, which must also be corrected when present. A potential complication of  $K^+$  therapy in redistributive hypokalemia is rebound hyperkalemia as the initial process causing redistribution rapidly resolves or is corrected; such patients can develop fatal hyperkalemic arrhythmias.

The goals of  $K^+$  replacement in patients with hypokalemia caused by  $K^+$  losses are to rapidly raise the serum  $[K^+]$  to a safe level and then replace the remaining deficit at a slower rate over days to weeks. Estimation of the  $K^+$  deficit and careful monitoring of the serum  $[K^+]$  helps to prevent hyperkalemia caused by excessive supplementation. This assumes that there is a normal distribution of  $K^+$  between

• **Fig. 59.5** The diagnostic approach to hypokalemia. See text for details. AME, Apparent mineralocorticoid excess; BP, blood pressure; CCD, cortical collecting duct; DKA, diabetic ketoacidosis; FHPP, familial hypokalemic periodic paralysis; GI, gastrointestinal; GRA, glucocorticoid remediable aldosteronism; HTN, hypertension; PA, primary aldosteronism; RAS, renal artery stenosis; RST, renin secreting tumor; RTA, renal tubular acidosis; TTKG, transtubular potassium gradient. (From Mount DB, Zandi-Nejad K. Disorders of potassium balance. In: Brenner BM, ed. *Brenner and Rector's the Kidney*. 9th ed. Philadelphia: Saunders; 2012.)

the cells and the extracellular fluid; the most common settings where this does not apply are diabetic ketoacidosis or nonketotic hyperglycemia and in redistributive causes of hypokalemia such as hypokalemic periodic paralysis. In patients with hypokalemia caused by K<sup>+</sup> losses, the deficit varies directly with the severity of hypokalemia. In hypokalemia, the serum [K<sup>+</sup>] drops by approximately 0.27 mEq/L

for every 100 mEq reduction in total body K<sup>+</sup> stores. However, estimates of this deficit are only an approximation of the amount of K<sup>+</sup> replacement required to normalize the serum [K<sup>+</sup>], and careful monitoring is therefore required with frequent measurement of serum [K<sup>+</sup>] during repletion.

K<sup>+</sup> chloride is the preferred form for oral repletion. If hypokalemia is severe (<2.5 mEq/L) and/or if oral

### • BOX 59.5 Causes of Hyperkalemia

- I. "Pseudo"-hyperkalemia
  - A. Cellular efflux; thrombocytosis, leukocytosis, in vitro hemolysis
  - B. Hereditary defects in red cell membrane transport
- II. Intracellular to extracellular shift
  - A. Acidosis
  - B. Hyperosmolality; radiocontrast, hypertonic dextrose, mannitol
  - C. Beta<sub>2</sub>-adrenergic antagonists (noncardioselective agents)
  - D. Digoxin or ouabain poisoning
  - E. Hyperkalemic periodic paralysis
  - F. Lysine and epsilon-aminocaproic acid (structurally similar, positively charged)
- III. Inadequate excretion
  - A. Inhibition of the renin-angiotensin-aldosterone axis; ↑ risk of hyperkalemia when used in combination
    1. ACE inhibitors
    2. Renin inhibitors; aliskiren (in combination with ACE inhibitors or ARBs)
    3. ARBs
    4. Blockade of the mineralocorticoid receptor; spironolactone, eplerenone
    5. Blockade of the ENaC; amiloride, triamterene, trimethoprim, pentamidine, nafamostat
  - B. Decreased distal delivery
    1. Congestive heart failure
    2. Volume depletion
    3. NSAIDs, cyclosporine
  - C. Hyporeninemic hypoaldosteronism
    1. Tubulointerstitial diseases; SLE, sickle cell anemia, obstructive uropathy
    2. Diabetes, diabetic nephropathy
    3. Drugs; NSAIDs, beta-blockers, cyclosporine
    4. Chronic kidney disease, advanced age
  - D. Renal resistance to mineralocorticoid
    1. Tubulointerstitial diseases; SLE, amyloidosis, sickle cell anemia, obstructive uropathy, post-ATN
    2. Hereditary; pseudohypoaldosteronism type I; defects in the mineralocorticoid receptor or the ENaC
  - E. Advanced renal insufficiency with low GFR
  - F. Primary adrenal insufficiency
    1. Autoimmune; Addison disease, polyglandular endocrinopathy
    2. Infectious; HIV, CMV, TB, disseminated fungal infection
    3. Infiltrative; amyloidosis, malignancy, metastatic cancer
    4. Drug-associated; heparin, low-molecular-weight heparin
    5. Hereditary; adrenal hypoplasia congenita, congenital lipid adrenal hyperplasia, aldosterone synthase deficiency
    6. Adrenal hemorrhage or infarction; may occur in antiphospholipid syndrome

ACE, Angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; ATN, acute tubular necrosis; CMV, cytomegalovirus; ENaC, epithelial sodium channel; GFR, glomerular filtration rate; HIV, human immunodeficiency virus; NSAIDs, nonsteroidal antiinflammatory drugs; SLE, systemic lupus erythematosus; TB, tuberculosis. From Mount DB. Electrolytes/acid-base. In: Fauci A, Braunwald E, Kasper D, et al, eds. *Harrison's Manual of Medicine*. 17th ed. New York: McGraw-Hill; 2009:3–21.

supplementation is not feasible or tolerated, intravenous K<sup>+</sup>-Cl<sup>-</sup> can be administered through a central vein with cardiac monitoring and frequent measurement of serum [K<sup>+</sup>] in an intensive care setting, at rates which should not exceed 20 mEq/h. Intravenous K<sup>+</sup>-Cl<sup>-</sup> should always be administered in saline solutions, rather than dextrose; the dextrose-induced increase in insulin can acutely exacerbate hypokalemia.

Chronic hypokalemia can generally be managed by correction of the underlying disease process or withdrawal of a causative medication, combined with oral K<sup>+</sup>-Cl<sup>-</sup> supplementation. If loop or thiazide diuretic therapy cannot be discontinued, a distal tubular K<sup>+</sup>-sparing agent, such as amiloride or spironolactone, can be added to the regimen if otherwise appropriate and indicated.

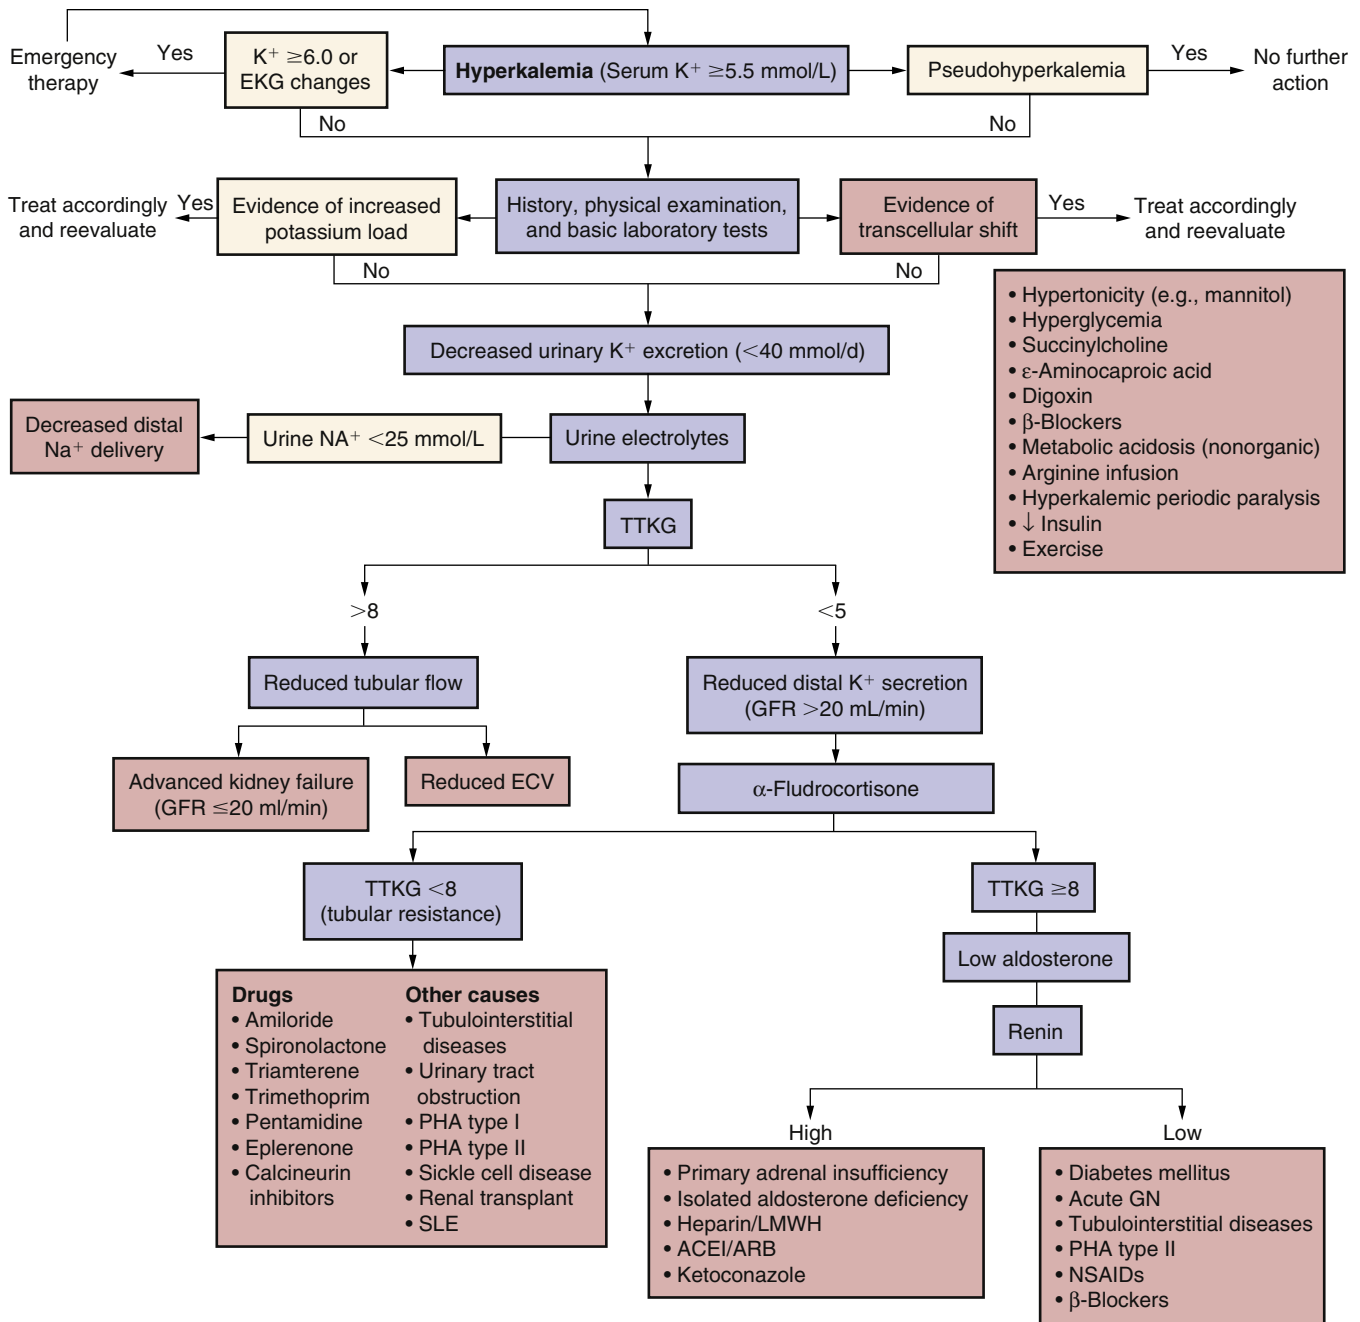

## Hyperkalemia

Hyperkalemia is usually defined as a serum [K<sup>+</sup>] of ≥5.5 mEq/L, occurring in up to 10% of hospitalized patients. Hyperkalemia is most frequently caused by a decrease in renal K<sup>+</sup> excretion (Box 59.5). However, dietary K<sup>+</sup> intake can have a major, rapid effect on serum [K<sup>+</sup>] in susceptible patients such as diabetics with hyporeninemic hypoaldosteronism and chronic kidney disease. Drugs that affect the RAA are also a frequent cause of hyperkalemia when these

agents are coadministered, for example spironolactone with an angiotensin receptor blocker.

The first priority in the management of hyperkalemia is to assess the need for emergency treatment (EKG changes and/or [K<sup>+</sup>] ≥6.5–7.0 mEq/L). This should be followed by a comprehensive workup to determine the cause (Fig. 59.6). History and physical examination should focus on medications (e.g., ACE inhibitors, NSAIDs, trimethoprim/sulfamethoxazole), diet and dietary supplements (e.g., salt substitutes), risk factors for acute kidney failure, reduction in urine output, blood pressure, and volume status. Initial laboratory tests should include electrolytes, BUN, creatinine, serum osmolality, Mg<sup>2+</sup>, and Ca<sup>2+</sup>, a complete blood count, and urinary pH, osmolality, creatinine, and electrolytes. A urine [Na<sup>+</sup>] <20 mEq indicates that distal Na<sup>+</sup> delivery may be a limiting factor in K<sup>+</sup> excretion; volume repletion with 0.9% saline or treatment with furosemide (Lasix) may then be effective in reducing serum [K<sup>+</sup>], by increasing distal Na<sup>+</sup> delivery. Serum and urine osmolality are required for calculation of the TTKG. The expected values of the TTKG are largely based on historical data and are <3 in the presence of hypokalemia and >7 to 8 in the presence of hyperkalemia.

$$\text{TTKG} = \frac{[\text{K}^+]_{\text{urine}} \times \text{Osm}_{\text{serum}}}{[\text{K}^+]_{\text{serum}} \times \text{Osm}_{\text{urine}}}$$

(From Mount DB, Zandi-Nejad K. Disorders of potassium balance. In: Brenner BM, ed. *Brenner and Rector's the Kidney*. 9th ed. Philadelphia: Saunders; 2012.)

### Treatment of Hyperkalemia

The most important consequence of hyperkalemia is altered cardiac conduction with the risk of bradycardic arrest. Fig. 59.7 shows the typical EKG patterns of hyperkalemia; EKG manifestations of hyperkalemia should be considered a true medical emergency and treated urgently. However, EKG changes of hyperkalemia are notoriously insensitive,

particularly in patients with chronic kidney disease; given these limitations, patients with significant hyperkalemia ( $[K^+] \geq 6.5$  to  $7$  mEq/L) in the absence of EKG changes should also be aggressively managed.

Urgent management of hyperkalemia includes a 12-lead EKG, admission to the hospital, continuous cardiac monitoring, and immediate treatment. Treatment of hyperkalemia

• **Fig. 59.7** Typical serial EKG changes in hyperkalemia. (Modified from Slovis C, Jenkins R. ABCs of electrocardiography; conditions not primarily affecting the heart. *BMJ*. 2002;324:1320–1323.)

(Table 59.3) is divided into three categories: (1) antagonism of the cardiac effects of hyperkalemia, (2) rapid reduction in [K<sup>+</sup>] by redistribution into cells, and (3) removal of K<sup>+</sup> from the body. Treatment of hyperkalemia is summarized in Boxes 59.1, 59.2, and 59.3. Kayexalate, an ion-exchange resin (Na<sup>+</sup> polystyrene sulfonate) that exchanges Na<sup>+</sup> for K<sup>+</sup> in the GI tract, is frequently prescribed for the acute and chronic treatment of hyperkalemia. Kayexalate is almost invariably administered with sorbitol, to prevent constipation. Unfortunately, the administration of Kayexalate with sorbitol has been associated with intestinal necrosis, a rare but often fatal complication. In September of 2009 the US Food and Drug Administration (FDA) warned against coadministering Kayexalate with sorbitol because of the risk of intestinal necrosis; more recently, case reports have appeared of intestinal necrosis from Kayexalate without sorbitol, such that avoiding coadministration may not prevent this complication. It should be emphasized that the onset of action of Kayexalate is at best 4 to 6 hours, such that it has little impact on the acute management of hyperkalemia. Therefore clinicians must carefully consider whether emergency treatment with Kayexalate is actually necessary for the treatment of hyperkalemia. However, there are settings where the risk-benefit analysis favors the administration of Kayexalate for treatment of hyperkalemia, for example in oliguric renal failure without possibility of dialysis. Notably, single 30-g doses of Kayexalate are rarely effective, with repeated doses required for a substantial effect on serum [K<sup>+</sup>]. Finally, an alternative to Kayexalate has recently emerged, with the FDA approval of patiomer, another binding resin that is not expected to have the same gastrointestinal toxicity; hypomagnesemia can, however, occur with patiomer, requiring replacement therapy.

**TABLE 59.3** Management of Hyperkalemia

Mechanism	Therapy	Dose	Onset	Duration	Comments
Stabilize membrane potential	Calcium	10% Ca-gluconate, 10 mL over 10 min	1–3 min	30–60 min	Repeat in 5 min if persistent EKG changes; use with caution in digoxin toxicity
Cellular K <sup>+</sup> uptake	Insulin	10 U R with 50 mL of D50, if BS <250	30 min	4–6 h	Can repeat in 15 min; initiate D10W IV at 50–75 mL/h to avoid rebound hypoglycemia
	β <sub>2</sub> -agonist	Nebulized albuterol, 10–20 mg in 4 mL saline	30 min	2–4 h	Can be synergistic/additive to insulin; should not be used as sole therapy; use with caution in cardiac disease; may cause tachycardia/hyperglycemia
K <sup>+</sup> removal	Kayexalate	30–60 g orally in 20% sorbitol	4–6 h	?	May cause ischemic colitis and colonic necrosis
	Furosemide	20–250 mg IV	15 min	4–6 h	Dependent on adequate renal response/function
	Hemodialysis		immediate		Efficacy depends on pretreatment of hyperkalemia, the dialyzer used, blood flow and dialysate flow rates, duration, and serum to dialysate K <sup>+</sup> gradient

BS, Blood sugar; EKG, electrocardiogram; IV, intravenously.

## Chapter Review

### Questions

1. You admit a 40-year-old woman with a one-week history of flu-like illness and profuse diarrhea. She has received 1.5 L of normal saline (N/S).

On examination, heart rate is 80 beats per minute supine, 105 beats per minute standing, and blood pressure is 110/70 mm Hg. Jugular venous pressure (JVP) is seen at 5 cm.

Admission laboratory studies:  $\text{Na}^+$  = 121 mEq/L;  $\text{K}^+$  = 3.6 mEq/L; urine  $\text{Na}^+$  = 12 mEq; urine Osm = 450 mOsm/kg.

Current laboratory data (6 h after admission to emergency department [ED]):  $\text{Na}^+$  = 130 mEq/L;  $\text{K}^+$  = 3.5 mEq/L; urine  $\text{Na}^+$  = 18 mEq; urine Osm = 300 mOsm/kg.

Which of the following therapies is the most appropriate?

- N/S at 200 mL/h
  - N/S with 40 mEq/L at 200 mL/h
  - Conivaptan 40-mg load then continuous infusion at 20 mg/d
  - D5W at 75 mL/h
  - D5W at 75 mL/h, after 1  $\mu\text{g}$  of DDAVP
2. Therapy with which of the following drugs is most likely to cause nephrogenic DI associated with acute renal insufficiency?
- Foscarnet
  - Interferon-alfa
  - Acyclovir
  - Ganciclovir
  - Vincristine
3. A 20-year-old woman is brought to the ED with altered mental status. She attended a “rave” in the South End of Boston the night before admission. She became drowsy at ~2 AM and vomited several times. At 8 AM she had a generalized seizure that lasted ~15 seconds.

On examination she was unresponsive, heart rate was 84 beats per minute, respiratory rate 16 breaths per minute, blood pressure 145/85 mm Hg. Her head and neck were normal. Her heart sounds were normal, she had a clear chest, and there was no peripheral edema. There was no evidence of trauma.

Laboratory studies:  $\text{Na}^+$  = 121 mEq/L; creatinine = 0.5 mg/dL;  $\text{K}^+$  = 3.6 mEq/L; uric acid = 3.7 mg/dL;  $\text{Cl}^-$  = 90 mEq/L; Osm = 242 mOsm/Kg.

Which of the following is the most likely cause of this syndrome?

- Ecstasy-induced hyponatremia
  - Hyponatremia secondary to seizure
  - Occult brain tumor
  - Acute intracerebral bleed
  - Compulsive drinking
4. Which of the following measures is the single most appropriate management of this patient’s hyponatremia (patient in Question 3)?

- IV infusion of conivaptan, the FDA-approved vasopressin antagonist
  - IV infusion of 3% saline
  - IV infusion of mannitol to reduce intracerebral edema
  - IV infusion of furosemide (Lasix)
  - Urgent neurosurgical consultation
5. A 32-year-old Hispanic man is admitted with weakness and a  $\text{K}^+$  of 2 mEq/L. He was very healthy until 2 months before admission, when he developed intermittent leg weakness. He denies drug or laxative abuse and is not taking any medications. Family history is notable for his mother who has diabetes mellitus and one sister with thyroid disease. On examination, his temperature is 97.2°F, blood pressure is 176/96 mm Hg, and heart rate is 102 beats per minute. His respiratory rate is 16 breaths per minute. The rest of his examination is normal.

### Laboratory Data

	At Admission	5 Months Before Admission
Na	139 mEq/L	143 mEq/L
K	2.0 mEq/L	3.8 mEq/L
Cl	105 mEq/L	107 mEq/L
$\text{HCO}_3^-$	26 mEq/L	29 mEq/L
BUN	11 mg/dL	16 mg/dL
Creatinine	0.6 mg/dL	1.0 mg/dL
Glu	145 mg/dL	136 mg/dL
$\text{PO}_4$	1.2 mg/dL	
Ca	8.8 mg/dL	8.8 mg/dL
Mg	1.3 mg/dL	1.9 mg/dL
Albumin	3.8 mg/dL	

Which of the following studies is most likely to be diagnostic?

- Serum parathyroid hormone
  - Serum aldosterone
  - Serum insulin
  - Urine pH and urine electrolytes
  - Thyroid function studies
6. A 63-year-old man is admitted to the hospital for confusion attributed to hepatic encephalopathy. You are asked to see him for evaluation of a low bicarbonate. Physical examination reveals mild jaundice and ascites.
- Laboratory studies:  $\text{Na}^+$  = 134 mEq/L; arterial blood gas = 7.32/29/80/15;  $\text{K}^+$  = 5.4 mEq/L; urine pH = 6.0;  $\text{Cl}^-$  = 110 mEq/L; urine  $\text{Na}^+$  = 2 mEq;  $\text{HCO}_3^-$  = 14 mEq/L; anion gap = 10.
- Which of the following is the most likely cause of this patient’s metabolic acidosis and hyperkalemia?
- Excessive backleak of  $\text{H}^+$  in the collecting duct
  - Diarrhea from lactulose
  - Impaired proximal bicarbonate reabsorption
  - Insufficient distal  $\text{Na}^+$  delivery
  - Adrenal insufficiency

## Acid-Base Disturbances

GEAROID M. MCMAHON

The tight regulation of acid-base balance in the body reflects the importance of pH in a biological function, and the extracellular hydrogen ion concentration is therefore maintained at very low levels (~40 nEq/L). This regulation is required because many cellular functions are extremely pH sensitive, for example, both protein synthesis and carbohydrate metabolism. Protein function is altered by the presence of bound hydrogen ions, and this binding changes with very small alterations in the pH. The delivery of oxygen to the brain and skeletal muscle is dependent on extracellular pH via the shift in the oxyhemoglobin dissociation curve. Cellular pH is generally lower than extracellular pH because of electronegativity within cellular structures whereas pH is also important in transcellular transport processes including increased acid extrusion from cells when the cellular pH drops fall.

### Signs and Symptoms of Acid-Base Disorders

Many of the symptoms of acid-base disorders are neurologic in nature. For example, patients who hyperventilate and develop respiratory alkalemia frequently feel light headed and may even lose consciousness, related to a marked elevation in pH and decreased oxygen delivery to brain cells. Fortunately, the brain can rapidly and almost completely compensate for acid-base disturbances. Alkalemia can also be associated with tetany because of low ionized calcium levels.

Patients with metabolic acidosis may have insensitivity to sympathomimetic drugs and may note fatigue, dyspnea on exertion, and deep ventilatory excursions known as *Kussmaul respiration*. Nausea and vomiting are common symptoms that may be mistaken for uremia in a patient with kidney disease.

### Definitions

The terms *acidosis* and *alkalosis* must be distinguished from *acidemia* and *alkalemia*. Abnormalities in blood pH are termed *acidemia* (pH of <7.36) or *alkalemia* (pH of >7.44). Acidosis and alkalosis refer to the abnormal processes that

contribute to the alterations in the blood pH. Multiple processes acting in opposing directions can be present simultaneously. These include respiratory or metabolic acidosis and respiratory or metabolic alkalosis. Because an individual can have many processes leading to a single alteration in blood pH in the acid or alkali direction, one must be able to single out those individual processes even if they are masked by other coinciding disturbances. The place to start in making these distinctions is from clues in the patient's history. Examples include vomiting, which would suggest an alkalotic process caused by chloride (Cl) losses in the vomitus, or diarrhea, which would be more likely to produce an acidotic rather than an alkalotic process caused by bicarbonate ( $\text{HCO}_3^-$ ) losses, although the latter is possible in the setting of Cl-rich diarrhea in patients with cholera. A patient with chronic lung disease might have chronic hypoventilation and respiratory acidosis, whereas a patient with chronic renal disease may be more prone to developing a metabolic acidosis attributed to an inability to excrete acid in the kidney. Because patients can have multiple processes, including more than one metabolic disturbance, it becomes necessary to try to recognize these independent disturbances that together may result in a blood pH that is normal, acidemic, or alkalemic.

### Analysis of Acid-Base Disorders

It is common practice to use the carbon dioxide ( $\text{CO}_2$ ) and  $\text{HCO}_3^-$  measurements in arterial or venous blood when analyzing an acid-base problem. Arterial blood gas measurements include a direct measurement of pH and partial pressure of  $\text{CO}_2$  ( $\text{Pco}_2$ ) and a calculated value of  $\text{HCO}_3^-$ . Venous measurements are less invasive but do not usually give information about oxygenation. Note that the venous pH is typically 0.05 pH units more acid than arterial pH, and venous  $\text{Pco}_2$  is usually 6 mm Hg higher than corresponding arterial  $\text{Pco}_2$ . These relationships may change in patients who are hypometabolic, hypothermic, or are in low cardiac output states.

The Henderson-Hasselbach equation is a logarithmic expression of the overall chemical reactions between  $\text{CO}_2$  in water, carbonic acid ( $\text{H}_2\text{CO}_3$ ), and the  $\text{HCO}_3^-$  concentrations. The determination of  $\text{CO}_2$  in solution is approximated

by the product of the measured  $P_{CO_2}$  and the solubility of  $CO_2$  in aqueous media. The equation is as follows:

$$pH = pK + \log \left( \frac{HCO_3^-}{0.03 \times P_{CO_2}} \right)$$

From this relationship, it is evident that the pH is proportional to the ratio of  $HCO_3^-/P_{CO_2}$  rather than simply  $HCO_3^-$  or  $P_{CO_2}$ . A rise in the  $HCO_3^-$  concentration without a proportional rise in the  $P_{CO_2}$  will result in alkalosis. Thus the compensatory process for a primary change in one of the variables,  $HCO_3^-$  or  $P_{CO_2}$ , is a change in the other variable in the same direction, tending to normalize the ratio and bringing the pH back toward normal.

## Compensations

*Compensations* refer to internal modifications, usually involving pulmonary or renal function, that help regulate body fluid pH. Such modifications are self-correcting: primary metabolic disorders result in respiratory compensation, and primary respiratory disorders lead to metabolic (renal) compensations (Table 60.1). Acidemia and alkalemia result from the inability to adequately compensate for the primary acid-base abnormality. For example, patients with severe lung disease may not be able to compensate adequately for metabolic disturbances, and patients with renal disease may not be able to compensate adequately for respiratory disorders. Patients with central nervous system (CNS) disease may also not compensate normally for respiratory or metabolic disturbances.

The pulmonary system acts along with the kidneys to mitigate the effects of primary respiratory acid-base disorders. For example, in patients with lung disease leading to  $CO_2$  retention (primary respiratory acidosis), the increased  $CO_2$  recognized in the carotid body chemosensor will send an afferent signal to the brainstem, which will then attempt to increase ventilation. This compensation may be inadequate with a persistent elevation in  $CO_2$ . The kidney will then both increase  $HCO_3^-$  reabsorption in the tubules and increase ammoniogenesis, allowing for more hydrogen ( $H^+$ ) to be eliminated leading to a secondary metabolic alkalosis. The limitation of this compensation will be the kidney's ability to generate ammonia.

Hyperventilation, in contrast, lowers  $P_{CO_2}$  and elevates the pH (primary respiratory alkalosis). The pulmonary response to the elevated pH and low  $P_{CO_2}$  is to signal the medullary centers of the brain to slow ventilation; yet, as in the respiratory acidosis setting, the respiratory response will be incomplete. The renal response is to decrease both  $HCO_3^-$  reabsorption (resulting in an alkaline,  $HCO_3^-$ -rich urine) and ammonium ( $NH_4^+$ ) excretion.

The expected degree of compensation for primary respiratory disorders is shown in Table 60.2. Because the compensatory mechanism takes time to be effective, the degree of expected compensation is different in acute versus chronic respiratory acidosis and alkalosis. In general, there is more complete compensation in chronic disorders with a greater degree of correction in patients with respiratory alkalosis.

**TABLE 60.1** Initial Changes in  $HCO_3^-$  and  $P_{CO_2}$  in Primary Acid-Base Disorders

pH	$P_{CO_2}/HCO_3^-$	Primary Disorder
Acidemia	$\downarrow HCO_3^-$	Metabolic acidosis
	$\downarrow P_{CO_2}$	Respiratory acidosis
Alkalemia	$\uparrow HCO_3^-$	Metabolic alkalosis
	$\downarrow P_{CO_2}$	Respiratory alkalosis

**TABLE 60.2** Compensations for Acid-Base Disorders

Abnormality	Adjustment
Metabolic acidosis	Expected $P_{CO_2} = 1.5 \times (HCO_3^-) + 8$
Metabolic alkalosis	Expected $P_{CO_2} = 0.9 \times (HCO_3^-) + 9$
Acute respiratory acidosis	Each increase in $P_{CO_2}$ of 1, pH should decrease by 0.008
Acute respiratory alkalosis	Each decrease in $P_{CO_2}$ of 1, pH should increase by 0.008
Chronic respiratory acidosis	Each increase in $P_{CO_2}$ of 1, pH should decrease by 0.003
Chronic respiratory alkalosis	Each decrease in $P_{CO_2}$ of 1, pH should increase by 0.003

Metabolic disturbances require both renal and pulmonary responses to compensate and adapt to a change in pH (see Table 60.2). For example, a metabolic acidosis from diarrhea, resulting in acidemia and a low  $HCO_3^-$  concentration, will stimulate the chemosensors signaling to the brain to initiate hyperventilation. This response will help bring the pH back toward normal, but it will fall short of complete compensation. Possible reasons for this include limitations on pulmonary function, but they could also be an energy-sparing adaptation that allows for a less severe degree of hyperventilation and use of respiratory muscles while the most dangerous drops in pH are avoided. The renal limitation for compensating for a metabolic acidosis has to do with physiologic limits on the production of ammonia.

Metabolic alkalosis causes chemosensor stimulation leading to medullary hypoventilation and a secondary respiratory acidosis. The kidney compensates by increasing  $HCO_3^-$  excretion. However, this compensation is incomplete because of a number of factors that develop in metabolic alkalosis that conserve  $HCO_3^-$  and therefore limit the correction in pH. These include Cl depletion, decreases in glomerular filtration rate, volume depletion, potassium ( $K^+$ ) depletion, and hypercapnia, all of which enhance proximal  $HCO_3^-$  reabsorption. This limitation may be partially beneficial by limiting fluid and  $K^+$  losses.

Compensatory responses are usually complete in hours to days. Table 60.2 shows the expected compensation in patients with a variety of acid-base disorders. Significant

differences between the calculated and observed values of  $P_{CO_2}$ , pH, and  $HCO_3^-$  suggest the presence of a mixed disorder. For example, the Winter formula expresses the relationship between  $P_{CO_2}$  and  $HCO_3^-$  in individuals with a metabolic acidosis:

$$P_{CO_2} = 1.5(HCO_3^-) + 8 \pm 2$$

In a patient with a primary metabolic acidosis, the calculated  $P_{CO_2}$  should lie within the range suggested by this formula. However, if the measured  $P_{CO_2}$  is lower than expected, this suggests the presence of a simultaneous primary respiratory acidosis. Alternatively, if the measured  $P_{CO_2}$  is higher than expected, this suggests the presence of a primary respiratory alkalosis. This classically occurs in patients with salicylate toxicity. These individuals develop an anion-gap metabolic acidosis because of increased lactic acid production. However, the salicylate directly stimulates the respiratory center leading to disproportionate hyperventilation and a simultaneous respiratory alkalosis.

The approach to diagnosing an acid-base disorder is shown in **Box 60.1**. First, identify whether the patient is acidemic or alkalemic. Second, determine if the primary disorder is respiratory or metabolic. Next, calculate the expected compensation to identify a second disorder. If an acidosis is present, calculate the anion gap, delta anion gap, and the osmolar gap.

## Metabolic Acidosis

A metabolic acidosis results from the consumption of endogenous alkali stores and is characterized by a fall in the serum  $HCO_3^-$ . There are four major mechanisms through which a metabolic acidosis can develop: (1) the pathologic overproduction of endogenous acids (ketoacids and lactic acid); (2) the ingestion of exogenous substances, which are either acids (salicylates) or are metabolized to acid in the body (methanol); (3) a failure of renal acid excretion and  $HCO_3^-$  regeneration (renal failure and distal renal tubular acidosis [RTA]); and (4) loss of alkali stores (diarrhea and proximal RTA).

### Anion-Gap Metabolic Acidosis

The classification of metabolic acidoses begins with the calculation of the serum anion gap. This is defined as the difference between the major measured cation (sodium [Na]) and the major anions (Cl and  $HCO_3^-$ ):

$$[Na] - [Cl + HCO_3^-] = \text{anion gap}$$

Physiologically, no gap truly exists, and the anion gap represents the presence of unmeasured anions in the serum that are not directly measured. The primary contributor to the anion gap is negative charges on circulating proteins (mostly albumin). This is because although other cations ( $K^+$ , calcium, magnesium) and anions (phosphates, sulphates) are present, the concentration of these is small and they tend to balance each other out. Thus

### • BOX 60.1 General Approach to an Acid-Base Disorder

1. Is there an acidemia or alkalemia?  
Acidemia =  $pH \leq 7.35$   
Alkalemia =  $pH \geq 7.45$
2. What is the primary process (metabolic or respiratory)?  
[ $HCO_3^-$ ] defines the metabolic component
  - Low ( $<24$  mEq/L) = metabolic acidosis
  - High ( $>28$  mEq/L) = metabolic alkalosis $P_{CO_2}$  defines the respiratory component
  - Low ( $<35$  mm Hg) = respiratory alkalosis
  - High ( $>45$  mm Hg) = respiratory acidosis
3. Is there an appropriate compensatory response?
  - Remember the direction of compensation
  - Remember that compensation is almost never complete
  - Remember the Winter formula  
In a metabolic acidosis, the predicted  $P_{CO_2}$  is  $(1.5 \times HCO_3^-) + 8 \pm 2$
4. If this is an anion-gap acidosis, are there other clues to a second primary process?  
Calculate the delta anion gap/delta  $HCO_3^-$  (delta-delta)
  - For every 1 mEq/L of acid added to circulation, the serum bicarbonate should decrease by 1 mEq/L, and the anion gap should increase by 1 mEq/L.
  - Thus the delta anion gap/delta  $HCO_3^-$  should be 1.  
Delta anion gap/delta  $HCO_3^-$ :  
1 Simple anion-gap acidosis  
 $<1$  Superimposed nongap acidosis  
 $>1$  Superimposed metabolic alkalosis
5. Is there an osmolar gap?  
Measured osmolarity – calculated osmolarity ( $2 \times [Na] + BUN/2.8 + \text{glucose}/18$ )  
Osmolar gap  $>10$  suggests the presence of an added osmole. Usually a toxic alcohol.

BUN, Blood urea nitrogen.

the normal value for the anion gap (8–12 mEq) must be adjusted for the albumin concentration. For every 1 g/dL reduction in the serum albumin concentration, the anion gap falls by 2.5 mEq/L. If the gap is higher than normal, this indicates the presence of an unmeasured anion such as lactate. If the gap is lower than normal (after adjusting for the serum albumin concentration), there may be an unmeasured cation. Although hypercalcemia and hypermagnesemia theoretically could cause a low anion gap, even in cases with markedly elevated values, the change in anion gap is no more than 2 to 3 mEq/L. Classically a low anion gap is seen in patients with lithium toxicity and in multiple myeloma (IgG paraproteins tend to be positively charged).

Anion-gap acidoses often do not exist in isolation, and there may be a simultaneous metabolic alkalosis or nongap acidosis. When an anion-gap acidosis develops, the hydrogen ions generated are buffered by the serum  $HCO_3^-$  such that there is a 1-point decrease in the  $HCO_3^-$  concentration for every one-point increase in the anion gap (unmeasured anion). This relationship is known as the delta-delta, and calculating this ratio can help determine if a mixed disorder is present.

**TABLE 60.3 Causes of a High Anion-Gap Metabolic Acidosis**

Cause	Notes
Glycols (ethylene, propylene)	
Oxoproline	Acetaminophen excess
L-Lactate	Type A: decreased perfusion or oxygenation Type B: medication/intoxication/ inborn error of metabolism
D-Lactate	
Methanol	
Aspirin	Often associated with respiratory alkalosis
Renal failure	May be simultaneous nongap acidosis
Ketosis	Starvation Alcoholic Diabetic

For example, if there is a large increase in the anion gap without a lesser decrease in the  $\text{HCO}_3^-$  concentration ( $\Delta\Delta > 1$ ), this suggests that there is a simultaneous metabolic alkalosis. This is classically seen in patients on hemodialysis who commonly have an elevated anion gap (caused by retention of sulphates and phosphates) and a normal  $\text{HCO}_3^-$  (caused by  $\text{HCO}_3^-$  administration during dialysis). A  $\Delta\Delta < 1$  (greater than expected fall in the  $\text{HCO}_3^-$  level relative to the anion gap) occurs in individuals with a mixed gap and nongap metabolic acidosis. This can occur in the setting of chronic kidney disease and may also be seen in patients treated with large volumes of normal saline in the setting of hypovolemic shock (lactic acidosis + hyperchloremic acidosis).

The causes of an anion-gap metabolic acidosis are shown in Table 60.3. Classically, the mnemonic MUDPILES was suggested to aid in remembering these; however, this has been superseded by the more modern GOLDMARK, which includes newly recognized, common causes of an anion-gap acidosis.

In cases where an ingestion of toxic alcohol is suspected, the osmolar gap may be useful as a preliminary test before getting alcohol levels, which may not be available immediately and where treatment cannot be delayed. The osmolar gap is the difference between the measured osmolarity (by freezing point depression) and the calculated osmolarity:

$$2 \times [\text{Na}^+] + [\text{Glucose}]/18 + [\text{BUN}]/2.8$$

The difference between the measured and calculated osmolarity should be  $< 10$  mOsm/kg. If it is greater than this, the presence of a nonelectrolyte should be suspected. Toxic alcohols, as they are uncharged, initially cause an increase in the osmolar gap. If they are metabolized to acids, over time, the osmolar gap will decrease while the anion gap

will increase. In cases where the underlying ingestion is unknown, there are particular clinical clues that can suggest the cause. These are summarized in Table 60.4. Note that isopropyl alcohol ingestion leads to ketosis with no anion-gap acidosis because the ketones are produced without consuming  $\text{HCO}_3^-$ . The goal of therapy is to prevent breakdown of these alcohols to their more toxic metabolites. All of these alcohols are metabolized by alcohol dehydrogenase and fomepizole, a competitive inhibitor of this enzyme, and an effective therapy in the early stages. Hemodialysis may be required to remove the metabolites if significant accumulation has occurred,

### Lactic Acidosis

Lactic acid is the normal end-product of anaerobic glucose metabolism. It exists in two forms: L-lactate and D-lactate. L-lactate is the only form produced in human cells. D-lactate is produced by bacterial lactate dehydrogenase in the gut and can accumulate in patients with intestinal overgrowth or short-gut syndrome. Remember that the usual test for lactate does not measure D-lactate, and if this is suspected, it must be ordered specifically.

Under normal circumstances, approximately 15 to 20 mmol/kg of L-lactic acid is produced daily. This lactate is metabolized to glucose and pyruvate in the liver and kidneys and does not accumulate. Lactic acidosis occurs when there is excessive lactate production or inadequate removal. Lactic acidosis is classified as type A or type B. Type A is the most common and results from tissue hypoperfusion (hypotensive shock, hypoxemia, or sepsis). Type B lactic acidosis is not associated with systemic hypoperfusion and is instead caused by reduced clearance or toxin-induced inhibition of oxidative phosphorylation. It is divided into three subtypes (Cohen-Woods classification). Type B1 is associated with systemic diseases including chronic kidney disease and liver failure (leading to decreased clearance) and malignancy. Lactic acidosis of malignancy may be caused by local ischemia in large tumors or increased aerobic glycolysis in tumor cells (Warburg effect). Type B2 is caused by drugs that are metabolized to lactic acid (propylene glycol) or that induce mitochondrial dysfunction (nucleoside reverse transcriptase inhibitors, propofol, linezolid, and the biguanides, phenformin and metformin). Type B3 results from congenital mitochondrial defects (MELAS [mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes]).

The treatment of lactic acidosis primarily involves managing the underlying disorder. The role of  $\text{HCO}_3^-$  therapy is controversial. For patients with a pH  $< 7.1$ , acidemia itself may cause myocardial depression, arterial vasodilatation, and impaired catecholamine responsiveness. In this setting,  $\text{HCO}_3^-$  therapy is recommended. However, there are no clinical studies that show a benefit of  $\text{HCO}_3^-$  therapy in lactic acidosis, and there are potential adverse effects. First,  $\text{HCO}_3^-$  may worsen intracellular acidosis. This is because  $\text{CO}_2$  is produced when  $\text{H}^+$  is buffered, and this rapidly moves into cells and accumulates. This may worsen cardiac

**TABLE 60.4** Clues in a Suspected Toxic Ingestion

Toxin	Metabolite	Anion-Gap Acidosis	Osmolar Gap	Clinical Features
Methanol	Formic acid	+	+	Alcoholic fetor Papilledema/visual problems
Ethylene glycol	Glyoxylic acid Oxalate	+	+	Acute kidney injury common Calcium oxalate crystals in the urine
Diethylene glycol	2-Hydroxyethoxy-acetic acid	+	+	Acute kidney injury common Ingestion of adulterated medicines
Propylene glycol	Lactic acid	+	+	Used as diluent for some medications (diazepam, Ativan)
Isopropanol	Acetone	-	+	History of rubbing alcohol ingestion Ketosis without acidosis
Ethanol	Acetic acid	+	+	Positive serum ketones Normal/low glucose History of alcohol abuse
Aspirin	Salicylic acid	+	-	Respiratory alkalosis Tinnitus/hearing problems

contractility and increase lactic acid production. Second, a rapid rise in extracellular pH may lower ionized calcium and thus increase the risk of cardiac arrhythmias. Third, in patients with inadequate ventilation,  $\text{HCO}_3^-$  therapy may worsen a respiratory acidosis. For these reasons,  $\text{HCO}_3^-$  therapy is not routinely recommended if the pH is  $>7.1$ .

### Salicylate Overdose

At physiologic doses, aspirin is rapidly absorbed from the stomach and is primarily protein bound meaning that it remains in the vascular space. It is metabolized in the liver to salicylic acid, which is then excreted in the urine. In the setting of overdose, the binding sites become saturated, and the ability of the liver to metabolize salicylate decreases, both of which lead to an increase in free salicylate levels and a prolongation of the half-life of the drug.

When the blood salicylate levels exceed 40 to 50 mg/dL, most patients will complain of symptoms including tinnitus, nausea, vomiting, and vertigo. Altered mental status is common and is caused by direct CNS toxicity of salicylate as well as cerebral edema.

Salicylates cause two major acid-base abnormalities. The initial disturbance is a respiratory alkalosis caused by direct stimulation of the respiratory center. Patients then develop an anion-gap metabolic acidosis. This is not caused by accumulation of salicylate itself (even at very high levels, it does not typically exceed 8 mmol/L) but results from interference with oxidative phosphorylation leading to a type B lactic acidosis and accumulation of ketoacids.

Alkalinization should be considered first-line therapy in all patients with salicylate toxicity. Salicylic acid is a weak acid, and in an alkaline environment it exists primarily in the ionized state thus preventing entry into the central nervous system. By maintaining salicylic acid in the ionized

form, alkalinization of the urine promotes excretion by preventing back diffusion from the tubular lumen and thus increases urinary losses. Alkalosis is not a contraindication to  $\text{HCO}_3^-$  therapy unless the blood pH is  $>7.6$ . Hemodialysis is an effective treatment for salicylate toxicity that should be reserved for severe cases. Indications for hemodialysis include the following:

1. Salicylate levels  $>100$  mg/dL (7.2 mmol/L)
2. Neurologic symptoms
3. Pulmonary or cerebral edema
4. Renal insufficiency
5. Poor response to conservative therapy

### Oxoproline

5-oxoproline acidemia is a relatively newly recognized but important cause of an anion-gap metabolic acidosis. In the past, it was seen in individuals with congenital glutathione synthase or oxoprolinase deficiency, but more recently it has been noted in patients with chronic acetaminophen use. Acetaminophen is metabolized to *N*-acetyl-*p*-benzoquinone imine (NAPQI). NAPQI is eliminated through conjugation with glutathione, which is depleted in the setting of chronic acetaminophen ingestion. The lack of glutathione disrupts the  $\gamma$ -glutamyl cycle leading to build-up of oxoproline causing a high anion-gap metabolic acidosis. This is often accompanied by hypokalemia as the oxoproline is freely filtered in the urine. For unclear reasons, the majority of affected patients are female. This may be related to lower levels of certain isoenzymes in the  $\gamma$ -glutamyl cycle in women. Most patients have other contributing factors including malnutrition, pregnancy, alcohol use, and low-protein diets. The treatment includes stopping the acetaminophen and administering  $\text{HCO}_3^-$ . In some cases, hemodialysis may be required. Other drugs that have been

**TABLE 60.5** Causes of a Nongap Metabolic Acidosis

Cause	Notes
Hyperalimentation	
Acetazolamide	And other carbonic anhydrase inhibitors (e.g., topiramate)
Renal tubular acidosis	Proximal and distal Associated with significant potassium losses
Diarrhea	Bicarbonate-rich
Ureteral diversions	
Pancreatic fistula	
Saline resuscitation	

associated with oxoproline include vigabatrin, flucloxacillin, and netilmicin through a similar mechanism.

Note that the anion-gap acidosis seen in acute acetaminophen toxicity is not related to oxoproline. Acetaminophen overdose rapidly depletes liver glutathione stores. This leads to a lactic acidosis from mitochondrial damage with new lactate formation along with decreased clearance of lactate resulting from liver toxicity.

## Hyperchloremic Acidosis

In this group of disorders (Table 60.5), the serum anion gap is normal because the fall in  $\text{HCO}_3^-$  concentration is balanced by an increase in the  $\text{Cl}^-$  concentration instead of an unmeasured anion. They are often associated with hypokalemia. For example, in the case of watery diarrhea with large stool volumes, the loss of  $\text{K}^+$  and  $\text{Na}^+$  are accompanied either by  $\text{HCO}_3^-$  or by organic anions of bacterial origin. Several forms of RTA are also associated with losses of  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{HCO}_3^-$ , resulting in a relatively increased  $\text{Cl}^-$  concentration in the blood to compensate for the loss of  $\text{HCO}_3^-$ . These disorders are usually distinguished from each other by the medical history, but evaluation of urine electrolytes may be useful. It can be useful to calculate the urinary anion gap (UAG):

$$\text{UAG} = (\text{U}_{\text{Na}} + \text{U}_{\text{K}}) - \text{U}_{\text{Cl}}$$

The primary mechanism for the excretion of acid in the kidneys is via  $\text{NH}_4^+$ . Under normal circumstances, this  $\text{NH}_4^+$  is excreted with  $\text{Cl}^-$  and other anions, and so the UAG is zero or negative. In the setting of a metabolic acidosis, if the kidneys are functioning normally, there is a marked increase in  $\text{NH}_4^+$  production leading to an increasingly negative UAG. A positive anion gap suggests that there is inadequate production of ammonia and is characteristic of a distal RTA. One situation where you can have preservation of renal ammonia generation with a positive UAG is if there is a large quantity of freely filtered anion in the urine, for example in individuals with toluene ingestion of

## • BOX 60.2 Type 1 Renal Tubular Acidosis (Distal)

### Pathophysiology

Distal tubule fails to excrete ammonium

### Causes

Autosomal dominant inherited disorder  
Systemic lupus erythematosus  
Sickle cell disease  
Nephrocalcinosis-related disorders  
  Hyperparathyroidism  
  Medullary sponge kidney  
Medications and toxins  
  Amphotericin B  
  Lithium  
  Toluene

### Clinical Features

Musculoskeletal weakness, recurrent nephrolithiasis

### Laboratory Data

Marked nongap metabolic acidosis ( $\text{HCO}_3^- < 15$  mEq/L)  
Elevated urine pH (>5.5) despite metabolic acidosis  
Hypokalemia

### Management: Bicarbonate Supplementation

Dose: 1–2 mEq/kg/d

ketoacidosis. However, in these cases, the urinary pH will be low, and generally, they will have a high anion-gap metabolic acidosis. RTA is an uncommon cause of metabolic acidosis in clinical practice. Key features of types 1 and 2 RTA are shown in Boxes 60.2 and 60.3.

There are some forms of hyperchloremic acidosis that are associated with high  $\text{K}^+$ . When these conditions involve renal disorders, they are frequently termed *type 4 RTAs*. Important disorders of the distal nephron at sites where both  $\text{K}^+$  and  $\text{H}^+$  are secreted and  $\text{Na}^+$  is reabsorbed include the following conditions. Hypoaldosteronism with low plasma renin can be the result of renin antagonists, beta-blockers, nonsteroidal antiinflammatory drugs, or autonomic neuropathies as in diabetes and amyloidosis. Hypoaldosteronism with a high plasma renin suggests adrenal insufficiency or selective hypoaldosteronism. There are renal tubular disorders that are associated with elevations of both renin and aldosterone. Of particular importance, when one notices a hyperkalemic hyperchloremic acidosis, is to consider systemic disorders such as systemic lupus, myeloma, light chain disease, or sickle cell nephropathy. It is critical to exclude urinary tract obstruction. In all of these conditions, the UAG will be positive, suggesting low  $\text{NH}_4^+$  excretion.

More  $\text{HCO}_3^-$  is needed to treat a proximal than distal RTA, because the proximal disorder is associated with large clearance of  $\text{HCO}_3^-$  as the serum  $\text{HCO}_3^-$  increases. It often requires very large quantities of  $\text{HCO}_3^-$  salts, whereas in distal RTA, an amount of  $\text{HCO}_3^-$  equal to the estimated acid load per day is all that is required to maintain acid-base balance. That amount is approximately 1 to 2 mEq of  $\text{H}^+$  per kilogram body weight per day.

### • BOX 60.3 Type 2 Renal Tubular Acidosis (Proximal)

#### Pathophysiology

Proximal tubule defect of bicarbonate reabsorption resulting in bicarbonate wasting

#### Causes

Medications  
Acetazolamide  
Topiramate  
Fanconi syndrome  
Medullary cystic disease  
Multiple myeloma

#### Clinical Features

Failure to thrive, growth retardation, dehydration, lethargy

#### Laboratory Data

Nonanion-gap metabolic acidosis ( $\text{HCO}_3^-$  not usually  $<15$  mEq/L)  
Urine pH exceeds 5.5 except in severe metabolic acidosis  
Fractional excretion  $\text{HCO}_3^-$  exceeds 15% if serum bicarbonate  $>20$  mEq/L

#### Management

High-dose bicarbonate supplementation  
Oral bicarbonate 10–25 mEq/kg/d  
Observe for hypokalemia  
Treat osteomalacia in adults and rickets in children  
Vitamin D supplementation  
Calcium supplementation  
Sodium phosphate 1.6 g/d

## Metabolic Alkalosis

Metabolic alkalosis is characterized by an elevation of the serum  $\text{HCO}_3^-$  concentration with compensatory hypoventilation resulting in an elevation of  $\text{Pco}_2$ . [ $\text{HCO}_3^-$ ] may be elevated either by exogenous alkali intake (e.g.,  $\text{HCO}_3^-$ , citrate, acetate) or by gastrointestinal or renal losses of excessive acid or Cl-rich fluids. There must be both a source of new  $\text{HCO}_3^-$  (generation) and stimuli to the kidney to maintain a new high level of  $\text{HCO}_3^-$  (maintenance).

Maintenance of metabolic alkalosis is usually achieved by increased rates of proximal tubular  $\text{HCO}_3^-$  reabsorption. This is in turn related to extracellular volume depletion, primarily mediated by angiotensin II, hypokalemia, and hypercapnia. The second major element of maintenance is the presence of hyperaldosteronism.

### Chloride-Responsive Alkalosis

The Cl-responsive alkaloses are usually associated with volume depletion and loss of Cl-rich fluids from the body. Common disturbances include gastric alkalosis from vomiting and Cl-wasting diuretics such as furosemide and thiazides. Occasionally diarrhea will result in high stool Cl, particularly in cases of villous adenomas of the colon and some infectious diarrheas including cholera. Renal Cl losses in Bartter and Gitelman

**TABLE 60.6 Importance of Urine Chloride in Diagnosing Hypokalemic Alkalosis**

Disorder	Blood Pressure	Urine Chloride
Hyperaldosteronism	↑	↑
Diuretics <sup>a</sup>	↓	↑
Vomiting	↓	↓
Bartter/Gitelman	↓	↑

<sup>a</sup>Note that the urine chloride will be low if the diuretics have been stopped before the test, and if surreptitious use is suspected, a diuretic screen should be sent also.

syndromes behave in a similar fashion to those from loop and thiazide diuretics, respectively. Many of these volume-depleted states are associated with hyponatremia, hypokalemia, high renin, and high aldosterone levels. This form of alkalosis corrects with the administration of normal saline. Note that the hypokalemia seen in patients with vomiting-induced metabolic alkalosis is not caused by gastric  $\text{K}^+$  losses but is instead a result of renal  $\text{K}^+$  wasting with secondary hyperaldosteronism.

### Chloride-Unresponsive Alkalosis

In these conditions, volume depletion is usually absent, and in fact hypertension may be the presenting finding. Most often there is a primary increase in mineralocorticoids as a result of either adrenal adenomas or hyperplastic adrenal glands. Because the primary increase is in aldosterone, leading to volume expansion, renin levels are usually low. Biochemically, patients have a hypokalemic metabolic alkalosis caused by the effect of aldosterone on the distal nephron. In unilateral renal artery stenosis, in contrast, the increase in renin from the affected kidney leads to an increase in angiotensin II and then aldosterone, which promotes  $\text{Na}^+$  retention,  $\text{K}^+$  wasting, and acid wasting. There are a number of intrarenal disorders that present with a similar clinical picture but are associated with low aldosterone levels. Activating mutations of the epithelial Na channel in the collecting duct (Liddle syndrome) or inhibition of the 11-beta-hydroxysteroid dehydrogenase will lead to the same peripheral picture of hypertension, hypokalemia, and alkalosis. In all of these conditions, the [ $\text{Na}^+$ ] in the blood may be elevated. In Liddle syndrome, both renin and aldosterone levels will be decreased. Licorice containing glycyrrhetic acid inhibits the dehydrogenase enzyme, allowing the normally present cortisol to activate the aldosterone receptor. There will be a high cortisol-to-cortisone ratio and low renin and aldosterone levels.

Distinguishing Cl-responsive and -unresponsive types of metabolic alkalosis is done by combining clinical features with the urinary Cl (Table 60.6). The Cl-responsive alkaloses are associated with a low urine Cl ( $<20$  mEq/L), whereas the Cl-unresponsive state will have high urine Cls ( $>20$  mEq/L). The only exception is in the setting of diuretics or

tubular disorders (which mimic diuretics) where the urine Cl will be high. However, these patients will typically not be hypertensive and, in the case of diuretic abuse, may have a positive urinary diuretic screen. Another distinction is that the Cl-responsive alkaloses will improve with infusion of saline, whereas the Cl-unresponsive states will not. In both cases a potential complication of saline infusion is a worsening of hypokalemia—in the first case owing to the rapid excretion of  $\text{HCO}_3^-$ , which will increase  $\text{K}^+$  excretion, and in the second case owing to the increased  $\text{Na}^+$  delivery to the aldosterone-acting site in the situation where aldosterone is not able to be suppressed.

## Respiratory Acidosis

Respiratory acidosis involves the primary retention of  $\text{CO}_2$  through alveolar hypoventilation. The most common causes of respiratory acidosis are listed in **Box 60.4**. The compensatory response by the kidneys is to generate new  $\text{HCO}_3^-$  by the excretion of an increased amount of  $\text{NH}_4^+$ . A high  $\text{PCO}_2$  also increases renal  $\text{HCO}_3^-$  reabsorption to help maintain the compensatory response. A patient with kidney disease may not compensate well for respiratory acidosis. The pH is more acidic acutely as it takes days to achieve renal compensation, which, although incomplete, significantly raises blood pH toward normal. A rapid drop in  $\text{PCO}_2$ , as may occur when after ventilation in a patient with compensated respiratory acidosis, may result in a posthypercapnic metabolic alkalosis as the  $\text{PCO}_2$  falls more rapidly than the  $\text{HCO}_3^-$ . This may be managed either by slowly decreasing  $\text{PCO}_2$  or by administration of adequate Cl salts to allow for renal excretion of the  $\text{HCO}_3^-$ .

## Respiratory Alkalosis

In respiratory alkalosis,  $\text{CO}_2$  elimination transiently exceeds production, leading to a decreased  $\text{PCO}_2$  and increased pH. The common causes are listed in **Box 60.5**. The compensatory decrease in  $\text{HCO}_3^-$  reabsorption leads to the renal excretion of  $\text{Na HCO}_3^-$  and retention of Cl. The alkalemia is more severe in an acute respiratory alkalosis and can lead to headaches, nausea, vomiting, and even syncope or tetany. pH can approach normal in the chronic state, as in pregnancy. CNS effects of respiratory alkalosis include transient

## Chapter Review

### Questions

1. A 34-year-old man with stage V chronic kidney disease presents with dyspnea on exertion, fatigue, and nausea. Hematocrit 28%, pH 7.30,  $\text{HCO}_3^-$  15 mEq/L,  $\text{PCO}_2$  30 mm Hg. Which statement is true?
  - A. This patient has a simple metabolic acidosis caused by failure to produce  $\text{NH}_3$ , with expected compensation.
  - B. This patient has a primary metabolic acidosis from chronic renal failure and a primary respiratory alkalosis from anemia.
  - C. This patient has an elevated anion-gap metabolic acidosis with expected compensation.
  - D. This patient has a hyperchloremic metabolic acidosis from an RTA; one should consider myeloma.
  - E. The symptoms of dyspnea, fatigue, and nausea are from uremia and could not be from his acidemia.
2. A 54-year-old woman with Sjögren syndrome has polyuria ( $U_{\text{osm}}$  200 mOsm/kg), hypokalemia, and hyperchloremic metabolic acidosis.

Expected urine electrolytes, in mEq/L, are:

- A. Na 90 mEq/L, K 60 mEq/L, Cl 50 mEq/L
  - B. Na 50 mEq/L, K 60 mEq/L, Cl 110 mEq/L
  - C. Na 20 mEq/L, K 35 mEq/L, Cl 80 mEq/L
  - D. Na 25 mEq/L, K 35 mEq/L, Cl 20 mEq/L
3. Which of the following distinguishing features of proximal versus distal RTA in a 65-year-old man with hyperchloremic acidosis would not be a distinguishing feature?
- A. Less severe acidosis in proximal
  - B. Absence of bone demineralization in proximal
  - C. Presence of Fanconi syndrome in proximal
  - D. Hypokalemia worse after treatment in proximal
  - E. Less  $\text{HCO}_3^-$  needed to treat a proximal RTA
4. A 79-year-old woman presents to the emergency department (ED) with a history of severe constipation, lethargy, and weakness. Past medical history is of chronic obstructive pulmonary disease (COPD), hypothyroidism, and osteoporosis. Her medications include Dulcolax, l-thyroxine, Tums, and Caltrate 600+D. On physical examination, she is drowsy and oriented only in place but not date. Her jugular venous pressure is 6 cm and blood pressure 106/72 mm Hg with a heart rate of 98 beats per minute. Cardiovascular, lung, and abdominal examinations are unremarkable. Her neurologic examination is nonfocal. She has mild reduction in skin turgor and no edema. Her electrolytes are as follows: Na 140 mEq/L,  $\text{K}^+$  3.9 mEq/L,  $\text{Cl}^-$  94 mEq/L,  $\text{CO}_2$  37 mEq/L, BUN 51 mg/dL, creatinine 2.4 mg/dL, glucose 110 mg/dL, calcium 13.8 mg/dL, serum albumin 3.4 mg/dL.

The most likely diagnosis is:

- A. Chronic respiratory acidosis from COPD
  - B. Metabolic alkalosis and milk-alkali syndrome
  - C. Paget disease
  - D. Adrenal insufficiency
  - E. Hyperthyroidism
5. A 78-year-old man presents to the ED with a 2-day history of confusion and bloody diarrhea. Blood chemistries drawn in the ED are as follows: Na 138 mEq/L,  $\text{K}^+$  4.0 mEq/L,  $\text{Cl}^-$  104 mEq/L,  $\text{CO}_2$  16 mEq/L, serum creatinine 1.4 mg/dL, BUN 29 mg/dL, glucose 129 mg/dL.
- With an appropriate physiologic response (i.e., well-compensated state), his predicted  $\text{Pco}_2$  should be, in mm Hg:
- A.  $\text{Pco}_2$  32
  - B.  $\text{Pco}_2$  45
  - C.  $\text{Pco}_2$  16
  - D.  $\text{Pco}_2$  20
  - E.  $\text{Pco}_2$  55

## Dialysis and Transplantation

J. KEVIN TUCKER

According to the United States Renal Data Service (USRDS), more than 660,000 individuals in the United States were receiving treatment for end-stage renal disease (ESRD) by the end of 2013, and there were more than 118,000 new cases of ESRD reported that year. The leading cause of ESRD in the United States is diabetes, followed by hypertension. Because the care of diabetes and related cardiovascular complications has improved, diabetic patients are living long enough to develop ESRD. As a consequence, the dialysis population has gradually become older with increasing numbers of comorbid conditions. Renal replacement therapy in the form of hemodialysis or peritoneal dialysis may serve as a bridge to the best form of renal replacement, renal transplantation. The demand for suitable kidneys for transplantation far exceeds the supply, leaving many patients on dialysis for extended periods of time.

### Preparing the Patient for Renal Replacement Therapy

Preparing a patient for renal replacement therapy requires a multidisciplinary team approach among the primary care provider, nephrologist, renal social worker, dietician, nephrology nurse educator, dialysis access surgeon, and transplant surgeon. The primary care provider must ensure timely referral to the nephrologist when chronic kidney disease (CKD) is recognized so that appropriate diagnostic testing may be done, and appropriate steps to retard progression may be taken. The recommendation from Kidney Disease: Improving Global Outcomes (KDIGO) is that patients with CKD progression, defined as a decline in glomerular filtration rate (GFR) staging category or rapid progression (a sustained decline in GFR of  $>5$  mL/min/1.72 m<sup>2</sup>/year) be considered for referral to a nephrologist. This approach emphasizes targeting patients for referral when interventions may retard or prevent progression to ESRD. The social worker plays a critical role in helping patients to cope with the psychological impact of impending ESRD and can assist with financial and insurance issues. The renal dietician helps patients to understand the importance of nutritional management in both the predialysis and the dialysis setting. As an example, dietary potassium restriction is an important element in treating the

hyperkalemia associated with type 4 renal tubular acidosis, which is common in patients with stages 4 and 5 CKD. The nephrology nurse educator, working in conjunction with the nephrologist, educates patients and their families regarding the various modalities of renal replacement therapy and helps patients make a well-informed decision regarding the most appropriate form of renal replacement. The dialysis access surgeon creates the vascular access for hemodialysis or places a peritoneal dialysis catheter if the patient chooses this modality for renal replacement. The access surgeon continues to follow the patient through the course of renal replacement therapy for any dialysis-access-related issues. The transplant surgeon and transplant team should see the patient early for evaluation for renal transplantation. In some cases, if an appropriate living donor is available, the patient may be transplanted preemptively, thus avoiding completely the need for dialysis.

### Hemodialysis Versus Peritoneal Dialysis

In the United States, only about 9% of dialysis patients are using peritoneal dialysis, whereas the numbers of patients choosing peritoneal dialysis in Canada, the United Kingdom, Europe, and Asia are proportionally higher. Peritoneal dialysis is underused in the United States for several reasons. First, incident dialysis patients are aging, and older patients are less likely to choose a home dialysis modality because they find the procedure technically challenging. Second, the accessibility of ambulatory dialysis facilities across the United States has made hemodialysis readily available to most patients. When patients are adequately educated regarding the two modalities, more patients choose peritoneal dialysis.

Most patients are capable of successful treatment with either hemodialysis or peritoneal dialysis; however, there are some physical conditions that may limit a patient's choices. As an example, the patient with crippling rheumatoid arthritis and ESRD may not have the manual dexterity required to perform peritoneal dialysis. A patient who has had multiple abdominal surgeries may have abdominal adhesions that would impede solute transport across the peritoneal membrane, rendering peritoneal dialysis ineffective. The patient with an abdominal hernia

needs to have it repaired before performing peritoneal dialysis. Similarly, there are physical limitations that make peritoneal dialysis the preferred dialytic modality. Severe congestive heart failure with chronic volume overload and chronic hypotension make volume removal (ultrafiltration) with hemodialysis difficult. The continuous nature of volume removal with peritoneal dialysis makes it better tolerated from a hemodynamic standpoint. Finally, patients who have been on hemodialysis for a number of years and have run out of vascular access sites may have to switch to peritoneal dialysis if transplantation is not imminent. Large body mass index (BMI) or body habitus per se are not contraindications to peritoneal dialysis. The peritoneal dialysis adequacy targets recommended by nephrology societies worldwide are generally achievable even in large patients.

Residual renal function is an important determinant of survival in both hemodialysis and peritoneal dialysis. For a number of reasons, patients who are treated with peritoneal dialysis maintain their residual renal function for longer periods than do patients who are treated with hemodialysis. This residual renal function is also relied on more for total solute clearance with peritoneal dialysis than with hemodialysis. A young patient newly diagnosed with ESRD is likely to need the full spectrum of renal replacement therapies (i.e., hemodialysis, peritoneal dialysis, and transplantation) over the course of his or her lifetime. Therefore in a young patient it is logical to start with peritoneal dialysis as a bridge to transplantation while there still may be some residual renal function. If the transplant fails and the patient has to return to dialysis 10 to 20 years later, the upper extremities have been preserved for vascular access.

Most studies suggest that hemodialysis and peritoneal dialysis are equivalent with respect to long-term survival. Randomized studies of survival with the two dialytic modalities are difficult to perform because of the primacy of patient choice with respect to dialysis modality, thus limiting recruitment for such studies.

### Technical Aspects of Hemodialysis

Hemodialysis is a two-step process of removing solutes and fluid from the blood. The two processes are solute removal by diffusion and convection and fluid removal by ultrafiltration. Blood is removed through a vascular access (e.g., a fistula, graft, or catheter) and run through the dialysis circuit, which includes an artificial kidney or dialyzer. By the principle of diffusion, solutes are removed from the blood, which is pumped through the dialyzer, and move down their concentration gradient into the dialysate compartment. The dialysate solution is lower in solute concentration and runs countercurrent through the dialyzer. A transmembrane pressure gradient is applied across the dialysis membrane, allowing the ultrafiltration of fluid. With ultrafiltration of fluid, some solutes are removed by convection.

Since the advent of chronic dialysis as a maintenance therapy, there have been numerous technologic advances that have improved dialysis outcomes. In the early years of chronic maintenance hemodialysis, dialysis was performed with low-flux dialyzers derived from cellulose; these membranes caused a higher incidence of dialyzer hypersensitivity reactions than the newer high-flux biocompatible membranes generally used in the United States. In addition, the low-flux membranes did not effectively clear beta-2 microglobulin, and high circulating levels of this protein are associated with the subsequent development of amyloidosis. Dialysis machines now have improved control of ultrafiltration, allowing physicians to determine volume removal to the milliliter with good precision, and other safety mechanisms have decreased the incidence of air embolus associated with dialysis. Systemic anticoagulation, most often with intravenous unfractionated heparin, may be administered to prevent clotting of the dialyzer and extracorporeal circuit. Because dialysis machines are used for multiple patients, protocols are in place to prevent the spread of blood-borne pathogens such as the hepatitis B and C viruses and HIV. Patients and dialysis staff are also routinely vaccinated to prevent hepatitis B.

In the United States, hemodialysis is most commonly performed three times weekly. There is, however, increasing interest in more frequent forms of dialysis including daily home dialysis and nocturnal in-center hemodialysis. In the latter modality, patients are dialyzed for 6 to 8 hours overnight three times per week, whereas the usual time on hemodialysis is typically 3.5 to 4 hours. Data from the Frequent Hemodialysis Network Trial group indicate that, when compared with conventional thrice-weekly hemodialysis, hemodialysis six times per week may confer advantages with respect to cardiac function, control of hypertension, and control of serum phosphate.

### Technical Aspects of Peritoneal Dialysis

Peritoneal dialysis uses the peritoneal membrane with its vast vascular supply as the dialysis membrane. A peritoneal dialysis catheter is placed surgically, usually at least 2 to 3 weeks before initiation of dialysis. Patients are trained to perform peritoneal dialysis in one of two ways: continuous ambulatory peritoneal dialysis (CAPD) or automated peritoneal dialysis (APD). In CAPD, dialysate is instilled into the peritoneal cavity through the peritoneal dialysis catheter (Fig. 61.1). The dialysate contains dextrose, which acts as the osmotic driving force for fluid removal. Solute move across the peritoneal membrane down their concentration gradient into the dialysate compartment. At the end of a period of 4 to 6 hours, the patient drains the dialysate and instills fresh dialysate into the peritoneal cavity. In states of volume overload, the patient may remove more fluid at his or her own discretion by increasing the concentration of dextrose in the dialysate. In APD, the patient uses an automated device that assists in performing dialysis, usually overnight with a cycler. The cycler performs several exchanges

• **Fig. 61.1** Continuous ambulatory peritoneal dialysis (CAPD). In CAPD, dialysate is instilled into the peritoneal cavity through the peritoneal dialysis catheter.

overnight such that the patient most often does not have to perform manual exchanges during the day. Because of the convenience of APD, more patients in North America are choosing this peritoneal dialysis modality over CAPD.

Icodextrin (Extraneal) is a glucose polymer colloid osmotic agent derived from maltodextrin used for the long peritoneal dialysis dwell in patients who need a long dwell for fluid and/or solute control. It has the advantage of maintaining an osmotic gradient to drive fluid removal, even with a long overnight dwell in CAPD or a long daytime dwell in APD. Diabetic patients who use icodextrin must use a specific glucometer that does not give a falsely high glucose reading because blood concentrations of maltose and other sugars may go up with the use of icodextrin.

## Vascular Access

Vascular access remains the Achilles heel of hemodialysis. Dialysis access complications are a major source of

• **Fig. 61.2** (A) Native arteriovenous (AV) fistula. (B) AV graft.

morbidity for ESRD patients and account for more than \$1 billion per year in health care expenditures.

The three primary types of hemodialysis access devices are the arteriovenous (AV) fistula, the AV graft, and the dialysis catheter. The native AV fistula (Fig. 61.2A) is the best and the preferred long-term dialysis access. It offers several advantages over the other hemodialysis access types: (1) It has the longest life; (2) because it has no synthetic material, it rarely becomes infected; and (3) it requires fewer interventions to maintain patency. The AV fistula is created by anastomosis of an artery to a vein, usually in the non-dominant arm, resulting in arterialization and dilation of the vein. The most commonly created fistulae are the radio-cephalic (Brescia-Cimino) fistula at the wrist and the brachiocephalic fistula at the elbow. The vascular access surgeon may use preoperative venous mapping with ultrasound to determine the best site for fistula creation.

An AV fistula may require 2 to 3 months to mature, that is, to be of sufficient caliber such that it can be cannulated with two 15-gauge or 16-gauge needles and support a blood flow through the dialysis circuit of 300 to 450 mL/min. Therefore the patient with stage 4–5 CKD should be referred to the vascular access surgeon at least 6 months before the predicted need for initiation of dialysis. Nephrology society guidelines suggest that patients be referred for vascular access when the serum creatinine is  $>4$  mg/dL or the GFR is  $<25$  mL/min. The failure to refer the CKD patient for vascular access in a timely manner puts that patient at risk

of starting dialysis with a catheter, which in and of itself carries a greater mortality risk than starting dialysis with an AV fistula. Patients with CKD should also be educated regarding the importance of preserving veins for vascular access. Venipuncture should be avoided in the nondominant arm to better preserve those veins for vascular access.

When the vasculature is not suitable for creation of an AV fistula based on physical examination or preoperative ultrasound venous mapping, the surgeon and nephrologist may decide that the best option is placement of an AV graft (Fig. 61.2B). The AV graft is created by interposing a synthetic tube, usually made from polytetrafluoroethane, between the artery and the vein. The most commonly placed AV grafts are the straight graft between the radial artery and the basilic vein and the loop graft between the brachial artery and the basilic vein. AV grafts have the advantage of being suitable for dialysis within 2 to 3 weeks of creation. However, grafts thrombose more frequently than fistulae and require more interventions to remain patent, and even with interventions to maintain patency, most grafts last only about 2 years. Many trials have attempted to prove that use of antiplatelet agents or systemic anticoagulation decreases graft thrombosis, but so far, the only agent having a proven benefit without increasing bleeding complications is dipyridamole. In patients who have no upper arm blood vessels suitable for access placement, an experienced vascular surgeon may be able to create a femoral AV graft, but these are associated with high rates of infection and thrombosis and are considered a vascular access of last resort.

Dialysis catheters are generally reserved for patients who have no other vascular access options or for patients who require a catheter as a “bridge” until a fistula is mature. Dual-lumen cuffed catheters are placed in the internal jugular vein and tunneled through subcutaneous tissues, usually under ultrasound guidance. The subclavian vein should be avoided because of the risk of subclavian vein thrombosis, which can render the whole upper extremity unsuitable for future vascular access creation. Nontunneled, noncuffed catheters are often used in cases of acute kidney injury in which a short course of dialysis (1–2 weeks at most) is anticipated. These catheters may be placed at the bedside with ultrasound guidance in the internal jugular or femoral vein. If the patient needs a longer course of dialysis, the nontunneled, noncuffed catheter should be exchanged for a more permanent tunneled, cuffed catheter.

### Complications Related to Dialysis Access

Infectious complications are the second most common cause of mortality for patients with ESRD. ESRD patients may have impaired cellular and humoral immunity. Furthermore, hemodialysis and peritoneal dialysis catheters carry infection risks because they are foreign bodies.

Hemodialysis catheter infections occur at a rate of 2 to 5.5 per 1000 patient days. Catheter-related bacteremia should be suspected in any patient who has fever and/or shaking chills. Empiric antibiotic therapy to cover both gram-positive and

gram-negative organisms should begin after blood cultures have been obtained. The gold standard treatment for hemodialysis catheter-related infections is to remove the catheter and to place a new tunneled catheter after the patient has been afebrile for 48 hours and surveillance blood cultures are documented as negative. This approach, however, may require that the patient remain in the hospital for several days and that the patient have a temporary (nontunneled, noncuffed) catheter placed for dialysis.

As an alternative approach to treating dialysis catheter-related bacteremia, some centers have successfully used the strategy of catheter exchange over a guidewire when there is no sign of a tunnel infection and the patient shows rapid clinical improvement with antibiotic therapy. Another treatment approach is to “lock” the infected catheter with an antibiotic solution to eliminate the layer of biofilm that adheres to the catheter surface.

Regardless of which treatment approach is used, the patient with catheter-related bacteremia warrants close monitoring for development of signs of a metastatic infection such as endocarditis, septic arthritis, osteomyelitis, discitis, or epidural abscess. These metastatic infections are not often clinically apparent for weeks to months following the episode of bacteremia. *Staphylococcus aureus* is the most virulent organism with respect to metastatic infections, and attempts at catheter salvage in cases of *S. aureus* bacteremia may lead to unacceptably high rates of metastatic infections.

Noninfectious complications of vascular access are frequent and include vascular access stenosis, thrombosis, limb ischemia, aneurysm, and congestive heart failure. Stenosis, which is narrowing of blood vessels, may occur at any location in the access circuit but most commonly occurs at the site of the AV anastomosis leading to decreased inflow of blood or in the central veins causing blood to recirculate in the access. Both conditions can significantly decrease dialysis adequacy. Because stenosis also increases the risk of access thrombosis, which itself leads to fistula and graft failure, nephrology society guidelines recommend routine surveillance of fistulae at the discretion of the clinician. Doppler ultrasound is an excellent noninvasive method of assessing access stenosis, but its use is limited to the arm; central stenosis is better assessed with conventional venography. Stenotic lesions can be treated with angioplasty and stenting using interventional radiology techniques, whereas thrombosis is treated with thrombectomy. In cases of access thrombosis, it is important to diagnose and treat concurrent stenosis to decrease the risk of repeated thromboses. Limb ischemia can occur from both AV fistulae and grafts because tissues distal to the access may not receive adequate perfusion. Severe ischemia, characterized by pain at rest, non-healing ulcers, or evidence of nerve injury, requires urgent surgical revascularization of affected tissues. Aneurysms of access result from repeated needle sticks, and rupture of an aneurysm can lead to catastrophic exsanguination. Congestive heart failure may occur if blood flow in an access is >1000 mL/min and may be treated by banding to decrease the size of the access.

The major infectious complication related to peritoneal dialysis access is peritonitis. Peritonitis is one of the major causes of failure of the modality and transfer to hemodialysis. Peritonitis may be asymptomatic, with the patient noticing only that the dialysate effluent is cloudy. When symptoms develop they typically include abdominal pain, fever, nausea, and vomiting. The workup for peritonitis should include laboratory examination of the effluent for cell count, Gram stain, and culture. A cell count  $>100/\mu\text{L}$  with more than 50% polymorphonuclear leukocytes is suggestive of peritonitis. Empiric antibiotics should be administered to cover both gram-positive and gram-negative organisms. Antibiotics may be administered intravenously or by the intraperitoneal route by adding them to the dialysis solution. If the cultures are positive for more than one organism, abdominal imaging and surgical consultation should be obtained because polymicrobial peritonitis is often associated with an intraabdominal catastrophe such as a perforated viscus. Peritonitis with mycobacterium or fungus almost always mandates removal of the catheter because these organisms are very difficult to eradicate with antimicrobial therapy alone.

Nasal carriage of *S. aureus* is a major risk factor for exit-site infections, tunnel infections, and peritonitis with this organism. The application of an antibiotic cream to the exit site has been shown to reduce peritoneal dialysis infections. Mupirocin applied to the exit site daily reduces rates of *S. aureus* infections; however, it does not help with gram-negative infections, particularly *Pseudomonas*. Gentamicin cream applied to the exit site prevents peritoneal dialysis catheter-related infections from both gram-positive and gram-negative organisms.

There are several noninfectious causes of peritoneal dialysis catheter malfunction. It is not uncommon for patients to experience problems with drainage of fluid after a dwell. This is most often caused by constipation, which should be aggressively treated with laxatives that do not contain magnesium or phosphorous. Catheter migration may also occur, where the catheter tip that is normally coiled and resting in the floor of the pelvis moves to another intraabdominal location. Abdominal x-ray will help to diagnose both of these problems. Occasionally strands of fibrin, which can be a result of peritonitis, will be visible in peritoneal dialysis effluent, but this may also occur spontaneously. Heparin may be added to dialysate bags at 500 or 1000 U/L to prevent fibrin plugging, but, if this is ineffective, thrombolytics such as tissue plasminogen activator may be used to unplug the catheter.

## Anemia Management

The anemia of chronic kidney disease usually becomes apparent before patients require renal replacement therapy. Although deficiency of the sialoglycoprotein erythropoietin (EPO) is an important cause of the anemia of CKD, numerous other factors play a role (Box 61.1) including iron deficiency, chronic inflammation, occult blood loss,

### • BOX 61.1 Causes of Erythropoietin Resistance

- Iron deficiency
- Infection
- Chronic inflammation
- Hyperparathyroidism
- Occult blood loss
- Malignancy
- Folate and B<sub>12</sub> deficiencies
- Hemoglobinopathies
- Aluminum intoxication

and secondary hyperparathyroidism. The mainstays of treatment of anemia in dialysis patients are administration of recombinant erythropoiesis-stimulating agents (ESAs) and intravenous iron. ESAs are typically administered intravenously or subcutaneously to hemodialysis patients and subcutaneously to peritoneal dialysis patients. Intravenous iron is given in the hemodialysis unit to maintain the transferrin saturation (serum iron/total iron binding capacity  $\times 100\%$ ) at  $>30\%$ . The administration of intravenous iron improves the bone marrow response to ESAs and reduces the total amount of ESAs required to maintain the hemoglobin at its target. Lower doses of ESAs confer substantial cost savings to the health care system because ESA costs are a major expenditure for the ESRD program. Intravenous iron is available in several different preparations in the United States: iron sucrose (Venofer), iron gluconate (Ferrlecit), ferumoxytol (Feraheme), and iron dextran. Iron dextran is used less commonly because it is associated with a substantial rate of anaphylactic reactions.

The recommended targets for hemoglobin in both CKD patients and dialysis patients have come under increased scrutiny since the publication of several studies showing that higher hemoglobins are associated with increased risk of cardiovascular events and strokes in both predialysis and dialysis patients. KDIGO published guidelines in 2012 recommending that ESA therapy should be used to avoid hemoglobin levels  $<9$  g/dL and maintain hemoglobin levels not  $>11.5$  g/dL. The US Food and Drug Administration (FDA) recommends that the hemoglobin not exceed 11 g/dL in CKD patients being treated with ESAs. Notably, KDIGO recommends caution and, if possible, withholding of ESAs in patients with a history of stroke or malignancy. Regular monitoring of the hemoglobin is recommended for any patient who is receiving an ESA to avoid the potentially dangerous overcorrection of anemia.

## Bone Disease and Mineral Metabolism Management

Disordered mineral metabolism may begin in CKD patients as early as stage 2. Prompt evaluation and treatment of mineral disorders are important to prevent more severe complications by the time the patient requires renal replacement therapy. The kidney's ability to excrete phosphorous

decreases as GFR falls because there are fewer nephrons and their function is impaired. Furthermore, levels of vitamin 1,25-(OH)<sub>2</sub>D<sub>3</sub> (calcitriol) decline because there are fewer renal tubular cells producing 1-alpha-hydroxylase, the enzyme responsible for its activation. The rise in serum phosphate levels and the fall in serum calcium both feed back on the parathyroid gland to increase production of parathyroid hormone (PTH). High levels of PTH lead to a condition of high bone turnover and resorption with eventual sclerosis, called *osteitis fibrosa*, but can also lead to the accumulation of unmineralized bone, known as *osteomalacia*. Uncontrolled hyperparathyroidism may lead to other systemic complications. Throughout the body, abnormal mineral metabolism fueled by high levels of PTH leads to calcification of the intima of arteries and arterioles, another pathologic change that leads to cardiovascular disease in patients with ESRD. This pathophysiology is responsible for calcific uremic arteriopathy (CUA), previously known as calciphylaxis, an unusual yet devastating and painful disease in which arteriolar calcification leads to tissue ischemia in the skin and subcutaneous tissues. Patients treated with warfarin are at increased risk of developing CUA.

Dietary phosphate restriction is an important early step in preventing secondary hyperparathyroidism. In animal studies, a rise in PTH can be prevented by stringent dietary phosphate restriction. In CKD stages 4 and 5, and particularly in dialysis patients for whom malnutrition may already be an issue, phosphate binders may be given with meals to control serum phosphate levels (Table 61.1). Aluminum hydroxide is the most potent binder of dietary phosphorus but should not be used chronically because of the risk of

aluminum toxicity. It may be used in short courses of 2 to 3 days for severe hyperphosphatemia. Calcium acetate (Phoslo) and calcium carbonate are commonly used phosphate binders, but they carry the risk of causing hypercalcemia, especially when given with a vitamin D analogue. Sevelamer hydrochloride (Renagel), sevelamer carbonate (Renvela), and lanthanum carbonate (Fosrenol) are noncalcium-based binders that may be used preferentially when serum calcium levels are >9.5 mg/dL. Sevelamer also has the advantage of lowering low-density lipoprotein cholesterol. Sucroferric oxyhydroxide (Velphoro) and ferric citrate (Auryxia) are two new iron-based phosphate binders.

When PTH exceeds upper limit of normal despite dietary phosphate control, the next step is addition of an analogue of vitamin 1,25(OH)<sub>2</sub>D<sub>3</sub>, which acts to suppress PTH production. Vitamin D analogues used in the United States are calcitriol (Rocaltrol), paricalcitol (Zemplar), and doxercalciferol (Hectorol). Serum calcium and phosphorus must be monitored with use of vitamin D analogues because they promote intestinal absorption of both minerals. Hypercalcemia is more likely to occur when vitamin D analogues are used with a calcium-based phosphate binder. Vitamin D analogues are usually given intravenously to hemodialysis patients and orally to peritoneal dialysis patients. 25-OH vitamin D deficiency is also common in dialysis patients. Although it is likely to be beneficial to replete vitamin D in such patients because of the extraosteal effects of vitamin D, there are no data to confirm that doing so is effective in treating secondary hyperparathyroidism.

More severe cases of hyperparathyroidism may not respond to vitamin D analogues but may respond to the calcimimetic agent cinacalcet (Sensipar), which acts on the parathyroid glands' calcium-sensing receptor to inhibit PTH release. Gastrointestinal side effects and hypocalcemia requiring supplemental calcium are possible with cinacalcet, and it is considerably more expensive than vitamin D analogues. Parathyroidectomy should be considered in patients for whom medical therapy has been ineffective, but a period of prolonged and sometimes intractable post-operative hypocalcemia called "hungry bone syndrome" may occur. Thus patients must be watched carefully following parathyroidectomy. Oversuppression of PTH (with activated vitamin D, calcimimetics, parathyroidectomy, or combination) can lead to adynamic bone disease, where both osteoclasts and osteoblasts are dysfunctional and bone formation is minimal. Patients with adynamic bone disease are prone to fractures, hypercalcemia, and vascular calcification, and the condition is thought to be irreversible.

**TABLE 61.1** Phosphate Binders

Binder	Comments
Aluminum hydroxide	Potent risk of aluminum toxicity; use only for short courses in cases of severe hyperphosphatemia
Calcium carbonate	Cost effective; runs risk of high serum calcium when coupled with vitamin D analogue
Calcium acetate	Same as with calcium carbonate
Sevelamer hydrochloride	Noncalcium-based binder; preferred for patients with hypercalcemia; risk of metabolic acidosis
Sevelamer carbonate	No risk of metabolic acidosis
Lanthanum carbonate	Alternative noncalcium-based binder
Sucroferric oxyhydroxide: iron-based binder	
Ferric citrate: iron-based binder	

## Evaluation of the Patient for Kidney Transplantation

Medical evaluation of a potential kidney transplant recipient is important to ensure that the recipient is stable enough to undergo the surgical procedure without

adverse perioperative (particularly cardiovascular) complications. Recipients should be screened for certain medical problems that may be adversely affected by immunosuppression, such as occult infections and occult malignancies. Given the prevalence of coronary artery disease and left ventricular dysfunction in patients with CKD, particular attention should be paid to screening for coronary artery disease. Most transplant centers use pharmacologic stress testing followed by cardiac catheterization and revascularization if indicated. The timing of cardiac catheterization with respect to initiation of dialysis must be studied in patients being considered for pre-emptive transplantation. In such patients, the dye load from cardiac catheterization may cause a steep enough decline in GFR such that dialysis must be initiated.

Patients being considered for kidney transplantation should also be screened for viral infections including HIV, hepatitis B, hepatitis C, cytomegalovirus (CMV), and Epstein-Barr virus (EBV) as well as for syphilis. Although HIV is no longer considered an absolute contraindication to renal transplantation, the viral load must be well controlled, and the transplant center should have expertise in managing this special transplant population. Patients with hepatitis C antibodies and positive titers for hepatitis RNA may need a pretransplant liver biopsy to determine the degree, if any, of underlying fibrosis or cirrhosis. The routine vaccination of dialysis patients against hepatitis B has greatly reduced the number of potential renal transplant recipients who are hepatitis B surface antigen positive. In the case of these patients who have evidence of active viral replication, antiviral therapy should be considered before kidney transplantation. CMV-naïve recipients who receive a kidney from a CMV-positive donor are at greater risk for CMV-associated disease in the posttransplant setting. Similarly, an EBV-negative recipient who receives a transplant from an EBV-positive donor is at greater risk for posttransplant lymphoproliferative disorder (PTLD), especially if heavily immunosuppressed. Screening for occult malignancies generally follows age-appropriate guidelines for the general population. Female recipients should have a Pap smear and a mammogram if age >40 years. Men should have a prostate-specific antigen test if age >50 years. All recipients age >50 years should have fecal occult blood testing with colonoscopy if positive.

Active malignancy, active infection, severe cardiovascular disease that makes the patient a high operative risk, and severe obesity are generally considered contraindications to transplantation. Psychiatric illness and a history of medical noncompliance are considered in the evaluation process. Psychiatric illness per se may be a contraindication if it interferes with the patient's ability to comply with the posttransplant regimen. Similarly, medical noncompliance is a relative contraindication because there are many patients who have been noncompliant with dialysis and medications but fully compliant with posttransplant medications and follow-up.

## Transplant Medications

Transplant medications have revolutionized the field of transplant medicine such that acute rejection rates reported to the US Renal Data System are now <10%. Newer medications are more specific and able to target differing parts of the immune system (Table 61.2). Glucocorticoids remain an important part of many immunosuppression protocols, although some centers have moved to steroid-free protocols. Glucocorticoids are also used in treating acute rejection, usually as pulses of methylprednisolone at doses of 500 to 1000 mg/d for 3 days. The side effects of glucocorticoids are well known and include weight gain, diabetes, osteoporosis, osteonecrosis, myopathy, and cataracts.

## Maintenance Therapies

Daily maintenance immunosuppression is required in almost all cases of solid organ transplantation; the very rare exception to this is the patient who has tolerance of his or her allograft, which has been reported in cases of same-donor bone marrow transplantation, either previous or simultaneous. Typically, an antimetabolite and either a calcineurin inhibitor or an mTOR (mammalian target of rapamycin) inhibitor are given, plus or minus low-dose prednisone.

**TABLE 61.2** Drugs Used in Kidney Transplantation for Immunosuppression

Drugs	Comments
Glucocorticoids	Block synthesis of cytokines including IL-2; side effects: weight gain, diabetes mellitus, cataracts, osteoporosis, osteonecrosis
Azathioprine	Imuran; inhibits purine biosynthesis; side effects: bone marrow suppression; major interaction with allopurinol
Mycophenolate mofetil	CellCept; selective effect on lymphocyte replication; side effects: bone marrow suppression and GI toxicity
Cyclosporine	Neoral and others; calcineurin inhibitor; side effects: gingival hyperplasia, hirsutism, hypertension
Tacrolimus	Prograf; calcineurin inhibitor; side effects: diabetes mellitus, hypertension, neurotoxicity
Sirolimus	Rapamycin; mTOR inhibitor; side effects: hyperlipidemia and bone marrow suppression
Monoclonal antibodies	Basiliximab (Simulect); Daclizumab (Zenapax); block activated T cells expressing IL-2 receptor
Polyclonal antibodies	ATGAM and thymoglobulin; nonspecifically block T cells

GI, Gastrointestinal; IL-2, interleukin-2; mTOR, mammalian target of rapamycin.

**TABLE 61.3** Drugs/Substances That Increase and Decrease Cyclosporine Levels

Increase	Decrease
Diltiazem	Barbiturates
Verapamil	Phenytoin
Nicardipine	Carbamazepine
Amlodipine	Isoniazid
Ketoconazole	Rifampin
Fluconazole	
Erythromycin	
Clarithromycin	
Grapefruit juice	

### Antimetabolites

Azathioprine (Imuran) has been used since the early days of transplantation, so there is much collective experience with this medication. It acts by inhibiting purine biosynthesis, thereby limiting lymphocyte replication. When used in conjunction with allopurinol for the treatment of gout, severe bone marrow suppression may occur because azathioprine is partially metabolized by xanthine oxidase, the enzyme inhibited by allopurinol.

Mycophenolate mofetil (MMF, CellCept) is a newer drug that has replaced azathioprine in many transplant centers' immunosuppression protocols. MMF inhibits inosine monophosphate dehydrogenase, the rate-limiting enzyme in de novo purine biosynthesis, and its effect is relatively lymphocyte specific. The major toxicities of MMF are gastrointestinal (nausea, vomiting, and diarrhea) and bone marrow suppression, but a newer form of the medication, mycophenolic acid (MPA, Myfortic), causes fewer gastrointestinal side effects. MMF and MPA are teratogenic and carry a black box warning.

### Calcineurin Inhibitors

The calcineurin inhibitors cyclosporine (Sandimmune, Neoral) and tacrolimus (FK 506, Prograf) block synthesis of interleukin-2 (IL-2) and many other molecules that are important for T-cell activation by inhibiting the nuclear factor of activated T-cell pathway, and they have transformed the field of solid organ transplantation since their introduction. Importantly, the calcineurin inhibitors are themselves nephrotoxic, and drug levels must be monitored to minimize toxicity; regardless, chronic use of calcineurin inhibitors can be responsible for graft destruction and loss in as little as 10 years in some patients. Because cyclosporine and tacrolimus are metabolized by the cytochrome P450 system, drugs that activate the P450 system may cause cyclosporine or tacrolimus levels to rise or fall (Table 61.3). Side effects related to cyclosporine include gingival hyperplasia, hypertension, hirsutism, neurotoxicity (manifested most commonly as tremor), malignancy, and new-onset diabetes after transplantation (NODAT). Although the overall side-effect profiles are similar, tacrolimus is thought to cause less hirsutism and is not generally associated with gingival hyperplasia, but it is more neurotoxic and more closely associated with NODAT.

### Mammalian Target of Rapamycin Inhibitors

Sirolimus (Rapamune) and everolimus (Zortress) are macrolide antibiotics that block the proliferative response of T and B cells to cytokines. Sirolimus and everolimus bind to the same intracellular protein to which tacrolimus binds, the FK binding protein, but they inhibit the mTOR kinase rather than block calcineurin. Sirolimus has a long half-life so may be given only once daily, but everolimus has a shorter half-life; both are dosed by blood levels. Patients are often switched to an mTOR inhibitor from a calcineurin inhibitor because of intolerable side effects or in the setting of malignancy, particularly squamous cell cancer of the skin. The major side effects of the mTOR inhibitors, in addition to bone marrow suppression, are hyperlipidemia and interstitial pneumonitis. These drugs are also embryotoxic so they may not be used in pregnancy, and they have a particularly negative impact on wound healing so they ought to be discontinued in patients undergoing major surgery. Although less nephrotoxic than calcineurin inhibitors, mTOR inhibitors can cause either new-onset or worsening of chronic proteinuria (in the worst cases even nephrotic-range proteinuria) possibly caused by toxic effects on the podocyte.

### Abatacept and Belatacept

Abatacept (Orencia) and belatacept (Nulojix) are intravenous medications that block the costimulatory pathway of T-cell activation. Abatacept is currently used to treat rheumatoid arthritis, but belatacept was approved in 2011 for use in renal transplant immunosuppression. Each of them is a combination of an Fc portion of an IgG1 antibody bound to the extracellular domain of the cytotoxic T-lymphocyte antigen 4. When the drug binds to the CD-80 (B7) receptor on the B cell, it blocks the B cell from then binding to the CD28 receptor of T cells, which is required for T-cell proliferation and cytokine production. Belatacept can be given every 4 to 8 weeks with daily MMF and steroids to avoid use of calcineurin inhibitors and prolong the life of an allograft.

### Induction and Antirejection Therapies

The purpose of induction therapy in kidney transplantation is to prevent acute allograft rejection by downregulating the actions of T cells and sometimes B cells before organ implantation. Antibodies to T lymphocytes come in both polyclonal and monoclonal varieties. Rituximab (Rituxan) is an anti-B-cell therapy used pretransplant to reduce anti-human leukocyte antigen (HLA) antibodies and to condition patients for ABO-incompatible transplants. Certain anti-T- and anti-B-cell therapies have dual functions and are also used to treat cellular and antibody-mediated rejection. Transplant kidney biopsy as well as immunologic laboratory testing can determine whether allograft rejection is caused by cytotoxic (cellular) or humoral (antibody-mediated) processes, and the mechanism of injury should be used to guide choice of the proper therapeutic agent.

### Polyclonal Antibodies

Antithymocyte globulin is a set of cytotoxic antibodies to human T cells produced by inoculating rabbits or horses with human lymphoid tissue (rabbit, Thymoglobulin; equine, Atgam). Thymoglobulin is more potent than Atgam and is used more frequently; it is FDA approved for treating acute cellular rejection but is most often used off-label for induction therapy. Intravenous immune globulins (IVIGs) are pooled antibodies from human plasma, and they inhibit anti-HLA antibodies effectively, making them useful for treating antibody-mediated (humoral) rejection caused by either precirculating or de novo antibodies to the HLA of the allograft; plasmapheresis is usually performed before its administration.

### Monoclonal Antibodies

OKT3 (Orthoclone), a mouse monoclonal antibody raised against the CD3 receptor complex on human T cells, was the first antilymphocyte therapy used, and it was FDA approved in 1987. It completely depletes T cells and causes them to release their cytotoxic cytokines, leading to high fevers and rigors. Thymoglobulin causes similar T-cell depletion but is far better tolerated with fewer side effects.

In 1998 basiliximab (Simulect), an anti-CD25 monoclonal chimeric mouse-human antibody, was produced that binds to the IL-2 receptor of activated T cells, and it can be used for both induction and acute cellular rejection therapy. The human-only form, daclizumab (Zenapax), is now also being used for this purpose. Both agents are very well tolerated and do not increase the incidence of opportunistic infections but should be used for induction therapy only in patients at a low risk of rejection as determined by the pre-transplant sensitization workup. Other biologics currently being studied for use in renal transplant induction and rejection include the T-cell inhibitors efalizumab (Raptiva) and alefacept (Amevive), the proteasome inhibitor bortezomib (Velcade) that is currently approved for treatment of multiple myeloma, and eculizumab, a monoclonal antibody to C5 of the complement cascade.

### Infectious Posttransplant Complications

Infections occurring in the kidney transplant recipient differ depending on the time period posttransplant. Those infections occurring in the first month posttransplant are usually associated with the surgical procedure itself. These include surgical wound infections, infections related to vascular catheters, and urinary tract infections. General surgical procedures designed to minimize infections in the postoperative period, such as removing indwelling catheters as soon as feasible, help to minimize risk of these early infections. Prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) also may help to prevent urinary tract infections.

Within 1 to 6 months posttransplant, the risk of opportunistic infections increases. Infection with organisms such as CMV, EBV, *Pneumocystis jiroveci*, *Nocardia*, and *Listeria monocytogenes* may occur during this time period unless

prevented by prophylaxis with antiviral drugs such as valganciclovir or antibacterial agents such as TMP-SMX. For recipients at risk for CMV infection (donor CMV IgG positive, recipient negative), valganciclovir should be given daily for 3 to 6 months after transplantation. *P. jiroveci* prophylaxis with TMP-SMX, or dapsone or atovaquone if patients are TMP-SMX intolerant, is recommended for all patients for at least 6 months posttransplant.

After 6 months following transplantation, the risk of opportunistic infections decreases as the amount of immunosuppression needed to maintain allograft function diminishes. Patients who require relatively high-dose immunosuppression during this time period because of poor allograft function or because of an episode of acute rejection are at higher risk and should remain on appropriate antimicrobial prophylaxis for longer periods of time. CMV infection is one of the more severe late infectious complications that may occur, particularly in patients who are heavily immunosuppressed. Symptoms and signs of CMV disease include fever, malaise, leukopenia, and allograft dysfunction. The virus is best detected by specialized antigen assays or by polymerase chain reaction. Treatment involves reduction in immunosuppression and antiviral therapy with intravenous ganciclovir for 2 to 4 weeks followed by oral antiviral therapy for 2 to 3 months. Another pathogen of note is BK virus, a polyoma virus that generally only affects the immunosuppressed patient. BK virus affects <10% of patients receiving a renal transplant, but it is highly associated with early graft dysfunction and loss; treatment involves reduction of immunosuppression, but sometimes changing MMF to the antirheumatic (and antiviral) drug leflunomide is advantageous.

### Noninfectious Posttransplant Complications

There are a number of complications unique to transplant recipients, many of them because of side effects of the immunosuppression administered. Diabetes mellitus, hypertension, and osteoporosis are common posttransplant complications, but their management generally relies on the same principles as for the general population in addition to reduction of immunosuppression as tolerated. Anatomic and postsurgical issues, such as abdominal wall hernias, transplant renal artery stenosis, and bladder dysfunction, among others, are possible complications of kidney transplant as well.

Malignancies, particularly those of squamous epithelia, occur more frequently in transplant recipients. Transplant recipients, especially those treated with azathioprine, should be monitored for the development of skin cancers and should be advised to use sunscreen. Women should undergo annual Pap smears to screen for cervical dysplasia and cervical cancer. Acquired cystic kidney disease, in which a person's native kidneys atrophy and become cystic, affects up to 25% of the dialysis and transplant population and can lead to development of renal cell carcinoma.

PTLD is a unique complication of transplantation occurring in 1% to 5% of renal transplant recipients. Those at highest risk are EBV-negative recipients who receive a kidney from an EBV-positive donor and those recipients who have required high total doses of immunosuppression. The pathogenesis of the disorder involves the infection and transformation of B lymphocytes by EBV. These transformed B cells undergo polyclonal proliferation from which a malignant clone may emerge. PTLD may present with fever, night sweats, and lymphadenopathy. Extranodal involvement of the kidney may present as allograft dysfunction. Other sites of extranodal involvement include the gastrointestinal tract, lungs, and the central nervous system. Treatment involves first reduction of immunosuppression followed by chemotherapeutic agents if the disease does not respond to reduction in immunosuppression alone.

## Chapter Review

### Questions

1. A 23-year-old woman with diffuse proliferative lupus nephritis has progressed to stage 4 CKD despite aggressive treatment with cytotoxic agents. A recent kidney biopsy has shown advanced fibrosis. Her BMI is 30. Which statement is true with respect to her renal replacement options?
  - A. She should be educated regarding hemodialysis, peritoneal dialysis, and transplantation.
  - B. Her age makes hemodialysis the preferred renal replacement modality.
  - C. Her obesity excludes her as a candidate for peritoneal dialysis.
  - D. Lupus nephritis excludes her as a candidate for peritoneal dialysis.
2. A 52-year-old man with ESRD secondary to diabetes is maintained on an immunosuppressive regimen of cyclosporine, MMF, and prednisone. He develops post-transplant hypertension. Which of the following antihypertensive medications may affect cyclosporine levels?
  - A. Losartan
  - B. Enalapril
  - C. Amlodipine
  - D. Hydrochlorothiazide
3. A 65-year-old man with severe osteoarthritis develops ESRD from chronic nonsteroidal antiinflammatory drug use. He develops uremic symptoms and begins hemodialysis via a tunneled catheter. Within his first month of dialysis he develops *S. aureus* bacteremia, for which he is treated with intravenous vancomycin with rapid clinical improvement. One month later he has a swollen right knee with a palpable effusion. He has low-grade fever and malaise. His anemia does not respond to EPO. Which of the following statements is true regarding the pathogenesis of this patient's constellation of findings?
  - A. Knee joint aspiration for cell count and culture is indicated.
  - B. Infection and inflammation may underlie this patient's EPO unresponsiveness.
  - C. Nasal carriage of *S. aureus* may be a risk factor for this patient's infection.
  - D. Attempted salvage of tunneled catheters in the setting of *S. aureus* infection carries an unacceptably high risk of metastatic infection.
  - E. All of the above
4. A 30-year-old woman with ESRD presents to your practice for evaluation. In review of her laboratories, she is found to have a calcium level of 10.5 mg/dL and a phosphorus level of 6.7 mg/dL, and she is not on a phosphate binder. Which of the following medications would be appropriate to add?
  - A. Sevelamer carbonate with meals
  - B. Calcitriol
  - C. Doxercalciferol
  - D. Calcium acetate with meals
5. A 30-year-old woman with ESRD secondary to type 1 diabetes receives a kidney transplant from a live donor. The donor is EBV positive, and the recipient is EBV negative. She has early rejection requiring treatment with high-dose steroids and a monoclonal antibody but recovers good allograft function. One year later she develops fever, night sweats, pulmonary infiltrates, and a pleural effusion. Pleural fluid cytology reveals a lymphocytic infiltrate that is suspicious for lymphoma. Which of the following is the most likely diagnosis?
  - A. Pseudomonas pneumonia
  - B. Rapamycin pneumonitis
  - C. Posttransplant lymphoproliferative disorder
  - D. *Pneumocystis carinii* pneumonia

## Hematuria and Proteinuria

HASAN BAZARI

**H**ematuria and proteinuria are common problems encountered in medicine that may be benign conditions or harbingers of severe systemic illness requiring vigorous evaluation and treatment. This chapter is categorized into conditions that are defined by the presence of hematuria alone, conditions limited to proteinuria alone, or those in which hematuria is combined with proteinuria. The evaluation and therapy of conditions when both are present are dealt with in the later part of the chapter.

### Hematuria

Hematuria can be classified as microscopic or gross hematuria when there is visible blood, and it can be symptomatic or not. There are a number of causes of red urine without hematuria, including porphyria and many drugs such as phenazopyridine, rifampin, B<sub>12</sub>, and phenytoin, as well as food components in beets and blackberries. Microscopic hematuria is defined as two or more red blood cells per high-powered field, although there are many different definitions. The dipstick is used as the screening test for hematuria and needs to be confirmed with microscopy. The dipstick will test positive with both hemoglobin and myoglobin in the setting of hemolysis and rhabdomyolysis, respectively. There can be transient hematuria that is associated with vigorous exercise, intercourse, trauma, or menses. In these circumstances, the evaluation should be repeated with appropriate instructions to the patient. Patients with persistent hematuria should be considered for evaluation, the approach to which is discussed subsequently. The prevalence of microscopic hematuria varies from 0.11% to 16.1% based on the series and screening method used. In evaluating hematuria, the crucial determination is whether there is confidence in identifying hematuria as glomerular (Fig. 62.1) or nonglomerular. Hematuria can be identified as being more likely to be glomerular when there is accompanying proteinuria, hypertension that is new, kidney insufficiency, the presence of acanthocytes or dysmorphic red blood cells, or the presence of cellular casts (especially red blood cell casts). In the absence of clear indication of glomerular origin of hematuria, a systematic evaluation should be undertaken. There have been valid arguments questioning the utility of screening and undertaking an exhaustive evaluation of hematuria.

Patients with documented glomerular hematuria, proteinuria, or kidney insufficiency will require evaluation for glomerular causes of hematuria. These are categorized in Box 62.1. The diseases include antineutrophil cytoplasmic antibody–associated vasculitis, anti–glomerular basement membrane (anti-GBM) disease, hypocomplementemic immune complex vasculitis, and normocomplementemic systemic vasculitis. The antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis includes granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (Fig. 62.2). Anti-GBM disease, also known as Goodpasture syndrome, is often associated with pulmonary involvement although it may be limited to just the kidneys in nonsmokers presumably secondary to better sequestration of the antigen in the lung. Hypocomplementemic immune complex glomerulonephritis includes poststreptococcal glomerulonephritis, systemic lupus erythematosus, cryoglobulinemia, hypocomplementemic vasculitis, membranoproliferative glomerulonephritis, subacute bacterial endocarditis, and visceral abscess. The normocomplementemic immune complex glomerulonephritides include IgA nephropathy and Henoch-Schönlein purpura (also named *IgA vasculitis*), both of which share the presence of IgA immune complexes as the major immune complexes. The last category of normocomplementemic glomerulonephritis also includes immunotactoid and fibrillary glomerulonephritis. The serologic evaluation should be tailored to the specifics of the particular case.

The presentation of isolated hematuria may be asymptomatic or part of an evaluation for a complaint that may or may not be related to the hematuria. The causes can be categorized as glomerular or nonglomerular. Glomerular causes can include all of the diseases discussed in Box 62.1. However, the absence of proteinuria, hypertension, and kidney insufficiency makes it less likely that these conditions are responsible for the hematuria. There have been several series in which patients with no other etiology for hematuria have undergone kidney biopsies. More than half of these patients had a normal kidney biopsy. Those with kidney disease had mainly IgA nephropathy and thin basement membrane disease. The latter is a familial disorder with autosomal dominant

• **Fig. 62.1** Glomerular hematuria.

• **Fig. 62.2** Micrograph of cell staining for antineutrophil cytoplasmic antibody.

### • **BOX 62.1** Rapidly Progressive Glomerulonephritis

- Anti-glomerular basement membrane disease
- Pauci-immune necrotizing glomerulonephritis
  - Granulomatosis with polyangiitis
  - Microscopic polyangiitis
  - Eosinophilic granulomatosis with polyangiitis
- Immune complex glomerulonephritis
  - Hypocomplementemic glomerulonephritis
    - Systemic lupus
    - Endocarditis
    - Cryoglobulinemia
    - Poststreptococcal glomerulonephritis
    - Membranoproliferative glomerulonephritis
  - Normocomplementemic glomerulonephritis
    - IgA nephropathy
    - Henoch-Schönlein purpura or IgA vasculitis
    - Fibrillary glomerulonephritis
    - Immunotactoid glomerulonephritis

inheritance and often represents the carrier state for the autosomal recessive form of Alport syndrome as well as classical Alport syndrome, which is an X-linked recessive disease with uniform onset of end-stage kidney disease in men and a variable but more benign clinical course in women. The mutations for classical X-linked Alport are in *COL4A5* and those for the autosomal diseases in *COL4A3* and *COL4A4* genes. In some series, the mutations in *COL4A5* mostly cause Alport syndrome and, in a small minority, thin basement membrane disease. Other focal glomerulonephritides make up a small number of cases presenting as isolated hematuria. The longer duration of the hematuria and the familial nature of the disease may reflect a better prognosis and allow most patients to forgo a kidney biopsy.

Nonglomerular causes of hematuria can be classified anatomically as detailed in **Box 62.2**. Upper tract sources of hematuria include sources from the kidney, including nephrolithiasis, pyelonephritis, kidney cell carcinomas,

### • **BOX 62.2** Nonglomerular Hematuria

Transient: exercise

Kidney: nephrolithiasis, pyelonephritis, polycystic kidney disease, kidney cell carcinoma, sickle cell disease or trait, transitional cell carcinoma, tuberculosis

Lower tract: transitional cell carcinoma of the bladder, urinary tract infection, prostatitis, prostate cancer, ureteral stricture, schistosomiasis, nutcracker syndrome, Osler-Weber-Rendu syndrome

Urethral

autosomal dominant polycystic kidney disease, medullary sponge kidney, kidney pelvis and ureteral transitional cell carcinoma, hypercalciuria, hyperuricosuria, sickle cell trait and disease, tuberculosis, kidney infarct, and papillary necrosis. Lower-tract sources include anything beyond the kidney parenchyma such as common benign conditions such as urinary tract infection, prostatitis, and urethritis as well as more malignant conditions such as bladder cancer and prostate cancer. Other conditions include ureteral strictures, schistosomiasis, and nutcracker syndrome with the left kidney vein compressed between the aorta and the superior mesenteric artery and retroaortic left kidney vein. Other unusual causes of gross hematuria include hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) and loin pain-hematuria syndrome. Patients with sickle cell trait can have gross hematuria from medullary ischemia. Rarely sickle cell trait can be associated with kidney medullary carcinoma, which has a poor prognosis. The epidemiology of hematuria varies with age. In children, there have been several large screening studies that have shown very rare instances of malignancies such as Wilms tumor. The incidence of malignancies is higher in patients with gross hematuria. Patients who are age >40 years, and definitely those who are age >50 years, have a higher prevalence of malignancies such as bladder cancer and warrant evaluation. Patients with macroscopic hematuria had an 18.9% prevalence of malignancy compared

with a 4.8% prevalence of malignancy with microscopic hematuria in one series.

### Risk Factors for Malignancies

In all patients with microscopic hematuria, about 5% will be found to have malignancies, predominantly transitional cell carcinoma of the bladder. The risk factors for malignancy include older age, cigarette smoking, occupational exposure to chemicals, leather manufacturing, rubber and tire manufacturing, phenacetin use, cyclophosphamide, mitotane, and aristolochic acid exposure. Gross hematuria is much more likely to be associated with a diagnosis of malignancy. Many patients with both bladder cancer and kidney cell carcinoma will have gross hematuria at presentation.

### Evaluation of Hematuria

#### History

The history should include the search for symptoms of stone disease, weight loss or flank pain, symptoms of systemic vasculitis, drug exposure, smoking, occupational exposure to aniline dyes in leather manufacturing, family history of hematuria, and kidney disease, as well as accompanying hearing loss. Radiation exposure, cyclophosphamide exposure, and analgesic use are all risk factors for the development of bladder and ureteral cancer. Bladder symptoms such as urinary urgency, dysuria, and frequency may reflect infection, inflammation, or malignancy. The history of use of anticoagulation may be an important part of the history, but the diagnostic evaluation cannot be truncated based on the presence of a coagulopathy.

#### Examination

The blood pressure (BP) may be important if elevated. Findings of sinusitis, eye findings, arteriovenous malformations, rash, arthritis, pulmonary findings of consolidation, cardiac dysfunction, and the detection of palpable masses, and prostate tenderness or enlargement may all be clues to the etiology of hematuria.

#### Laboratory Evaluation

Patients with suspected glomerular hematuria should have a panel of tests including antinuclear antibody (ANA), ANCA, anti-GBM antibody, C3 and C4 complements, cryoglobulins, blood cultures when indicated, anti-DNAse B or antistreptolysin O, serum immune electrophoresis, and serum free light chains.

The urinalysis is crucial in the evaluation of proteinuria. The presence of proteinuria often points to a glomerular origin, but small amounts of proteinuria are nonspecific. The presence of dysmorphic red blood cells, especially the presence of acanthocytes, is also consistent with a glomerular source, but care should be exercised in being an expert in the recognition of acanthocytes. Competency in the assessment of red cell morphology comes with experience but can streamline the evaluation of hematuria avoiding unnecessary tests with cost and risks such as CT scans and cystoscopy.

Red cell casts are pathognomonic for glomerular disease and will preclude the evaluation for a nonglomerular hematuria.

Patients with proteinuria on the dipstick should have a protein:creatinine ratio for quantification of the degree of proteinuria.

Urine cytology is crucial in patients who are older. The sensitivity of urine cytology is about 70%, but the specificity is close to 100%. There have been a small number of patients in whom all other tests may fail to reveal a source, but a positive cytology can lead to a diagnosis of bladder cancer. Urine cytology should be done in patients age >40 years, and the failure to find the etiology in those age <40 years should dictate a case-by-case approach erring on the conservative side and positive results pursued with cystoscopy as well as imaging studies.

### Imaging

#### Intravenous Urography

Intravenous urography (IVU) had been traditionally used in the evaluation of hematuria. The limitations of the study include the limitations of sensitivity and the inability of the study to distinguish solid and cystic lesions. The use of contrast may be an issue for patients with kidney insufficiency. The use of IVU has waned with time, and both ultrasound and CT scan have become more the standard of care, with sensitivity for CT above 90%, slightly lower for ultrasound with less sensitivity for stones and only 50% for intravenous urography. Kidney stones are better visualized with CT scan.

#### Ultrasound

Ultrasound has many advantages including ease of use and availability, lack of radiation, and lack of contrast exposure. Ultrasound may miss small lesions, with lesions <3 cm yielding a sensitivity of 80%. Ultrasound can miss ureteral lesions and stones in the collecting system. Ultrasound may be the preferred modality in pregnancy and in younger patients who are at lower risk for malignancies.

#### Computed Tomography Scan

Over the last few years, CT scanning has emerged as the best modality for imaging the genitourinary tract. A non-contrast CT scan is done for patients in whom a kidney stone is suspected as the cause of the hematuria based on the presentation. Following this, contrast-enhanced CT scan is performed to look for enhancing masses as well as delineation of the collecting system. The sensitivity of CT for the detection of ureteral stones approaches 100%. CT scan may also image the bladder and define lesions that cause ureteral or bladder deformities. This may preclude the need for cystoscopy in a younger patient population age <40 years, where the incidence of bladder cancer is much lower. Nonetheless, the performance of cystoscopy would not be discouraged because there are small numbers of patients in every series who have bladder cancer in their twenties. Multidetector CT scan was found in a large study to have a sensitivity of 64% and a specificity of 98% and had a higher accuracy compared with intravenous urography.

### Retrograde Pyelogram

Retrograde pyelograms have largely been replaced by cystoscopy and cystourethroscopy, which allow for both diagnostic biopsies and occasional therapeutic interventions on small lesions. There may be instances of hematuria where a retrograde pyelogram may need to be done.

### Cystoscopy

Cystoscopy should be performed in all patients in whom there is a significant risk of bladder cancer. These include patients age >40 years, those with a smoking history, and those with significant exposure to carcinogens for the genitourinary tract such as aniline dyes and cyclophosphamide. Women have a lower incidence of bladder cancer, and there may be lower yield in the performance of cystoscopy. Patients with gross hematuria have a higher likelihood of having a malignant lesion as the etiology and warrant a full evaluation including cystoscopy even at younger ages.

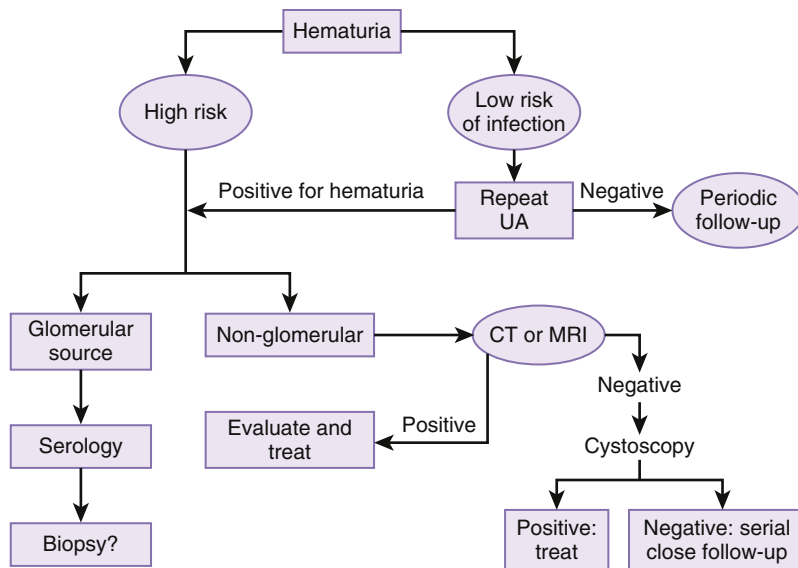

## Approach to the Patient With Hematuria

The patient with a single episode of microscopic hematuria should be instructed to have a repeat evaluation and also be instructed to avoid heavy exertion before testing (see Fig. 62.1). A single episode of microscopic hematuria in a high-risk patient or a single episode of gross hematuria in adults warrants evaluation. If the patient is low risk, the repeat urine testing is negative, and the evaluation ends with periodic follow-up. In those who have persistent microscopic hematuria, a single episode but with risk factors for bladder cancer, and in those with a single episode of gross hematuria, there should be a comprehensive evaluation. Urine microscopy done by someone with experience in the identification of dysmorphic red cells in the urine may obviate the need for evaluation for a nonglomerular source of hematuria, as may the presence of proteinuria, new hypertension, abnormal kidney function, or the presence of cellular casts. Gross hematuria is classically seen in certain forms of glomerulonephritis such as IgA nephropathy, poststreptococcal glomerulonephritis, and occasionally anti-GBM disease. Gross hematuria related to glomerulonephritis is often “tea” colored.

If there is evidence for glomerular disease, the workup typically involves serologic evaluation followed by a decision to do a kidney biopsy before the institution of therapy. Therapy may be instituted empirically before a biopsy in certain conditions where there is rapid decline in kidney function or a serologic test with a high degree of specificity such as an ANCA (see Fig. 62.2) or anti-GBM test in the context of a high-probability clinical situation. In the presence of only microscopic hematuria and a negative serologic evaluation, the decision to proceed with a kidney biopsy has to be individualized (Fig. 62.3). There may be no specific diagnosis on the kidney biopsy in the majority of cases of patients with microscopic hematuria. Among those who do have a diagnosis, the majority have IgA nephropathy or thin basement membrane disease. The former is treated when it manifests with high-grade proteinuria, progressive kidney deterioration, or rapidly progressive

glomerulonephritis but not with just asymptomatic hematuria. Benign treatments such as fish oil and close monitoring of kidney function as well for proteinuria are recommended for patients with mild IgA nephropathy. Thin basement membrane disease has been traditionally thought of as a benign disease with autosomal dominant inheritance. Many of these patients have mutations in the alpha-3 and alpha-4 chains of type 4 collagen and represent the carrier state for the autosomal recessive form of Alport. The finding of thin basement membrane disease has also been reported with mutations in the alpha-5 chain, which is more traditionally associated with the X-linked Alport, the cause of Alport syndrome in 85% of patients. Thin basement membrane disease has also been associated with focal sclerosis in certain families, and caution needs to be exercised in prognosticating in a very young patient with no family history and thin basement membrane disease on kidney biopsy. Given that a kidney biopsy incurs a small risk of significant bleeding, and the lack of therapeutic options and potential prognostic uncertainty for both IgA nephropathy and thin basement membrane disease, it would be reasonable to discuss the risks and benefits with a patient before a decision to biopsy. Most patients are comfortable with close follow-up except under unusual circumstances. One setting in which a biopsy may be done with a lower threshold is in the transplant donor evaluation, in which there will be risk to the donor if donation occurs in the setting of intrinsic kidney disease. In this circumstance, a kidney biopsy that is normal would allow for the organ donation to proceed if the remainder of the evaluation for hematuria is negative. There are reports of patients with thin basement membrane being organ donors after confirmation with a kidney biopsy. This is an area of uncertainty, and caution should be used, especially if there is not a benign family history and definitely in the young organ donor.

For those with no evidence for glomerular bleeding, the evaluation should include treatable conditions that may resolve the hematuria, specifically urinary tract infections (UTIs). Those with documented infection should have a repeat urinalysis after treatment of the infection. If the hematuria resolves, no further evaluation is needed. In those without a UTI, imaging with an ultrasound or CT scan is recommended. The need for imaging has to be tempered with the likelihood of finding a treatable lesion. The probability of malignancy in children is exceedingly low. Routine screening for hematuria in children and adults who are asymptomatic is not recommended. Although this issue is controversial, a kidney ultrasound is sufficient, in the presence of hematuria in children, if imaging is undertaken. In adults and especially those age >40 years, those with risk factors for bladder cancer, and those with gross hematuria of nonglomerular origin, CT scan with and without contrast as well as cystoscopy should be done. Imaging of the bladder with CT scan will miss mucosal lesions, and cystoscopy also allows for biopsies to be obtained. Urine cytology is also recommended in high-risk patients because it may occasionally detect the presence of lesions that are not found on initial cystoscopy and imaging, leading to further evaluation.

• Fig. 62.3 Approach to the patient with hematuria. UA, Urinalysis.

Patients who have undergone an extensive workup with a negative evaluation are at low risk for malignancy. Those of a younger age and only microscopic hematuria require no further evaluation. Patients with gross hematuria with a negative evaluation may warrant further evaluation such as angiography and do require close follow-up for lesions that may have been missed on the initial evaluation.

## Proteinuria

Proteinuria is often an incidentally noted laboratory finding and, at other times, the central finding of a critically ill patient. The kidney filters 180 L of ultrafiltrate a day, and the concentration of albumin in Bowman's space is about 1 mg/dL. Normal protein excretion is <150 mg per day with <10 to 20 mg of albumin excretion a day. The proteins that are filtered, which are lower-molecular-weight proteins and some albumin, are reabsorbed for the most part in the proximal convoluted tubule, and most of the secreted proteins originate from the kidney tubular epithelial cells and are called *Tamm-Horsfall proteins*.

## Classification of Proteinuria

Proteinuria can be classified as overt proteinuria or microalbuminuria, which is detected by radioimmunoassay, enzyme-linked immunosorbent assay, or nephelometry. The dipstick is sensitive to albumin but not to other proteins such as light chains. Low-level proteinuria that is not detectable by the dipstick may be clinically very significant. Microalbuminuria is the excretion of between 30 and 300 mg of albumin per gram of creatinine. Initially defined in the setting of type 1 diabetes mellitus (DM) as the earliest stage of diabetic nephropathy, it has become a marker of kidney disease with prognostic significance for cardiovascular outcome, as have overt proteinuria and chronic kidney disease.

## Classification of Overt Proteinuria

Proteinuria can be classified in the following categories (Box 62.3):

1. **Overflow proteinuria:** The kidney may provide an excretory function for low-molecular-weight proteins that are produced in abnormal quantities and are freely filtered and excreted. The most common cause of overflow proteinuria is in the setting of monoclonal gammopathies, in which excessive light chain production can lead to a number of kidney manifestations including myeloma kidney with acute kidney failure, amyloidosis, and light chain deposition disease with concurrent albuminuria and nephrotic syndrome as well as an isolated finding of Bence-Jones proteinuria with no kidney manifestations. Another rarer cause of overflow proteinuria is lysozymuria in the setting of acute myelogenous leukemia. Light chains may not be detected by the dipstick, but a discrepancy between the dipstick and the quantitative measurement of proteinuria is a telltale sign for the presence of paraproteins. Sulfosalicylic acid can be used to detect light chains in the setting of a negative dipstick test for proteinuria.
2. **Tubular proteinuria:** The protein excretion in patients with tubular injury mainly reflects failure of the proximal convoluted tubule to reabsorb filtered protein and some tubular secretion of protein. The quantity will be <1 g per day, and on electrophoresis these are mainly low-molecular-weight proteins.
3. **Albuminuria**
  - a. Microalbuminuria has been discussed earlier.
  - b. **Transient proteinuria:** Transient excretion of a small amount of albumin is common in certain acute settings including fever, pneumonia, exercise, and congestive heart failure. The proteinuria resolves with resolution of the acute illness. The total amount of protein seldom exceeds 1 g per day.

### • BOX 62.3 Proteinuria

Overflow proteinuria  
 Bence-Jones or monoclonal light chain proteinuria  
 Lysozymuria  
 Tubular proteinuria  
 Albuminuria  
 Microalbuminuria  
 Transient proteinuria  
 Orthostatic proteinuria  
 Nonnephrotic albuminuria  
 Nephrotic syndrome

- c. Orthostatic proteinuria: Young patients with asymptomatic proteinuria should be evaluated for this condition in which there is predominantly proteinuria with upright position and not on recumbency. Although this is deemed to be a benign condition based on lack of kidney pathology on biopsy and a benign course with long-term follow-up over decades, this condition may occasionally reflect the initial stage of a more serious kidney lesion and hence should be followed closely.
- d. Nonnephrotic proteinuria: Proteinuria in the non-nephrotic range if not from overflow proteinuria can represent tubulointerstitial disease or glomerular disease. If the protein:creatinine ratio is  $>1$ , it is likely glomerular in origin. Patients with a ratio of  $<1$  could have either a glomerular or tubulointerstitial source for their proteinuria. Urine protein electrophoresis is useful in distinguishing between the two. In general, for glomerular lesions, the degree of proteinuria reflects the extent of kidney disease unless there is advanced chronic kidney disease.
- e. Nephrotic syndrome is defined by the excretion of  $>3.5$  g of protein per day associated with hypertension, edema, hypoalbuminemia, and hyperlipidemia. The presence of nephrotic syndrome is usually clinically evident and can be associated with a hypercoagulable state.

### Differential Diagnosis

The differential diagnosis of proteinuria is summarized in Table 62.1 and includes the following:

1. Transient proteinuria: fever, pneumonia, exercise, congestive heart failure.
2. Overflow proteinuria: Bence-Jones proteinuria, multiple myeloma, amyloidosis, lymphoma, Waldenstrom, monoclonal gammopathy of uncertain significance. Lysozymuria is seen with acute myelogenous leukemia.
3. Microalbuminuria is seen in DM and hypertension as well as syndrome X. Diabetics should be screened yearly for type 2 DM and yearly starting at year 5 after onset for type 1 DM.
4. Orthostatic proteinuria can be idiopathic and benign or rarely an early manifestation of a primary kidney disease.

**TABLE 62.1 Etiology of Proteinuria**

Type	Etiology
Transient proteinuria	Fever, exercise, CHF
Overflow proteinuria	Myeloma, AML
Microalbuminuria	Diabetes mellitus
Orthostatic proteinuria	Usually benign
Tubular proteinuria	Acute kidney injury, interstitial nephritis
Glomerular proteinuria	All kidney glomerular diseases
Nephrotic syndrome	Primary and secondary GN, familial
Nephritic syndromes	RPGN, indolent GN, familial and genetic

AML, Acute myelogenous leukemia; CHF, congestive heart failure; GN, glomerulonephritis; RPGN, rapidly progressive glomerulonephritis.

Patients need an appropriate laboratory evaluation and close follow-up.

5. Tubular proteinuria: These can be transient in the setting of acute tubular injury such as aminoglycoside- or cisplatin-induced tubular injury as well as acute ischemic injury. The differential diagnosis of acute interstitial nephritis includes collagen vascular diseases such as systemic lupus erythematosus where glomerular lesions are more characteristic and Sjögren, as well as sarcoidosis, IgG4-associated interstitial nephritis, and tubulointerstitial nephritis with uveitis (TINU) syndrome. Infections such as *Legionella* pneumonia, leptospirosis, and ehrlichiosis can cause acute interstitial nephritis. Bence-Jones proteins can induce tubular dysfunction and cause tubular proteinuria.
6. Glomerular proteinuria and nephrotic syndrome: This can be subclassified as either primary kidney disease, genetic, or secondary to a systemic disease.
  - a. Primary kidney disease in adults includes membranous nephropathy, focal and segmental glomerulonephrosclerosis, minimal change disease, and membranoproliferative glomerulonephritis in order of frequency, although recent series have shown that focal segmental glomerulosclerosis (FSGS) may now be the leading cause of idiopathic nephrotic syndrome.
  - b. Familial nephrotic syndrome with a number of mutations identified in podocyte proteins including nephrin, podocin, and alpha-actinin-4. These cause predominantly pediatric disease but are increasingly being recognized in adults as a cause of nephrotic syndrome, with mutations in new proteins such as TRPC6.
  - c. Secondary causes of nephrotic syndrome include the following:
    - i. Malignancies with membranous nephropathy from solid tumors such as lung cancer. Hodgkin

- disease is associated with minimal change disease, membranous nephropathy from non-Hodgkin, primary (AL) amyloidosis from myeloma or lymphoma, and secondary (AA) amyloidosis from kidney cell carcinoma.
- ii. Drugs such as nonsteroidal antiinflammatory drugs (NSAIDs) induce minimal change disease and focal sclerosis; captopril is associated with membranous nephropathy, and pamidronate is associated with focal sclerosis.
  - iii. Infections associated with membranous nephropathy include hepatitis B, hepatitis C, malaria, syphilis, and schistosomiasis. Endocarditis, osteomyelitis, and tuberculosis with chronic infections can cause the AA form of amyloidosis.
  - iv. Chronic inflammatory conditions such as familial Mediterranean fever lead to AA amyloidosis.
7. Nephritic diseases and rapidly progressive glomerulonephritis. These can be classified into four categories:
- a. Anti-GBM disease with kidney and pulmonary disease manifest as pulmonary hemorrhage, usually in smokers.
  - b. ANCA-associated vasculitis with granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis. These all share pulmonary involvement, with asthma and eosinophilia being unique to eosinophilic granulomatosis with polyangiitis. These diseases also have kidney involvement, mononeuritis multiplex, arthritis, and skin lesions as well as a variety of other organ involvement.
  - c. Immune complex glomerulonephritis with low complements including systemic lupus, subacute bacterial endocarditis, cryoglobulinemia, membranoproliferative glomerulonephritis, and visceral abscess.
  - d. Immune complex glomerulonephritis with normal C3 and C4. This includes IgA nephropathy and Henoch-Shönlein purpura and immunotactoid and fibrillary glomerulonephritis.

## Evaluation of Proteinuria

The evaluation of patients with proteinuria starts with a careful review of the history and a meticulous physical examination. Central to the extent and pace of the evaluation are the quantification of the proteinuria, the presence of a nephritic component, and the level of accompanying kidney function.

### History

The history should review and look for features of systemic disease. Systemic lupus erythematosus, ANCA-associated vasculitis, and amyloidosis all may have distinct skin manifestations. Easy bruising is seen in amyloidosis. Photo-sensitivity is a feature of lupus. A careful history of drug intake, both prescribed and over-the-counter medications, may be useful in the evaluation of proteinuria. Nonsteroidal antiinflammatory drugs are common causes of both proteinuria

and kidney insufficiency. Pulmonary involvement is characteristic of Goodpasture syndrome as well as ANCA-associated vasculitis. A unique combination of interstitial nephritis with nephrotic syndrome secondary to minimal change disease is induced by NSAIDs. Systemic features of weight loss and constitutional symptoms may reflect an underlying malignancy. The history of abrupt onset of edema, foamy urine, and hypertension is often the initial and dramatic presentation of nephrotic syndrome. Sinusitis can be seen in ANCA-associated vasculitis. Intravenous drug use and high-risk sexual behavior can lead to infections such as HIV, hepatitis B, and hepatitis C, all of which are associated with kidney involvement. A family history of kidney disease may be a clue to Alport syndrome, especially if there is an X-linked inheritance pattern.

### Physical Examination

The blood pressure may be very elevated in certain forms of kidney disease such as membranous nephropathy, whereas it tends to be less elevated in minimal change disease and HIV-associated nephropathy. The physical examination may reveal a classical rash of amyloidosis or systemic lupus, or there can be joint swelling, macroglossia, hepatosplenomegaly, or edema. Lymphadenopathy that is pathologic may be a clue for an underlying lymphoma with a paraneoplastic nephrotic syndrome.

### Laboratory Evaluation

The laboratory evaluation (Table 62.2) includes the hematocrit, which may be low in certain systemic diseases, especially if the kidney function is normal. The anion gap may be low with multiple myeloma. There may

**TABLE 62.2** Evaluation of Hematuria and Proteinuria

Hematocrit	ANA
Cr or eGFR	Complements C3, C4
Anion-gap	Antineutrophil cytoplasmic antibody
Serum bicarbonate	Anti-glomerular basement membrane antibody
Urinalysis and sediment	Cryoglobulins
Calcium	Hepatitis serology with hepatitis B surface antigen and antibody as well as hepatitis C antibody and viral RNA
Globulins	Antistreptolysin O or anti-DNAse B acute titers
Urine protein:Cr ratio	Serum free light chains, ACE level
Transaminases	IgG subsets, IgG4 levels
HIV	Serum immune electrophoresis
Urine eosinophils	Antibody to M-type phospholipase A2 receptor
Urine <i>Legionella</i> antigen	
24-hour urine collection for proteinuria	
Split collection for orthostatic proteinuria	
Urine for Bence-Jones	
Antibody to phospholipids	
Lupus anticoagulant	

ACE, Angiotensin-converting enzyme; ANA, antinuclear antibodies; Cr, creatinine; eGFR, estimated glomerular filtration rate.

be evidence for a renal tubular acidosis or hypercalcemia with myeloma. The liver function tests may be abnormal with viral hepatitis. The lipids may be markedly elevated in patients with nephrotic syndrome in addition to hypoalbuminemia. The urinalysis is central in the evaluation of proteinuria. The urine protein dipstick is more sensitive to albumin than other proteins and therefore will underestimate the degree of Bence-Jones proteinuria. 1+ proteinuria is approximately 30 mg/dL, and 3+ is about 500 mg/dL. The presence of hematuria and leukocytes in the dipstick as well as examination of the urine sediment is crucial in the evaluation of the patient with proteinuria. Dysmorphic red blood cells and red cell casts are indicative of glomerular pathology. Granular (Fig. 62.4)

• Fig. 62.4 Granular cast.

• Fig. 62.5 Hyaline cast.

and hyaline casts (Fig. 62.5) suggest tubular injury. White cell casts are seen in cases of interstitial nephritis, which can be idiopathic as seen in TINU syndrome, sarcoidosis, IgG4-related interstitial nephritis, infections such as *Legionella* pneumonia, or in drug-induced allergic interstitial nephritis.

The 24-hour urine collection used to be the cornerstone of quantifying proteinuria, but this has been replaced by the spot urine protein:creatinine ratio in large part because of inaccuracies in the 24-hour urine collection and the cumbersome nature of the 24-hour urine collection. The urine protein:creatinine ratio, which is the ratio of protein to creatinine expressed as a mg/dL-to-mg/dL ratio, has been validated to be accurate in large studies. There have been arguments against its use based on the diurnal variation in protein excretion as well as variations in creatinine excretion based on dietary intake. There are patients in whom the evaluation will include a split 24-hour collection to evaluate for orthostatic proteinuria.

The next step in the evaluation of proteinuria is ensuring that the proteins are predominantly albumin in certain circumstances. Both overflow proteinuria with Bence-Jones proteins and tubular proteinuria can be detected by the urine immune electrophoresis looking for monoclonal light chains. The serum immune electrophoresis and urine for Bence-Jones allow diseases such as multiple myeloma and certain kinds of amyloidosis to be screened for. In amyloidosis, there will be large amounts of albumin and light chains that are monoclonal in most patients. The newer serum free light chain assay allows for higher sensitivity in detecting monoclonal disorders.

Other serologies that may be obtained include the following:

- ANA when indicated and, if appropriate, more specific lupus tests such as anti-dsDNA antibody and anti-phospholipid antibody
- Complements C3 and C4
- ANCA in patients with a systemic vasculitis, especially if there is also pulmonary involvement
- Anti-GBM antibody is essential in patients with an active sediment and often pulmonary involvement
- Cryoglobulins and rheumatoid factor
- Hepatitis serology with hepatitis B surface antigen and antibody as well as hepatitis C antibody and viral RNA if indicated HIV serology and viral load
- Antistreptolysin O or anti-DNAse B acute titers for the diagnosis of poststreptococcal glomerulonephritis
- Serum free light chains for multiple myeloma, amyloidosis, and light chain deposition disease
- Serum immune electrophoresis for myeloma, amyloidosis, and light chain deposition disease
- Antibody to phospholipids, lupus anticoagulant
- Urine for Bence-Jones protein
- Antibody to M-type phospholipase A2 receptor for idiopathic membranous nephropathy
- IgG4 levels in patients with interstitial nephritis

## Imaging

Imaging will often be done when appropriate to look for underlying systemic disorders such as malignancies, which may be the underlying cause for nephrotic syndrome. Both solid tumors and lymphomas can present with nephrotic syndrome, especially in the elderly. The malignancy is usually detected by a careful history and physical examination combined with age-appropriate screening for malignancies. An exhaustive evaluation for an underlying malignancy does not need to be undertaken for all cases of nephrotic syndrome.

Kidney ultrasound will reveal congenital absence or hypoplasia of one kidney, which leads to focal sclerosis. Kidney ultrasound may reveal hydronephrosis, and a voiding cystoureterogram may reveal reflux as the etiology for proteinuria, especially in children.

## Kidney Biopsy

Kidney biopsies are usually done under real-time ultrasound guidance with a severe complication rate of about 1% to 2% of significant bleeding requiring transfusion. Therefore biopsies should be undertaken with a clear discussion of risks and benefits. The current indications for a percutaneous kidney biopsy are rapidly progressive glomerulonephritis of unknown etiology, in certain cases of ANCA-associated vasculitis, with a negative serologic evaluation, patients with nephrotic syndrome, patients with acute kidney failure of uncertain etiology, patients with lupus nephritis to determine optimal therapeutic approach, and in patients with both hematuria and proteinuria. Consideration of kidney biopsy in patients with <1 g of proteinuria per day and in patients with isolated hematuria has to be individualized. Patients with proteinuria of between 1 and 3.5 g per day may be considered for kidney biopsy if they do not have far advanced chronic kidney disease and are candidates for aggressive management.

## Therapy of Specific Kidney Conditions

Therapeutic approaches are summarized in [Table 62.3](#) and include the following possibilities:

1. Transient proteinuria resolves spontaneously and requires no specific treatment.
2. Overflow proteinuria is fully evaluated, and treatment is of the underlying myeloma, leukemia, or lymphoma.
3. Microalbuminuria should be managed with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) as well as BP control.
4. Patients with tubulointerstitial disease should have treatment for the underlying disorder including withdrawal of offending drugs. Multiple myeloma with myeloma kidney or cast nephropathy will need specific therapy.
5. Patients with albuminuria that is <1 g per day should have an extensive evaluation unless they have a commonly associated disorder such as DM, and the decision to biopsy will be influenced by the presence of hematuria, chronic kidney disease, hypertension, and age. Clear therapy will be undertaken only when a clear diagnosis is established.
6. Patients with proteinuria of between 1 and 3.5 g should have an evaluation including a kidney biopsy unless they have a known diagnosis such as DM, have advanced chronic kidney disease, or are not candidates for aggressive therapy.
  - a. Idiopathic nephrotic syndrome is treated with steroids alone for minimal change disease and focal sclerosis and a combination of steroids and melphalan or cyclophosphamide for membranous nephropathy.
7. Patients with nephrotic syndrome should be evaluated unless they have a known etiology such as NSAID use or diabetes. Therapeutic considerations, stage of kidney disease, and risks of treatment need to be considered.

**TABLE 62.3** Therapy of Proteinuria

Specific Patients	Specific Treatments
<ul style="list-style-type: none"> <li>• Overflow proteinuria</li> <li>• Orthostatic or transient proteinuria</li> <li>• Microalbuminuria</li> <li>• Proteinuria in nonnephrotic range</li> <li>• Nephrotic syndrome</li> <li>• RPGN</li> <li>• Anti-HCV medications for those with HCV infection</li> <li>• All patients with renal involvement</li> </ul>	<ul style="list-style-type: none"> <li>• Treat myeloma if indicated</li> <li>• No specific therapy needed</li> <li>• BP control, ACEi/ARB therapy</li> <li>• ACEi/ARB ± specific therapy</li> <li>• ACEi/ARB ± specific therapy</li> <li>• Steroids/Cytosan or rituximab/± PE</li> <li>• BP control</li> <li>• Lipid management</li> <li>• ACEi/ARB use when proteinuria is present</li> <li>• Aldosterone antagonists for proteinuria watching K</li> <li>• Modest protein restriction</li> <li>• Vitamin D therapy for deficiency</li> <li>• Anticoagulation for thrombosis</li> </ul>

ACEi/ARB, Angiotensin-converting enzyme inhibitor/angiotensin receptor blocker; BP, blood pressure; HCV, hepatitis C virus; PE, plasma exchange; RPGN, rapidly progressive glomerulonephritis.

Trials of rituximab and use of rituximab for membranous nephropathy are now common. Refractory cases of minimal change disease and focal sclerosis may be treated with steroids combined with mycophenolate or cyclophosphamide. Other considerations include intravenous IgG and cyclosporine.

- b. Secondary causes of nephrotic syndrome are treated with more disease-specific approaches. Diabetic nephropathy is treated with the more general treatments for proteinuric kidney disease. Empagliflozin has recently been shown to slow the rate of progression in type II DM. Systemic lupus is treated, based on the stage of disease after kidney biopsy, with steroids and adjuvant immunosuppressive therapy. Amyloidosis of the AL variety, either primary or secondary to multiple myeloma, is treated with myeloma-directed therapy. Treatment for nephrotic syndrome secondary to malignancy is directed on treatment of the malignancy. HIV, hepatitis B–associated diseases, and hepatitis C–associated diseases are treated with antiviral therapy, and cases of rapidly progressive glomerulonephritis may be treated with steroids and cyclophosphamide or other appropriate therapy in the context of using antiviral therapy as soon as feasible and minimizing exposure to steroids and cyclophosphamide.
8. Rapidly progressive glomerulonephritis is often treated empirically while a diagnostic evaluation is in progress because delay in treatment may lead to irreversible kidney dysfunction. In general, high-dose pulse steroids of methylprednisolone at doses of 500 to 1000 mg per day for 3 consecutive days with intravenous cyclophosphamide 2 mg/kg/d for 3 days are often used in severe cases. Thereafter the doses are weaned. In ANCA-associated vasculitis, rituximab has been shown to be non-inferior to cyclophosphamide. Anti-GBM disease and ANCA-associated vasculitis with advanced kidney failure may in addition to immunosuppression be treated with plasma exchange. Subacute bacterial endocarditis is treated with antibiotics without immunosuppression, although in certain cases, immunosuppression may be used with caution. Cryoglobulinemia is treated with plasma exchange in the acute setting and immunosuppression with steroids and cyclophosphamide after plasma exchange. Hepatitis C–associated cryoglobulinemia is treated with anti-HCV therapy with the new oral agents.

## General Management of Proteinuria

All patients with proteinuria are managed with some common approaches:

1. ACE inhibitors or ARBs alone should be used as initial agents for kidney protection. They have been shown to be effective in the earliest stages of chronic kidney disease. Side effects include hyperkalemia, cough, and angioedema. In some patients, an acute rise in serum creatinine may occur and a certain amount should be expected.
2. BP control: BP control is essential in the management of patients with proteinuria and chronic kidney disease. The Joint National Committee 8 (JNC8) recommends a BP goal of <140/90 mm Hg. The National Kidney Foundation recommends goals of systemic BP <125 mm Hg and diastolic BP <75 mm Hg for patients with chronic kidney disease. Certain drug classes such as ACE inhibitors and ARBs are more effective at controlling proteinuria than others.
3. Protein intake: Protein restriction is controversial and should be used cautiously in malnourished patients.
4. Sodium intake and diuretic use: Sodium restriction is recommended. Loop diuretics are useful for the control of edema.
5. Lipid control: Lipid control is essential from two perspectives. Patients with chronic kidney disease are at increased risk for cardiovascular disease and need meticulous management of risk factors. Patients with nephrotic syndrome tend to develop hyperlipidemia, which increases the risk for cardiovascular disease.
6. Aldosterone antagonists: Aldosterone antagonists should be considered for the control of proteinuria. Hyperkalemia associated with aldosterone antagonists frequently limits the use.
7. Anticoagulation: Patients with nephrotic syndrome are at risk for thromboembolic complications. In patients with severe nephrotic syndrome (albumin <2 g/dL) anticoagulation may be favored. Because patients with membranous glomerulonephritis are at highest risk, this may be particularly true in these patients. Empirical anticoagulation of patients with severe membranous nephropathy is controversial. However, patients should be monitored for the development of renal vein thrombosis, deep venous thrombosis, and pulmonary emboli, all of which warrant anticoagulation until resolution of the nephrotic syndrome.
8. Vitamin D deficiency: Patients with nephrotic syndrome and those with kidney insufficiency develop vitamin D deficiency, which should be evaluated for and treated with replacement.

## Chapter Review

### Questions

1. A 22-year-old male presents with a complaint of dark urine. He describes 2 days of a sore throat, low-grade fever, and a dry cough. He has no family history of kidney disease. Urinalysis shows 1+ protein, 3+ blood, but is otherwise negative. His urine sediment examination shows 20 to 50 erythrocytes per high-power field, but

no leukocytes or casts are present. A rapid throat swab (rapid antigen detection testing) is negative. His blood urea nitrogen (BUN) and serum creatinine level are 20 mg/dL and 0.8 mg/dL, respectively. Which one of the following is the most likely diagnosis?

- A. Poststreptococcal glomerulonephritis
- B. Nephrolithiasis

- C. Transitional cell carcinoma of the bladder  
 D. IgA nephropathy  
 E. UTI
2. A 52-year-old female patient presents with asymptomatic painless gross hematuria. Which of the following factors is not an added risk factor for malignancy?  
 A. Age >40 years  
 B. A positive BTA stat test  
 C. History of pelvic irradiation  
 D. History of occupational exposure to benzenes  
 E. A smoking history
3. A 45-year-old man is referred for fatigue and dyspnea on exertion. He has a history of progressive symptoms over the last 8 weeks. He was anorectic and had lost about 10 pounds. His BP was 130/82 mm Hg, heart rate is 84 beats per minute, and respiratory rate is 20 breaths per minute. His examination was remarkable for decreased breath sounds at the bases. The rest of his examination was normal. His laboratory results showed a creatinine of 4.2 mg/dL, BUN is 43 mg/dL, and hematocrit is 25%. His urinalysis showed 3+ protein and 3+ heme, and the sediment showed many red cells many of which were dysmorphic. Chest x-ray was remarkable for dense left lower lobe infiltrate. The etiology was most likely:  
 A. Systemic lupus erythematosus  
 B. Poststreptococcal glomerulonephritis  
 C. Legionella pneumonia  
 D. Granulomatosis with polyangiitis  
 E. Polyarteritis nodosa
4. A 45-year-old white male presents with massive lower extremity edema and foamy urine. On physical examination, he has a BP of 132/84 mm Hg and heart rate of 72 beats per minute. He has 2+ to 3+ lower extremity edema. There is no rash. Laboratory data show 4+ for dipstick protein but were otherwise negative. His urine sediment examination shows fatty casts and an oval fat body cast but no cellular casts. His serum creatinine is 1.1 mg/dL. His serum albumin is 1.2 g/dL. His complements are normal.
- The most likely diagnosis is:  
 A. Henoch-Schönlein nephritis  
 B. Lupus nephritis  
 C. Membranous glomerulopathy  
 D. Membranoproliferative glomerulonephritis  
 E. Postinfectious glomerulonephritis
5. A 41-year-old African-American male with a history of hypertension and long-standing substance abuse presents to your urgent care clinic with generalized edema of 3 weeks duration. He says that he noticed progressive lower extremity edema and had been seen by your colleague in urgent care the previous week and started on furosemide, 40 mg twice daily. His past medical history includes depression, hypertension for the past 1 year, and drug dependency. He is on atenolol 50 mg once daily as well as the furosemide 40 mg twice daily. He is single, lives alone, and volunteers a history of longstanding intermittent cocaine abuse, heavy alcohol consumption (he says he quit 2 years ago), and tobacco consumption (1 pack per day for the past 25 years). Physical examination shows no acute distress and is remarkable for vital signs showing a temperature of 36.8°C, heart rate 72 beats per minute, respiratory rate of 16 breaths per minute, and a BP of 160/79 mm Hg. He has 4+ pitting edema to his knees. His urinalysis shows 4+ protein but is otherwise negative. His urine microscopy shows several fatty casts and one oval fat body. His BUN is 12 mg/dL and creatinine is 0.9 mg/dL. The most likely diagnosis is:  
 A. Minimal change disease  
 B. Focal segmental glomerulosclerosis  
 C. Membranous nephropathy  
 D. Systemic lupus erythematosus  
 E. Hypertensive nephrosclerosis

## Parenchymal Renal Disease

AJAY K. SINGH AND VANESA BIJOL

**P**arenchymal renal disease can be considered anatomically under the headings of glomerular, tubular, tubulointerstitial, and vascular disease. Most patients present with a clinical syndrome of nephron injury. Other manifestations of the nephrotic syndrome depend on how the kidney is affected; for example, glomerulonephritis (GN) presents with worsened kidney function, hypertension, hematuria, proteinuria, and red cell casts. Tubulointerstitial nephritis presents with azotemia, pyuria, and/or white cell casts.

### Syndromes of Nephronal Injury

#### Isolated Glomerular Hematuria

Isolated glomerular hematuria is defined as persistent microscopic hematuria with dysmorphic red blood cells (RBCs), negative “dipstick” for proteinuria, normal serum creatinine concentration, and normal blood pressure. Common causes include IgA, hereditary nephritis, and thin basement membrane disease (Fig. 63.1).

#### Isolated Nonnephrotic Proteinuria

Isolated nonnephrotic proteinuria is defined as proteinuria  $>150$  mg/dL (60% of which is usually albuminuria). Fig. 63.2 depicts causes of functional and persistent proteinuria. A renal biopsy is rarely indicated in those with low-grade proteinuria ( $<500$ – $1000$  mg/d) if there is an absence of hematuria, absence of clinical or serologic evidence of systemic disease that can cause GN, and normal renal function (see Fig. 63.2).

### Nephrotic Syndrome

The nephrotic syndrome is defined as heavy proteinuria ( $\geq 3.5$  g/d/1.73 m<sup>2</sup> surface area), edema, hypoalbuminemia, and hyperlipidemia.

Causes of nephrotic syndrome are shown in Box 63.1. The most common causes of the nephrotic syndrome in adults are primary focal and segmental glomerulosclerosis and membranous GN. In children, the most common cause of nephrotic syndrome is minimal change disease. Selected causes of nephrotic syndrome are discussed subsequently.

### Acute Nephritic Syndrome

This is characterized by hematuria, red cell casts, azotemia, variable proteinuria, oliguria, edema, and hypertension. It is often caused by a systemic disease that requires a renal biopsy to establish its diagnosis and guide treatment. The classic example of this is acute postinfectious GN (PIGN). Examples include systemic lupus erythematosus (SLE), microscopic polyangiitis, Wegener granulomatosis (granulomatosis with polyangiitis), and antglomerular basement membrane (anti-GBM) disease.

### Unexplained Acute Kidney Injury

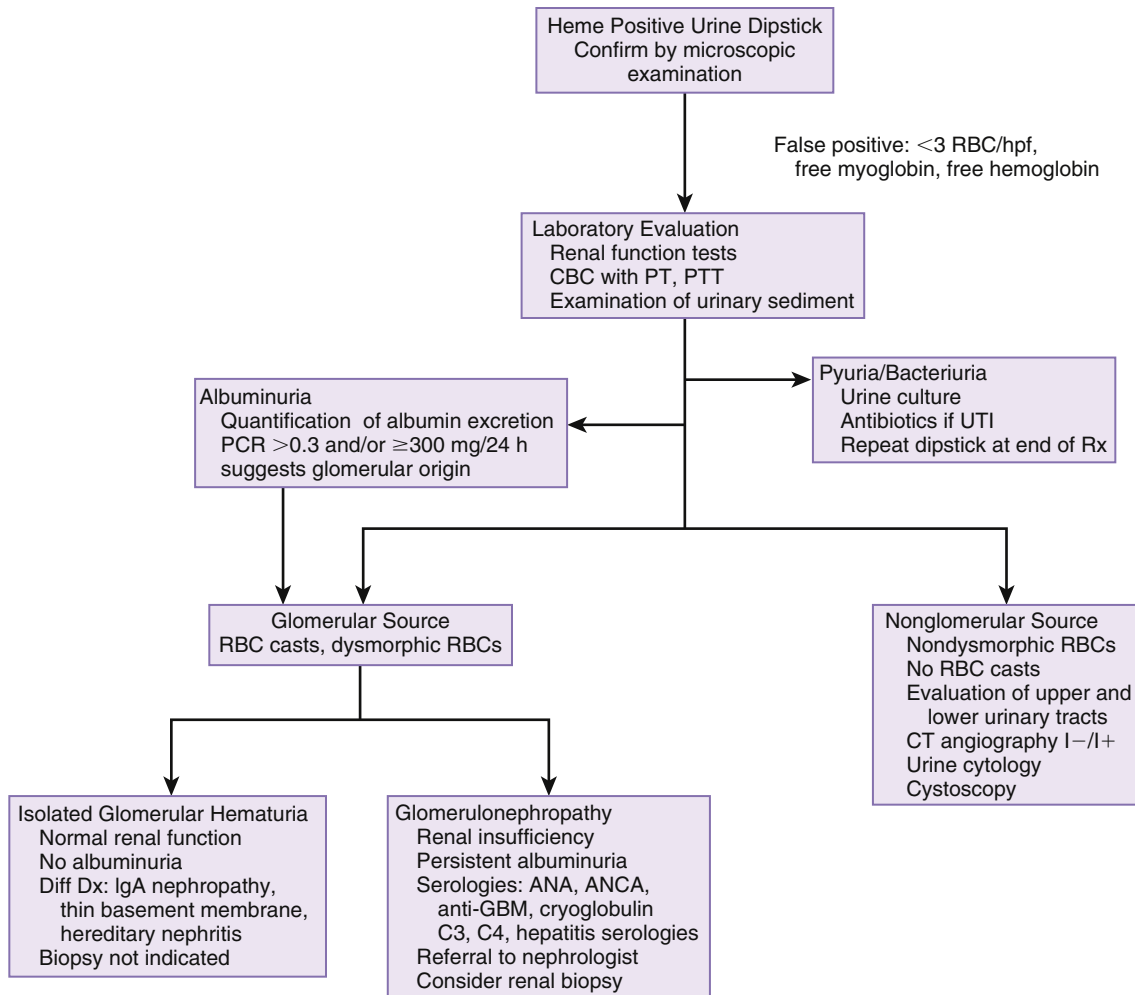

Most often the diagnosis is not based on a renal biopsy. Biopsy is indicated in those settings in which the diagnosis is uncertain, as may sometimes be the case with acute interstitial nephritis secondary to drugs.

### Important Causes of Nephrotic Syndrome

#### Minimal Change Disease

Minimal change disease (MCD) is a major cause of nephrotic syndrome in children and accounts for 15% to 20% of adult cases. The exact underlying cause of MCD is unclear. Accumulating evidence suggests that systemic T-cell dysfunction results in the production of a circulating permeability factor or cytokine abnormality. Interleukin (IL)-13, an antiinflammatory Th2 cytokine, is implicated. These circulating factors directly affect the podocytes, resulting in foot process effacement and marked proteinuria. Although idiopathic (primary) MCD is the most common form, secondary forms of MCD occur in various settings that include Hodgkin disease and other lymphoproliferative disorders, allergic response (bee sting, immunization, drugs such as nonsteroidal antiinflammatory drugs), and infections (HIV).

The abrupt onset of a nephrotic syndrome (glomerular proteinuria  $>3.5$  g/d in an adult or  $>40$  mg/h/m<sup>2</sup> in a child, hypoalbuminemia, and edema) is the typical presentation of MCD. Hematuria and/or hypertension may be present in about 20% of cases. Renal function (as evaluated by either serum creatinine or estimated glomerular filtration rate [eGFR]) is usually normal, but 15% to 30% of adults (usually age  $>40$  years) may present with or develop acute kidney injury (AKI).

• **Fig. 63.1** Hematuria workup. ANA, Antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; Anti-GBM, anti-glomerular basement membrane; CBC, complete blood count; Dx, diagnosis; IgA, immunoglobulin A; PCR, polymerase chain reaction; PT, prothrombin time; PTT, partial thromboplastin time; RBC/hpf, red blood cell/high-power field; Rx, reaction; UTI, urinary tract infection.

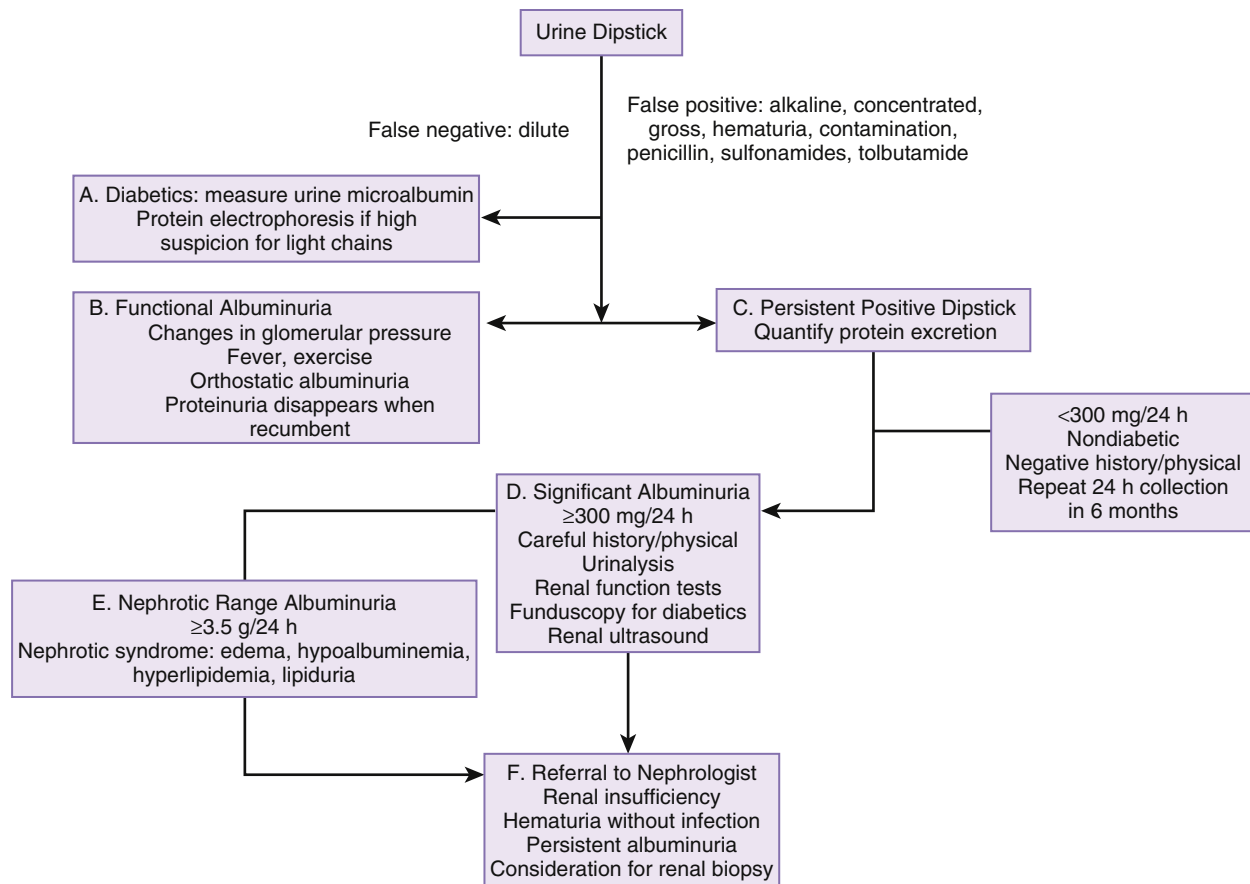

The renal pathology is characterized by minimal or absent glomerular abnormalities by light or immunofluorescent microscopy (Fig. 63.3). The most consistent observation is seen on electron microscopy: simplification of the visceral epithelial cells with widespread and diffuse effacement of the podocyte foot processes.

Treatment is with a trial of prednisone at 1 mg/kg/d. The response to steroids is usually dramatic. Treatment in children consists of prednisone 60 mg/m<sup>2</sup>/d (maximum doses of 80 mg/m<sup>2</sup>/d) until a remission has been induced (or for 4 weeks, whichever is shorter) and then 35 to 40 mg/m<sup>2</sup> every other day for about 12 weeks followed by slow tapering. Adults with established MCD are treated with prednisone 1 mg/kg/d until remission (or for 6 weeks, whichever is shorter) followed by slow tapering. Treatment is generally continued for about 8 weeks in children and 16 weeks in adults, with slow tapering thereafter. About 95% of children and about 90% of adults will respond with a complete remission of proteinuria with this initial regimen, earlier in children and later in adults. However, many patients (40%–60%) will relapse either during the tapering phase of

treatment (steroid-dependent relapses) or weeks, months, or even years later. Intercurrent infections or allergies may trigger a relapse. Some patients have frequent relapses (>2 year) and require repeated courses of therapy.

### Focal and Segmental Glomerulosclerosis

Focal and segmental glomerulosclerosis (FSGS) is a pattern of injury that results from glomerular podocyte injury. The broad category includes primary and secondary forms. Primary FSGS is a clinicopathologic diagnosis characterized by the absence of clinical or histologic evidence of an antecedent GN, immune complex deposition, or systemic disease with glomerular involvement. The primary form of FSGS is caused by podocyte injury of unknown origin. Secondary forms of FSGS may be caused by familial/genetic abnormalities ( $\alpha$ -actinin-4 mutations), drug-induced (heroin, pamidronate), adaptive structural and functional responses of the glomerulus (in the setting of reduced nephron mass such as renal agenesis, dysplasia, cortical necrosis, oligomeganephronia) or normal nephron mass (e.g., obesity, hypertension), or viruses (e.g., HIV).

• Fig. 63.2 Proteinuria workup.

### • BOX 63.1 Causes of Nephrotic Syndrome

#### Primary Causes

Membranous  
Focal segmental glomerulosclerosis  
Minimal change disease  
Immunoglobulin A

#### Secondary Causes

Medications

- Gold, nonsteroidal antiinflammatory drugs, interferon- $\alpha$ , heroin, captopril

Allergens

- Bee sting, pollen

Infections

- Bacterial, viral, helminth

Cancer

- Solid (lung, colon, stomach), leukemia, Hodgkin

Autoimmune diseases

- Lupus nephritis

Metabolic diseases

- Diabetes mellitus

Pregnancy

- Preeclampsia

The typical clinical presentation is with the insidious onset of nonnephrotic proteinuria or the nephrotic syndrome. Hypertension and renal insufficiency are common at the time of presentation. Urinary protein excretion may be very high, sometimes  $\geq 20$  g/d, and the proteinuria is nonselective with a high fractional excretion of IgG (often  $>0.2$ ). Serum complement components are normal.

It is important to differentiate primary from secondary forms of FSGS. A history of subnephrotic-range proteinuria, slower onset of symptoms, and predisposing factors accompanied by typical biopsy findings are useful in making the diagnosis of secondary FSGS.

Renal biopsy findings of FSGS are variable. There are several histologic variants: collapsing, tip, cellular, perihilar, and FSGS (NOS). In FSGS (not otherwise specified [NOS]) there is at least one glomerulus with segmental matrix expansion with obliteration of capillary lumina (Fig. 63.4). The collapsing variant, observed in HIV-associated nephropathy, is less common and shows collapse of the segment or entire glomerular tuft with hyperplasia and hypertrophy of the overlying podocytes. In the tip variant, electron microscopy is useful to differentiate primary and secondary forms of FSGS. In primary forms of FSGS, in addition to the abnormalities on light microscopy, there are distinct abnormalities on electron microscopy, diffuse effacement of epithelial cell foot processes even in areas where there are no light

• **Fig. 63.3** Normal comparison (A) versus minimal change disease (B). (Courtesy Dr. Helmut Rennke.)

• **Fig. 63.4** Focal segmental glomerulosclerosis. (Courtesy Dr. Helmut Rennke.)

microscopic abnormalities and an electron microscopy in the absence of microvillous degeneration, and focal detachment of foot processes from the GBMs. Secondary FSGS is characterized by relative preservation of the podocyte foot processes in nonsclerosed glomeruli.

Unlike MCD, FSGS is generally resistant to steroid therapy. If steroids are used alone, oral prednisone in a dose of 1 mg/kg/d or 2 mg/kg every other day is given for 2 to 3 months with slow tapering over another 2 to 3 months. However, only about one-half of the patients respond to steroid therapy, and patients frequently need adjunctive therapy, such as cyclosporine (4–5 mg/kg/d for 3–6 months). Acthar gel (adrenocorticotrophic hormone, repository corticotropin injection) has been shown to be efficacious in a variety of refractory nephrotic syndrome settings, including in patients with resistant FSGS. Unfortunately, evidence is largely based on observational data, and treatment is expensive (Madan et al., 2016; Tune et al., 1997). Among children, ofatumumab, a humanized anti-CD20 monoclonal antibody, has demonstrated promise although larger studies

will be needed to draw definitive conclusions. Treatment resistance (lack of a complete or partial remission) is strongly associated with a high risk of progression to end-stage renal disease (ESRD), which may be very rapid if proteinuria is >15 to 20 g/d. Patients with FSGS may relapse after a complete or partial remission. A higher incidence of recurrence after transplantation is also present.

### Membranous Glomerulopathy

Membranous nephropathy (MN) is among the most common causes of the nephrotic syndrome in nondiabetic adults age >40 years. MN can be primary/idiopathic (75%–85% of adults). Only about 25% of children with MN have the idiopathic form.

The autoimmune nature of MN was demonstrated by Beck et al. in 2009 with the identification of the glomerular-deposited IgG (a predominantly IgG4 autoantibody, anti-PLA2R) to the phospholipase A2 receptor (PLA2R) on the glomerular podocyte in ≈70% of patients with primary MN. Anti-PLA2R antibody can be assayed and used in the diagnosis and monitoring of treatment of patients with MN. In 2014, a second autoantigen, thrombospondin type 1 domain-containing 7A, was identified.

MN may be secondary to other diseases such as hepatitis B antigenemia, autoimmune diseases, thyroiditis, malignancies, the use of certain drugs such as gold, penicillamine, captopril, and nonsteroidal antiinflammatory drugs, and more recently it has been associated with IgG4 related diseases.

MN may affect all age groups but has a peak incidence in the 40s and 50s. It has no racial predilection. At presentation, 60% to 70% of patients have the nephrotic syndrome with the remainder having subnephrotic proteinuria (<3.5 g/24 h). Microscopic hematuria is common (30%–40%), but macroscopic hematuria and red cell casts are rare. At presentation, most patients are not hypertensive (<20%), and

• **Fig. 63.5** Membranous glomerulopathy. (Courtesy Dr. Helmut Rennke.)

most do not have renal insufficiency (<20%). In patients with severe nephrotic syndrome, clinical manifestations of hypercoagulability may arise (deep venous thrombosis, pulmonary embolism, or renal vein thrombosis).

On renal biopsy, the characteristic lesion on light microscopy is a diffuse uniform and global thickening of the GBM in the absence of significant mesangial or endocapillary hypercellularity (Fig. 63.5). Spikes and craters are identified on silver stains. The thickness is caused by subepithelial deposits with basement membrane response. The basement membrane encases the subepithelial deposits, resulting in “spike formation.” There are four stages of evolution: stage 1 is irregular subepithelial electron-dense deposits without basement membrane response. When GBM material accumulates between deposits forming spikes, it is stage 2. The basement membrane completely encircles and incorporates the deposits (stage 3), and then resolution of the deposits occurs with partial resorption and areas of lucencies (stage 4).

Treatment with glucocorticoids alone is insufficient therapy for membranous glomerulopathy. Recommended treatment is with a combination of steroids and alkylating agents such as cyclophosphamide or chlorambucil. The efficacy of mycophenolate mofetil for treatment of MN is unknown. Rituximab, an anti-CD20 monoclonal antibody, has been found efficacious in case series and case reports, and a randomized controlled trial (the MENTOR [Membranous Nephropathy Trial of Rituximab] study led by Fervenza et al.) is currently under way. A pilot study by Waldman et al. from the NIH has reported encouraging results using a combination of cyclosporine and rituximab (Kidney Int Rep, 2016). A recent case series of 15 patients (Cortazar et al., 2017) with median follow-up of 37 months supports the use of combination therapy with rituximab, low-dose, oral cyclophosphamide, and an accelerated prednisone taper (revlimid cyclophosphamide prednisone [RCP]). One hundred percent of patients achieved partial remission and 93% of patients achieved complete remission at a median time of 2 and 13 months. The authors cite the importance of performing larger studies before drawing definitive

conclusions. Angiotensin blockade at high doses with either an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) should be used to treat hypertension and control proteinuria. The disease may recur in the renal transplant, but this is relatively uncommon (10%–15%).

The prognosis of MN is very much a function of the quantity of proteinuria. Patients with nephrotic-range proteinuria, over 6 g for over 6 months, tend to pursue a progressive course. Young women with moderate proteinuria tend to do very well; older males fare less well. Spontaneous complete or partial remissions of proteinuria occur in about 40% of patients, usually within 3 to 5 years of diagnosis. Overall, at 20 years after diagnosis about one-third of patients will have developed ESRD, about one-third will be in remission, and about one-third will have varying levels of persisting proteinuria and renal function. Among those who undergo remission either spontaneously or with drugs, about 67% remain in remission, whereas the rest either have recurrent relapses without progression to renal failure (20%) or progress to renal insufficiency (13%).

## Nephritic Syndrome

Glomerulonephritis is defined as acute inflammation of the glomerular compartment. Nephritis results from injury to one or more of the cell types or structures that comprise the glomerulus; endothelial, epithelial, or mesangial cells; or the basement membrane. Injury can be categorized into several different pathologic patterns, which are broadly grouped into nonproliferative or proliferative types. The etiology of these different types of nephritis can be either primary causes, that is, ones that are intrinsic to the kidney, or secondary causes, which are associated with certain infections (bacterial, viral, or parasitic pathogens), drugs, systemic disorders (SLE, vasculitis), or diabetes (Box 63.2). Serologic testing for autoantibodies and evaluation of the pattern of hypocomplementemia are usually very helpful in the workup of patients (Table 63.1). Ultimately, however, renal biopsy is often necessary to make a definitive diagnosis.

The nephritic syndrome is characterized by hematuria, red cell casts, azotemia, variable proteinuria, lipiduria, edema, and hypertension.

### Important Causes of Nephritic Syndrome

#### *Acute Diffuse Proliferative Glomerulonephritis (Postinfectious Glomerulonephritis)*

This syndrome is most commonly seen in children and less often in adults. Males are affected more frequently (male:female [M:F] ratio 2:1). Presentation is either in a sporadic or epidemic form, 1 to 3 weeks after infection with nephritogenic strains of group A beta-hemolytic streptococcal infection (pharyngitic strains 12, 2, 1, and 25) affecting the throat or 3 to 6 weeks after a skin infection (pyoderma strains 49, 2, 42). The delay in the renal symptoms after the throat or skin infection is related to the time period required to produce the antibodies that mediate the renal disease.

### • BOX 63.2 Causes of Nephritis

#### Primary Causes

- Diffuse and global
  - Minimal change disease
  - Membranous nephropathy
- Proliferative
  - Acute diffuse (endocapillary, postinfectious)
  - Mesangial (e.g., IgA)
- Focal and segmental
  - Focal proliferative
  - Focal segmental

#### Secondary Causes

- Antineutrophil cytoplasmic antibody-associated (e.g., Wegener)
- Antibody-associated
  - Anti-GBM nephritis
- Immune complex-mediated (e.g., lupus nephritis)

**TABLE 63.1 Hypocomplementemia in the Workup of Glomerular Disease**

Pathway	Complement	Disease
Classical	Low C3, C4, CH50	Lupus nephritis Mixed essential cryo
Alternate	Low C3, Normal C4	Poststreptococcal GN Postinfectious GN SBE Shunt Hepatitis B MPGN type 2
Reduced synthesis	Acquired Hereditary (C2 def)	Liver disease Lupus-like syndrome

GN, Glomerulonephritis; MPGN, membranoproliferative glomerulonephritis; SBE, subacute bacterial endocarditis.

Clinical presentation is characterized by an abrupt onset of cola-colored urine, puffiness of face and eyelids, moderate proteinuria, and hypertension.

Laboratory investigations include elevated antistreptolysin O (ASLO) titer (in cases of skin infections, anti-DNAse-B and antihyaluronidase are more often positive) and decreased C3 and CH50. Additional positive findings in PIGN include elevated erythrocyte sedimentation rate, dysmorphic RBCs in urine, and RBC casts. Reduction of C3 seldom persists for >8 weeks (an important finding to differentiate from membranoproliferative glomerulonephritis, which shows a persistent decrease in complement levels). In children, with symptomatic management, 95% recover clinically within 2 months of onset and morphologically within 3 years, although a few may progress to chronicity.

Many other infections can produce PIGN resembling poststreptococcal GN. These include, but are not limited to, *Mycoplasma pneumoniae*, cytomegalovirus, *Streptococcus*

pneumonia, *Neisseria meningitidis*, *Salmonella*, toxoplasmosis, diphtheroids, *Propionibacter* species, and *Staphylococcus aureus* and *albus*.

Renal pathology is characterized by global hypercellularity of endothelial and mesangial cells in the glomeruli and an increase in the mesangial matrix. There is abundant polymorphonuclear cell infiltration within glomerular capillaries; this is often referred to as “exudative” GN. Occasional crescents may be present. Immunofluorescence shows three patterns of immune deposits: a starry-sky pattern, which is most typical, garland pattern, and mesangial pattern. The deposits are IgG and C3 with variable presence of IgM. Electron microscopy shows subepithelial “humps” and mesangial deposits.

Treatment should be focused on eliminating the streptococcal infection with antibiotics and providing supportive therapy until spontaneous resolution of glomerular inflammation occurs. Even if the patient presents with AKI, short-term prognosis is good, and >95% of the children will recover from the initial episode. Immunosuppressive therapy and dialysis are rarely necessary. Adults with PIGN have a 60% chance of recovery. Persistent proteinuria is a sign of poor prognosis.

PIGN in the elderly is most often caused by staphylococcal infection and often occurs in a background of diabetes. Alcoholism and intravenous drug use are also predisposing factors.

#### IgA Nephropathy or Berger Disease

In 1968 Berger and Hinglais described a group of patients with episodic macrohematuria, persistent microhematuria, and moderate proteinuria. Their kidney biopsies revealed a proliferative glomerular lesion with dominant deposition of IgA in the glomeruli. The acute form was characterized by Volhard and Fahr as a “synpharyngitic” episode (most often caused by *S. aureus* and *albus*) of hematuria, usually without azotemia, edema, and hypertension.

IgA nephropathy (IgAN) has an estimated prevalence of 25 to 50 cases per 100,000 people (considered by some to be the most common form of GN worldwide). It is more common among Asian and Native American populations and rare in African Americans. All ages may be affected; however, IgAN is most prominent in the second and third decades (80% between age 16–35 years). Males are affected more than females. Genetic predisposition is likely questionable because there are no consistent associations with human leukocyte antigen (HLA) except that HLA-B35 is more common in French patients. There are also rare cases described of a familial form of IgAN that is associated with deafness. Henoch-Schönlein purpura is a systemic form of IgAN with vasculitis manifesting as palpable purpuric lesions, abdominal pains, and joint pains.

Gross hematuria is often the first presenting symptom 24 to 48 hours following a pharyngeal or gastrointestinal infection, vaccination, or strenuous exercise. Asymptomatic cases present with microscopic hematuria during a routine physical. There is an array of presentations ranging from intermittent gross hematuria to persistent microhematuria.

• **Fig. 63.6** IgA nephropathy. (A) Light microscopy. (B) IgA mesangial staining on immunofluorescence. (Courtesy Dr. Helmut Rennke.)

Constitutional symptoms (fever, muscle aches, malaise, fatigue, and flank/abdominal pain) often accompany the nephritis.

There are no specific tests short of a renal biopsy that are diagnostic of IgAN.

Although nonspecific, IgA levels may be elevated in >50% of patients. C3/C4 may be normal or even elevated in some patients. The typical pathologic finding is a focal or diffuse mesangioproliferative GN and diffuse mesangial IgA immune deposits on immunofluorescence (Fig. 63.6), which are deposited in a diffuse granular pattern located primarily within the mesangium. There are pathologic classifications, such as Haas Classification, which categorize IgAN into five classes: (I) minimal or no mesangial cellularity; (II) FSGS lesions; (III) focal proliferative GN; (IV) diffuse proliferative GN; and (V) >40% global glomerulosclerosis and tubular atrophy. The Oxford classification emphasizes prognostic histologic features such as mesangial hypercellularity, endocapillary hypercellularity, and segmental sclerosis.

There is no specific treatment for IgAN. ACE inhibitors slow the progression of renal decline (some studies suggest that this more so particularly in patients with DD genotype of the *ACE* gene). Treatment with steroids has been used, and some studies suggest efficacy. However, the use of steroids remains controversial and may be more effective in IgA patients with nephrotic syndrome and minimal change disease. Treatment with fish oil is controversial; a metaanalysis suggests that patients at high risk of progression (male gender, hypertension, presence of microhematuria, presence of proteinuria, and renal insufficiency) may benefit. A combination of oral cyclophosphamide, dipyridamole, and low-dose warfarin has not demonstrated long-term benefits. Similarly, cyclosporine has not demonstrated benefit. A recent randomized trial by [Rauen et al. \(2015\)](#) comparing immunosuppression versus supportive care (blockade of the renin-angiotensin system) demonstrated a 3-fold higher rate of complete remission, a higher rate of resolution of hematuria, and a reduction in proteinuria among immunosuppression-treated patients versus those assigned to supportive care alone. However, there was no change in eGFR decline between the two

groups, and patients treated with immunosuppression had a higher rate of severe infections and other adverse events. Adapting recommendations from a recent review by [Pozzi \(2016\)](#), the following approach may be considered in patients with IgAN:

1. In patients with macro-microscopic hematuria and proteinuria <0.3 g/d, annual follow-up
2. In patients with proteinuria between 0.3 and 0.9 g/d, ACE-I and/or ARB, with titration of the drugs to maximally reduce proteinuria as tolerated
3. In patients with proteinuria >1 g/d, hypertension, and GFR >30 mL/min/1.73m<sup>2</sup>, 6-months' course of corticosteroids in addition to ACE-I or ARB
4. In patients with GFR <30 mL/min, ACE-I/ARB with corticosteroids considered for patients with persistently high or increasing proteinuria
5. In patients with rapidly progressive IgAN or vasculitic lesions on kidney biopsy, immunosuppressants (cyclophosphamide and azathioprine) may be considered

Overall prognosis is variable and depends on the histologic class at baseline. Among all those presenting with IgAN, 20% to 50% of the patients will eventually develop ESRD within 20 years. Markers for a worse prognosis are persistent hypertension, proteinuria, nephrotic syndrome, persistent microhematuria, old age, and male sex (present at initial presentation).

### Rapidly Progressive or Crescentic Glomerulonephritis

The presentation is an abrupt-onset acute nephritis characterized by a rapid decline in kidney function (a doubling of serum creatinine or a 50% reduction in GFR within a 3-month period). Typically, patients rapidly progress to renal failure within weeks. An accurate and urgent diagnosis is essential in these patients. A renal biopsy and checking of serologies (antineutrophil cytoplasmic antibody [ANCA], anti-GBM antibodies, antinuclear antibodies, anti-dsDNA antibodies, and complements) are essential. Renal biopsy reveals a crescentic GN.

• **Fig. 63.7** Anti-glomerular basement membrane nephritis. (A) Light microscopy. (B) Linear IgG staining on immunofluorescence. (Courtesy Dr. Helmut Rennke.)

### Four Classes of Crescentic Glomerulonephritis Based on Pathogenetic Mechanisms

Four classes of crescentic GN are type 1 (anti-GBM positive), type 2 (immune complex disease; anti-GBM and ANCA negative), type 3 (pauci immune; ANCA positive), and type 4 (double-antibody-positive disease, which has features of both types 1 and 3).

#### Antiglomerular Basement Membrane Nephritis (Type 1)

Anti-GBM nephritis presents with rapidly progressive renal failure with hematuria and red cell casts. A presentation that includes dyspnea and hemoptysis (i.e., pulmonary hemorrhage) is termed Goodpasture syndrome. There is a bimodal distribution with the first peak at age 30 years and second peak at age 60 years. In 20% to 60% of patients, there is a prodrome of an upper respiratory tract infection that precedes the disease. Patients usually have subnephrotic proteinuria (<3 g/24 h), hematuria, a nephritic urinary sediment, and hypochromic microcytic anemia of the iron deficiency type. Hypertension is uncommon (20% of the patients). Risk factors for anti-GBM nephritis include a history of exposure to hydrocarbons, cigarette smoking, metallic dust, d-penicillamine, cocaine, and influenza A2 infections.

Anti-GBM nephritis is caused by the presence of anti-GBM autoantibodies that react with the noncollagenous domain of the alpha-3 chain of type IV collagen. Autoantibodies may also be noted to noncollagenous-1 domain of the alpha-5 chain of type IV collagen. This collagen is expressed predominantly in the glomerular and pulmonary alveolar capillary basement membrane. Anti-GBM autoantibodies bind antigen after chronic insult of the GBM. This reaction induces activation of complement and leukocyte recruitment, resulting in necrotizing segmental proliferative GN, disruption of capillary walls, and eventually crescent formation.

The pathologic abnormalities are striking (Fig. 63.7). Light microscopy shows a diffuse crescentic GN with linear deposits of IgG along the GBM on immunofluorescence

(a similar immunofluorescence pattern is observed in biopsies of the alveolar basement membrane). It is most often IgG1. IgG4 has been reported, but in such cases, it is weak involvement of the kidneys.

The clinical course is that of rapid deterioration in renal function (days to weeks), frequently with the need for dialysis. A chest x-ray showing abnormal bilateral hilar and basilar interstitial shadowing would point strongly to associated pulmonary hemorrhage and a diagnosis of Goodpasture syndrome. Anti-GBM enzyme-linked immunosorbent assay (ELISA) can be used to detect circulating anti-GBM antibodies; the assay is specific for the NCI domain of the alpha-3 chain of type IV collagen. This antibody is detected in more than 90% of individuals with anti-GBM nephritis. The level of plasma creatinine is usually a good indication of the degree of progression. The gold standard for diagnosis is renal biopsy.

Without treatment, patients with anti-GBM nephritis and/or Goodpasture syndrome have a very poor prognosis. Most patients die of either severe renal or pulmonary complications. ESRD is not uncommon in patients who are oliguric, anuric, or present with a serum creatinine of >5 to 7 mg/dL. The goal of therapy is to suppress the formation of new antibodies and remove preexisting antibodies. This strategy has markedly reduced mortality (<10% at 1 year). Therapy is plasmapheresis with plasma exchange for 2 weeks on consecutive days, prednisone 1 mg/kg (after an initial methylprednisone pulse of 1 g/d for 3 consecutive days), and cyclophosphamide 2 to 3 mg/kg orally once each day. Patients with rapidly progressive glomerulonephritis (RPGN) have a worse prognosis. In patients who present with pulmonary hemorrhage (the Goodpasture syndrome), emergent plasmapheresis is recommended. The endpoint of treatment is when the anti-GBM antibodies are undetectable in the blood.

#### Lupus Nephritis (Example of Type 2)

Renal involvement is frequently observed in patients with SLE. The overall prevalence of SLE is 12 to 64 cases per 100,000. Lupus nephritis (LN) predominantly affects women

**TABLE 63.2** American Rheumatism Association Criteria for the Diagnosis of Systemic Lupus Erythematosus

Serositis	Blood Abnormalities	Malar Rash
Oral ulceration	Renal involvement	Discoid rash
Arthritis	Antibodies	
Photosensitivity	Immunologic abnormalities	
	Nervous system	

of childbearing age (M:F ratio = 1:9); 85% of the patients will be age <55 years. SLE appears to be more common and to have more severe renal involvement in the African-American population. Between 40% and 85% of patients with SLE will have complications involving the kidney (LN), but the spectrum of renal disease (histologic class) is highly variable. There is no clearly defined genetic pattern for predisposition to SLE. However, a significant percentage of family members of patients with SLE develop the disease (5%–12%). In addition, there is evidence for a predisposing role of hormonal factors, including the strong predominance of women of childbearing age and the increased incidence of SLE in postmenopausal women taking estrogen. Other predisposing factors include exposure to sunlight, ultraviolet radiation, medications, and viral/bacterial exposure.

SLE can affect any organ system (see [Box 63.2](#)). Renal involvement often develops concurrently or shortly following the onset of SLE and may follow a protracted course with periods of remission and exacerbations. A special rare subset of patients (“silent LN”) have no clinical findings of renal involvement but will present with proliferative LN on biopsy. Transformation from one class to another is relatively frequent.

The diagnosis of SLE is based on both clinical and laboratory criteria. The American Rheumatism Association has developed criteria under which 4 of the 11 findings are required for a 96% sensitivity and specificity to diagnose SLE ([Table 63.2](#)). The criteria encompass the following clinical and laboratory features: malar rash; discoid lupus; dermal disease; photosensitivity; oral or nasal ulcerations; nondeforming arthritis; serositis, including pleuritis and pericarditis; central nervous system disease, such as seizures or psychoses; hematologic involvement manifested by the presence of anemia, leukopenia, lymphopenia, or thrombocytopenia; immunologic markers of disease manifested by a positive lupus band test, a positive anti-DNA or anti-Sm antibody test, a false-positive venereal disease research laboratory test, or a positive antinuclear antibody (ANA) reaction; and renal involvement, defined as persistent proteinuria exceeding 500 mg daily (3+ on the dipstick), or the presence of cellular casts, consisting of erythrocyte, hemoglobin, granular, tubular, or mixed.

Renal biopsy is an important part of the management of LN and should be considered in all patients both for diagnosis and treatment ([Fig. 63.8](#)). The International Society

• **Fig. 63.8** Lupus nephritis class IV. Light microscopy. (Courtesy Dr. Helmut Rennke.)

of Nephrology and Renal Pathology Society Classification (ISN/RPS) is used to classify LN. This classification divides LN into various classes ([Table 63.3](#)). The most common class (in nearly 50% of patients) is diffuse proliferative lupus nephritis (class IV LN). Class IV disease generally presents with all or most of the features of the acute nephritic syndrome or RPGN.

The presence of activity and chronicity of disease are incorporated into the ISN/RPS LN classification. Features of activity include endocapillary hypercellularity, wire loop lesions, fibrinoid necrosis, cellular crescents, and interstitial inflammation. Chronicity includes glomerular sclerosis, tubular atrophy, interstitial fibrosis, and fibrous crescents. Class II disease carries a good prognosis, and treatment may not be indicated. It is difficult to predict the course and prognosis of class III patients because of its varied course. Steroids and cytotoxic therapy are usually necessary to treat class III LN. Patients with class IV require steroids and cytotoxic therapy. The standard of care in many hospitals for severe forms of class IV disease is three consecutive doses of pulse methylprednisone (1 g intravenously each day), followed by high-dose prednisone starting at 1 mg/kg/d and tapered over 3 months to approximately 10 to 30 mg/d. Adjunctive cytotoxic therapy is recommended. There is debate about whether oral or intravenous pulse cyclophosphamide should be given. In many centers, mycophenolic acid (MMF) is now preferred over cyclophosphamide because of its similar efficacy but lower adverse risk profile. MMF is also preferred over azathioprine. However, some centers continue to use cyclophosphamide at either full dose or at half dose (the latter regimen is termed the *Euro-Lupus protocol*).

### **Antineutrophil Cytoplasmic Antibody–Associated Vasculitis (Example of Type 3): Wegener Granulomatosis (Renamed as Granulomatosis With Polyangiitis)**

Vasculitis may affect the large, medium, or small blood vessels. Small-vessel vasculitis may be further classified as ANCA-associated or non-ANCA-associated vasculitis.

**TABLE 63.3 International Society of Nephrology and Renal Pathology Society Classification of Lupus Nephritis (ISN/RPS Classification)**

Class I	Minimal mesangial lupus nephritis Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence.
Class II	Mesangial proliferative lupus nephritis Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits. A few isolated subepithelial or subendothelial deposits may be visible by immunofluorescence or electron microscopy but not by light microscopy.
Class III	Focal lupus nephritis Segmental or global, endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, with focal subendothelial immune deposits, with or without mesangial alterations. Lesions could be active or inactive.
Class IV	Diffuse lupus nephritis Segmental or global endocapillary or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This is divided into diffuse segmental when (IV-S) lupus nephritis ≥50% of the involved glomeruli have segmental lesions (<50% of tuft involvement) and diffuse global (IV-G) when glomeruli have global lesions (≥50% of tuft involvement). Lesions could be active or inactive.
Class V	Membranous lupus nephritis Global or segmental subepithelial immune deposits with or without mesangial alteration in class V lupus may occur in combination with class III or IV, in which case both will be diagnosed.
Class VI	Advanced sclerotic lupus nephritis ≥90% of glomeruli globally sclerosed without residual activity.

ANCA-associated small-vessel vasculitis includes microscopic polyangiitis, granulomatosis with polyangiitis, Churg-Strauss syndrome (also known as eosinophilic granulomatosis with polyangiitis), and drug-induced vasculitis (Box 63.3).

Granulomatosis with polyangiitis may occur at any age of life; peak incidence is in the fourth to sixth decade of life. Granulomatosis with polyangiitis is associated with increased titers of ANCA. ANCAs are directed against antigens present within the primary granules of neutrophils and monocytes. Whether the ANCA is the cause or an epiphenomenon remains controversial.

The clinical presentation of granulomatosis with polyangiitis is quite variable and ranges from a subclinical presentation with progressive involvement of the respiratory tract and mild renal findings to a more fulminant presentation with acute GN or RPGN.

Granulomatosis with polyangiitis predominantly affects the respiratory tract, but vasculitic multisystemic involvement is not uncommon. Upper respiratory involvement includes sinusitis, tinnitus, and hearing loss with otic discharge and pain. Lower respiratory tract symptoms include cough with dyspnea progressing to hemoptysis and alveolar hemorrhage.

Multisystemic disease may include skin (e.g., papules, purpura), joints (arthralgias, arthritis), eyes (conjunctivitis, episcleritis), nervous system, the liver, the thyroid, the gallbladder, and the heart. The renal presentation varies from an RPGN and renal failure to a more gradual decline in GFR with nonnephrotic-range proteinuria, hematuria, and red cell casts.

The key serologic abnormality is the presence of ANCAs detected on indirect immunofluorescence or ELISA. There are two main types of antibodies defined by their pattern of staining on indirect immunofluorescence: cytoplasmic, or C-ANCA, and perinuclear, or P-ANCA. The antigen

### • BOX 63.3 Organ Involvement in Systemic Lupus Erythematosus

#### Rash

- 50%–60% of patients
- Butterfly rash on face, livedo reticularis, purpuric rash
- Associated patchy alopecia + oral ulceration (10%)

#### Arthralgia

- 75% of patients
- Usually nondeforming, usually several joints
- Hands, also other joints
- Associated myalgias and weakness

#### Heme

- 75% of patients
- Normochromic normocytic anemia, thrombocytopenia

#### Central Nervous System

- 30% of patients, 12% presenting feature
- Mood disorders, headache common
- Chorea, facial nerve palsies seizures, hemiparesis
- Frank psychosis/coma

proteinase-3–ANCA results in a cytoplasmic pattern of staining (C-ANCA), whereas myeloperoxidase-ANCA results in a perinuclear (P-ANCA) pattern of staining. Between 88% and 96% of patients with granulomatosis with polyangiitis are ANCA positive, most commonly C-ANCA, but P-ANCA is also observed. The typical pathology on renal biopsy is a focal segmental necrotizing and crescentic GN. Vasculitis may involve the small and medium-size renal arteries, veins, and capillaries. Immunofluorescence shows a pauci immune pattern (i.e., with minimal immunoglobulin deposition).

Untreated patients have a 1-year survival rate of 20% to 50%. The recommended initial treatment is methylprednisone (500–1000 mg intravenously daily for 3 consecutive days) followed by high-dose oral prednisone (1 mg/kg/d) and oral cyclophosphamide (2 mg/kg/d, not to exceed 200 mg/d). Pulse intravenous cyclophosphamide is an acceptable alternative regime but may be associated with a higher rate of relapse especially if the total cumulative dose is lower than that used in continuous oral therapy. Remission with corticosteroids and cyclophosphamide occurs in 85% to 95% of patients. Intravenous cyclophosphamide with plasmapheresis may be better in patients with pulmonary hemorrhage or those who are critically ill. However, not all patients treated with cyclophosphamide respond, and as many as one-half of all patients treated with cyclophosphamide relapse within 5 years.

In a posthoc analysis of rituximab for ANCA-Associated Vasculitis Trial, patients with ANCA-associated vasculitis and renal involvement respond similarly to remission induction with rituximab plus glucocorticoids compared with cyclophosphamide/azathioprine plus glucocorticoids

over 18 months of follow-up. Furthermore, adverse events are similar.

A Cochrane review (Walters et al., 2015) examining the effectiveness of various treatments for ANCA-associated vasculitis with renal involvement came to the following conclusions:

1. Plasma exchange was effective in patients with severe AKI secondary to vasculitis.
2. Pulse cyclophosphamide results in an increased risk of relapse when compared with continuous oral use but a reduced total dose.
3. Cyclophosphamide is standard induction treatment, but rituximab and MMF were also effective. Azathioprine, methotrexate, and leflunomide are effective as maintenance therapy.

## Chapter Review

### Questions

1. A 22-year-old woman is admitted with a diagnosis of Goodpasture syndrome. This diagnosis is confirmed by an ELISA and Western blot analysis demonstrating anti-GBM antibodies. A preliminary reading of the renal biopsy confirms the diagnosis of anti-GBM nephritis. Her serum creatinine is 3.2 mg/dL. Two weeks previously, her serum creatinine was 0.7 mg/dL. Which of the following therapeutic options would be most appropriate for her?
  - A. Prednisone 60 mg/d for 1 month followed by a gradual weaning of her prednisone dose
  - B. Pulse methylprednisone accompanied by daily plasmapheresis with exchange, followed by high-dose oral prednisone coupled with cyclophosphamide, until her anti-GBM titer is undetectable
  - C. Pulse methylprednisone followed by high-dose oral prednisone coupled with cyclophosphamide until her anti-GBM titer is undetectable
  - D. Prednisone 60 mg/d plus cyclophosphamide, 3 mg/kg/d
  - E. Plasmapheresis alone
2. A 42-year-old woman presents to your office with a 4-week history of a petechial rash on her legs, gross hematuria, and edema. She relates a 2-year history of intermittent polyarthralgias. Physical examination is notable for mild periorbital edema. Vital signs show a blood pressure of 164/88 mm Hg and a heart rate of 66 beats per minute. Her lungs, cardiovascular examination, and abdominal examinations are normal. She has 3+ edema. Urinalysis shows 4+ blood, 4+ proteinuria, 1+ leukocytes. Urine sediment examination shows 15 to 20 dysmorphic red cells and 1 RBC cast per high-powered

field. Her electrolytes are normal, blood urea nitrogen (BUN) was 36 mg/dL, and creatinine 1.8 mg/dL. Serologic examination shows an ANA, ASLO, ANCA, and anti-GBM that are negative. Complements are normal. Skin biopsy showed a leukocytoclastic vasculitis. A renal biopsy is performed.

The most likely finding on the renal biopsy is:

- A. An ISN/RPS class IV diffuse proliferative glomerulonephritis
  - B. A minimal change lesion
  - C. Glomeruli showing fibrinoid necrosis
  - D. Kimmelstiel-Wilson lesions with nodular glomerulosclerosis
  - E. A mesangial proliferative lesion
3. A 14-year-old patient presents with periorbital and lower extremity swelling approximately 10 days after complaining of a sore throat and feverishness that was diagnosed as streptococcal throat. She has been treated with penicillin, and her throat symptoms and fever have cleared completely. Urine microscopy shows red cells and red cell casts. Complements show a low C3. The next step in management is to:
    - A. Pulse the patient with 1 g of methylprednisone for three consecutive doses and then 60 mg/d or oral prednisone tapered over 1 month
    - B. Restart the patient on penicillin
    - C. Treat the patient with oral prednisone (60 mg/d) tapered over 1 month
    - D. Observe; the illness may resolve spontaneously
    - E. Pulse the patient with methylprednisone, 1 g, for three consecutive doses, and arrange for a 7-day course of daily plasmapheresis with plasma exchange

4. A 22-year-old man presents with hematuria detected on a routine physical. He is completely asymptomatic. He tells you that he has had one prior episode of what he thinks was hematuria (during an upper respiratory infection 3 years previously, he noticed pinkish urine); however, it resolved spontaneously. Medical history, family history, and social history are all negative. Physical examination is normal. Urine dipstick is negative except for 2+ blood. Urine microscopy shows 5 to 10 RBCs per high-powered field. ASLO, ANA, and ANCA titers are negative. Complements are normal. The most likely diagnosis is:
- Subclinical poststreptococcal glomerulonephritis
  - IgAN
  - LN
  - Alport syndrome
  - Thin basement membrane disease
5. A 24-year-old African-American office worker presents to her primary care provider with a 5-day history of feverishness, severe exhaustion, and painful and stiff joints in her hands and feet. Medical history is negative. Family history is notable for a maternal aunt who has a history of lupus. Physical examination shows a normal head and neck examination except for a mild malar flush. Vital signs reveal a blood pressure of 144/94 mm Hg, heart rate of 72 beats per minute, and a temperature of 37.8°C. Cardiac, lung, and abdominal

examinations are normal. She has swollen joints in her hands and feet. There is 1+ lower extremity edema. Laboratory analysis shows 2+ blood and 4+ albumin on her urine dipstick. Urine microscopy shows 10 to 15 RBCs per high-powered field and 1 red cell cast. Serum creatinine is 1.1 mg/dL, and BUN is 22 mg/dL. Electrolytes are normal. ANA is positive at 1:640, anti-dsDNA antibody titer is 650 U/L. Both C3 and C4 are low. The next step in management is:

- Urgently refer the patient to a nephrologist for same-day pulse methylprednisone therapy and a renal biopsy.
- Start the patient on 1.5 g twice daily of MMF and prednisone 60 mg/d.
- Start the patient on prednisone, 60 mg daily, and arrange for follow-up in 1 week's time.
- Arrange for an urgent CT-guided renal biopsy.
- Start the patient on prednisone 60 mg/d and urgently refer the patient to hematology for initiation for cyclophosphamide therapy.

## Chronic Kidney Disease

AJAY K. SINGH

Chronic kidney disease (CKD) is defined by the National Kidney Foundation (NKF) as either (1) a glomerular filtration rate (GFR) of  $<60$  mL/min with or without kidney damage for  $\geq 3$  months or (2) the presence of kidney damage for  $\geq 3$  months demonstrated by pathologic abnormalities, markers of kidney damage (e.g., blood or urine composition), or imaging tests. In the United States, it is estimated that CKD affects 7% to 10% of the adult population or 15 to 20 million individuals, although specific subgroups such as African Americans and Hispanics are at especially high risk. [Chapter 60](#) reviews the complications of CKD.

### Staging and Classification of Chronic Kidney Disease

CKD is staged by using GFR categories. The NKF Kidney Disease Outcomes Quality Initiative (KDOQI) has classified CKD into five stages ([Box 64.1](#)). The strengths of the NKF KDOQI classification are its simplicity and its use of estimated GFR (eGFR) to classify CKD into different stages. The widespread adoption of the classification has resulted in a uniform system understood and applied worldwide. However, the NKF CKD classification does have several limitations. It stages the severity of kidney disease on the basis of GFR without incorporating other important parameters such as albuminuria. Two patients with similar GFR but with wide differences in the degree of proteinuria at baseline are likely to have very different prognoses. The patient with large amounts of proteinuria is more likely to progress to end-stage renal disease (ESRD). The NKF classification also leaves unaddressed the significance of reduced GFR below  $60$  mL/min/ $1.73$  m<sup>2</sup> in certain subgroups, such as the elderly, the undernourished, and members of specific ethnic groups. For example, elderly individuals with reduced GFR may never develop ESRD. Patients with congestive cardiac failure may have a low GFR because of hemodynamic reasons but do not have any structural evidence of kidney disease, and kidney function may normalize once the heart failure is treated. Furthermore, the NKF CKD criteria may not apply to some racial groups because their GFR may be lower than Western levels because of smaller stature, lower muscle mass, and/or vegetarianism.

#### • BOX 64.1 National Kidney Foundation Classification of Chronic Kidney Disease

##### Stage 1

Kidney damage with normal or supranormal glomerular filtration rate (GFR), GFR  $\geq 90$

##### Stage 2

Kidney damage with mild reduction in GFR, GFR 60–89

##### Stage 3

Moderate reduction in GFR, GFR 30–59

##### Stage 4

Severe reduction in GFR, GFR 15–29

##### Stage 5

Kidney failure, GFR  $<15$  or on dialysis

GFR expressed in mL/min/ $1.73$  m<sup>2</sup>.

From K/DOQI clinical practice guidelines for chronic kidney disease: evaluation, classification, and stratification. *Kidney Disease Outcome Quality Initiative. Am J Kidney Dis.* 2002;39;(2 suppl 1):S17–S31.

More recently, the Kidney Disease Improving Global Outcomes group has proposed modifications to the NKF staging system by subdividing stage 3 of CKD into stage 3a representing mild-to-moderate CKD (GFR of  $45$ – $59$  mL/min/ $1.73$  m<sup>2</sup>) and stage 3b representing moderate-to-severe CKD (GFR of  $30$ – $44$  mL/min/ $1.73$  m<sup>2</sup>). In addition, each CKD stage is classified according to the degree of albuminuria: A1 representing optimum and high-normal albuminuria ( $<29$  mg/g); A2 representing high degree of albuminuria ( $30$ – $299$  mg/g); and A3 representing very high and nephrotic ( $>300$  mg of albumin/g urinary creatinine [Cr]). Greater levels of albuminuria and more advanced stage of CKD are associated with higher all-cause mortality, cardiovascular mortality, and progression to end-stage renal failure.

### Epidemiology of Chronic Kidney Disease

It is estimated that approximately 19 million individuals in the United States have CKD ([Table 64.1](#)). Most individuals

**TABLE 64.1** Prevalence of Chronic Kidney Disease in the United States by Chronic Kidney Disease Stage

Stage	Description	GFR <sup>a</sup>	Population (thousands)	Prevalence
1	Kidney damage with normal or supranormal GFR	≥90	5900	3.3%
2	Kidney damage with mild decrease in GFR	60–89	5300	3.0%
3	Moderate decrease in GFR	30–59	7600	4.3%
4	Severe decrease in GFR	15–29	400	0.2%
5	Kidney failure	<15	300	0.2%

<sup>a</sup>GFR expressed in mL/min/1.73 m<sup>2</sup>.  
GFR, Glomerular filtration rate.

with CKD are people with earlier stages of CKD, but it is unclear whether all of these patients have CKD as opposed to reduced GFR because of old age or other factors. There are estimated to be approximately 11.2 million individuals with stage 1 or 2 CKD (persistent albuminuria with normal or mildly decreased GFR [GFR <60 mL/min/1.73 m<sup>2</sup> or higher]) and about 8.3 million individuals with stage 3 CKD or worse (GFR <60 mL/min/1.73 m<sup>2</sup>). Of those with stage 5 CKD, the number of individuals with kidney failure treated by dialysis and transplantation exceeded 300,000 in 1998, and although the prevalence is likely to demonstrate continued growth, recent data reported from the US Renal Data System (USRDS) demonstrate that the incidence rate of ESRD (new cases of kidney failure) has actually decreased for the first time after 20 years of annual increase of 5% to 10% per year (in the latest numbers from 2010 USRDS data, the ESRD incidence rate was 348 per million).

### Screening for Chronic Kidney Disease

Screening for CKD is cost effective in high-risk populations such as African Americans, Native Americans, Hispanics, and in patients with diabetes mellitus (DM) and hypertension. This is because therapeutic strategies such as angiotensin blockade and tighter blood pressure (BP) control are proven to be effective at earlier stages. Thus early detection of CKD could potentially prevent ESRD in a significant proportion of high-risk patients. African Americans and Native Americans develop kidney failure at a 4-fold higher rate than white Americans (953 and 652 cases per million in African Americans and Native Americans, respectively, compared with 237 per million among Caucasians). Patients with DM and hypertension and those with urine dipstick positive for protein have a higher risk of developing CKD. The NKF KDOQI guidelines for CKD recommend that all individuals should be assessed as part of routine health examinations to determine whether they are at increased risk for developing CKD. Individuals at high risk for kidney disease, particularly those with diabetes, hypertension, or a family history for these conditions and/or for kidney disease, should undergo formal testing. Such testing can be performed easily with a urinalysis, a first morning or a

random “spot” urine sample for albumin or protein and Cr assessment, and a serum Cr level. The American Diabetes Association (ADA) recommends that for all type 2 diabetics at the time of diagnosis and all type 1 diabetics 5 years after initial diagnosis, an evaluation for microalbuminuria should be performed. If the dipstick is positive for either red or white blood cells, a microscopic analysis of the urinary sediment should be done.

### NKF KDOQI Guidelines for Chronic Kidney Disease Screening in Patients With Hypertension

- Serum Cr measurement for GFR estimation
- Protein-to-Cr ratio in a first morning or random “spot” urine specimen
- Either dipstick testing or urine sediment examination for red blood cells or white blood cells

#### *In Patients With Hypertension Found to Have Chronic Kidney Disease*

- Imaging of the kidneys, commonly by ultrasound
- Measurement of serum electrolytes (Na<sup>+</sup>, K<sup>+</sup>, Cl<sup>-</sup>, HCO<sub>3</sub><sup>-</sup>)

### Measurement of Kidney Function

#### Use of Serum Creatinine

Measurement of serum Cr is currently the most widely used measure for the assessment of kidney function. However, the use of serum Cr has several limitations (Table 64.2). Because Cr production is dependent on muscle mass, it needs to be interpreted cautiously among individuals with low muscle mass, among females, and in elderly patients. In patients with low muscle mass, the serum Cr underestimates the degree of kidney function impairment, whereas among individuals with large muscle mass (such as body builders), the serum Cr overestimates actual GFR. Another source of inaccuracy is the effect of non-Cr chromogens when the alkaline picrate assay (Jaffe reaction) for Cr is used. These factors include acetoacetate, cephalosporins, and high

**TABLE 64.2** Limitations of Serum Creatinine as a Measure of Kidney Function

Influence of muscle mass on creatinine generation	High-muscle-mass patients, higher serum creatinine (e.g., athletes, body builders) Low-muscle-mass patients, lower serum creatinine
Effect of creatinine secretion	Patients with CKD: greater proportion of creatinine is secreted than filtered
Medications blocking proximal secretion	Cimetidine Trimethoprim Probenecid

CKD, Chronic kidney disease.

concentrations of furosemide. Modern versions of the Jaffe assay have reduced these effects by adjusting temperature, assay constituents, and various calibration settings.

Given these limitations with serum Cr as a measure of actual GFR, the NKF KDOQI and the National Kidney Disease Education Program (NKDEP) have recommended the use of actual or, when this is unavailable, a prediction equation for estimating GFR. Because in most situations, direct measurement of GFR is not feasible, a prediction equation to estimate GFR is the most practical and accurate method to assess kidney function. The modification of diet in renal disease (MDRD) and Cockcroft-Gault (CG) equations are now the most popular prediction equations to assess GFR in adults.

The MDRD (MDRD 3) equation is as follows:

$$175 \times [\text{SCr}]^{-1.154} \times [\text{Age}]^{-0.203} \times [0.742 \text{ if patient is female}] \times [1.21 \text{ if patient is black}]$$

## Prediction Equations for Glomerular Filtration Rate

### Cockcroft-Gault Equation

The CG prediction equation is commonly used in clinical practice. Its major limitations are as follows:

1. It has limited generalizability. This is because it was originally formulated to calculate the Cr clearance in patients without kidney disease (Canadian males). It has not been widely validated in different populations and under different clinical situations.
2. This equation tends to overestimate GFR, especially among patients with CKD. This is because it uses serum Cr to estimate Cr clearance. The limitations of measuring Cr clearance apply to the CG equation. Among patients with moderate-to-severe kidney disease, Cr secretion as a proportion of total Cr excretion increases, resulting in an overestimation of the Cr clearance.
3. Similar to the MDRD equation, the CG equation is inaccurate among individuals with normal or near-normal kidney function.

### • BOX 64.2 Advantages of the Modification of Diet in Renal Disease (MDRD) Over Cockcroft-Gault (CG) Equation

- Direct comparison of the MDRD and the CG equation demonstrates the MDRD equation to be superior for estimating glomerular filtration rate (GFR), particularly in the range GFR <60 mL/min/1.73 m<sup>2</sup>
- More widespread validation of MDRD than CG (e.g., in various populations)
- No requirement for additional information for MDRD (e.g., measurements of weight) beyond that already collected by pathology laboratories

### • BOX 64.3 When the Modification of Diet in Renal Disease Equation Should Be Used Cautiously

- Populations in which the modification of diet in renal disease equation is not validated or in which validation studies have not been performed
- Individuals with near-normal or normal kidney function
- Severe malnutrition or obesity
- Extremes of body size and age
- Exceptional dietary intake (e.g., vegetarian diet or creatine supplements)
- Disease of skeletal muscle, paraplegia
- Rapidly changing kidney function

4. The CG equation uses weight, which frequently results in inaccuracies at extremes of weight and/or when there is a measurement error in the assessment of weight. Despite these limitations, CG remains popular, especially among pharmacists who use it for drug-dosing adjustments in patients with reduced kidney function.

### Modification of Diet in Renal Disease

The MDRD Study GFR prediction equation was developed in 1999. This equation has been validated in American black and white racial groups. It has also been validated in diabetics, predialysis patients, renal transplant recipients, and Asians. The MDRD formula yields an eGFR normalized to 1.73 m<sup>2</sup> body surface area. Adjusting for body surface area is necessary when comparing a patient's eGFR with normal values or when determining the stage of CKD. However, an uncorrected eGFR may be preferred for clinical use in some situations, such as drug dosing.

The advantages of the MDRD equation over the CG equation are shown in [Box 64.2](#). However, there are several clinical situations in which caution should be applied in using the MDRD equation ([Box 64.3](#)).

More recently, a new equation called the CKD-Epi equation has been proposed. This equation has less bias at high eGFRs and can be used to report eGFRs >60 mL/min/1.73 m<sup>2</sup>. However, it has not yet been applied widely by clinical laboratories.

## Clearance by Radiologic Contrast Agents and Radioactive Isotopes

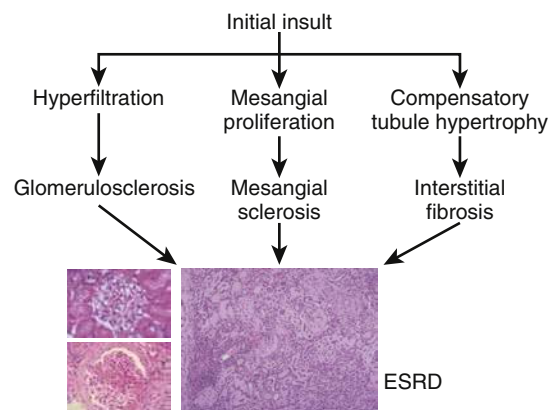

GFR can be calculated by the measurement of urinary or plasma clearances of isotopes or via images produced from a gamma camera. There are four different agents that are used in clinical practice:  $^{125}\text{I}$ -iothalamate,  $^{51}\text{Cr}$ -ethylenediaminetetraacetic acid,  $^{99\text{m}}\text{Tc}$ -diethylenetriaminepentaacetic acid, and iohexol. These agents have been shown to correlate well with inulin clearance. They also have high precision in the setting of moderate-to-severe renal dysfunction. Inulin clearance is the gold standard for measurement of actual GFR because it is freely filtered and neither secreted nor reabsorbed by the kidney. However, it is not widely used in clinical practice largely for logistic reasons.

## Creatinine Clearance Measurement by 24-Hour Urine Collection

Difficulties with 24-hour urine Cr measurements include variations in urine collection (i.e., incorrect collections) and variations in the tubular secretion of Cr. Studies have shown that in trained patients, there can be up to a 14% variation in urine Cr quantity secondary to incorrect collection, and in untrained patients, this can be as high as 70%. With regard to variations in tubular secretion, in patients with moderate-to-severe renal dysfunction, >50% of the urinary Cr can result from tubular secretion, thus leading to overestimation of the Cr clearance by this method. To compensate for overestimation of GFR from tubular secretion of Cr in the 24-hour urine collection, the collection can be performed after oral administration of cimetidine, an organic cation that is a known competitive inhibitor of Cr secretion. Alternatively, the use of the mean of urea and Cr clearance measurements calculated from 24-hour urine collections has been suggested. Cr clearance overestimates GFR because Cr is both filtered by the glomerulus and, to a lesser degree, secreted by the proximal tubule. On the other hand, urea underestimates GFR because it is both filtered and reabsorbed. The mean value of the Cr and urea clearance more closely approximates the actual GFR in the setting of GFR measurements  $<15\text{ mL/min/1.73 m}^2$ .

## Cystatin C

Cystatin C is a nonglycosylated basic protease inhibitor produced by nucleated cells at a constant rate, is freely filtered by glomeruli, and is completely metabolized after tubular reabsorption. Unlike Cr, serum cystatin C level is not dependent on muscle mass and is not differentially expressed based on gender. GFR as estimated from the plasma cystatin C concentration has been found to correlate well with iothalamate GFR measurements in Pima Indians with DM and normal or supranormal GFR. Cystatin has greater sensitivity than Cr for small changes in GFR. Recent studies suggest that cystatin C may be a better indicator of predicting risk for cardiovascular disease than either serum Cr or a GFR prediction equation.

## Management of Chronic Kidney Disease Progression

CKD is characterized by reduced kidney function and impaired ability to adequately excrete waste products and maintain the constancy of the body's homeostatic functions. Mild CKD is asymptomatic; moderate CKD is frequently characterized by hypertension, anemia, and abnormalities in mineral metabolism and advanced CKD by uremia. CKD may become relentlessly progressive as the damage to functioning nephrons leads to a maladaptive response among the remaining nephrons. The progressive decline in kidney function in individuals with CKD is variable and depends both on the cause of the underlying insult and patient-specific factors. There is consensus that renal disease progression rates are heterogeneous both between different etiologies and within the same etiology. Thus patients with polycystic kidney disease (PKD) may progress more slowly than patients with diabetic nephropathy; however, among patients with diabetic nephropathy there are patients who progress fast and others who progress hardly at all. Evidence also points to the importance of several factors in modulating kidney progression. These include albuminuria, the presence of systemic hypertension, age, gender, genetic factors, and smoking. However, regardless of the initial insult, the end result from a pathology standpoint is a scarred end-stage kidney (Fig. 64.1).

ESRD is the term used to denote CKD requiring renal replacement therapy (dialysis or transplantation). The incidence of ESRD in the United States is approximately 268 cases per million population per year. However, ESRD is overrepresented by about 4-fold among black Americans compared with white Americans. The major causes of ESRD in the United States are DM (44%), hypertension (30%), glomerular disease (15%), PKD, and obstructive uropathy. Elsewhere in the world, where the incidence of DM has not reached epidemic proportions (e.g., in Europe and parts of the developing world) chronic glomerulonephritis (20%) and chronic reflux nephropathy (25%) are the most common causes of ESRD.

• **Fig. 64.2** Clinical manifestations of uremia. *CNS*, Central nervous system; *GI*, gastrointestinal; *LVH*, left ventricular hypertrophy.

• **Fig. 64.3** Biochemical and endocrine imbalances in uremia. *K*, Potassium; *PTH*, parathyroid hormone.

CKD is usually asymptomatic when there is mild impairment in kidney function, whereas when GFR is markedly reduced, the patient is usually markedly symptomatic and may be severely disabled. In the early stages of CKD (stages 1 and 2 using the NKF KDOQI CKD stages), patients may present simply with an elevated serum Cr and blood urea nitrogen (BUN) level but no symptoms. These individuals are usually unaware that they have any abnormalities in their kidney function, and they usually fail to register on the “radar screen” of their internists. However, even at this early stage, insidious effects on target organs may become manifest. For example, patients may have mild-to-moderate hypertension, mild anemia, left ventricular hypertrophy, and subtle changes in bone structure from renal osteodystrophy. As kidney function gradually declines, with GFRs reaching 15 mL/min, early features of uremia become evident. These include worsening or more difficult-to-control hypertension, extracellular volume expansion (manifesting as edema and dyspnea), hyperkalemia and acidosis, anemia, and abnormalities in cognitive, psychologic, and physical functions. Uremia reflects the accumulation of metabolic toxins, some characterized and others unknown, that influence the functioning of a variety of organ systems. The clinical presentation is often quite heterogeneous (Fig. 64.2) and is thought to reflect a variable balance between biochemical and endocrine deficiencies and excesses (Fig. 64.3). In this late stage,

#### • **BOX 64.4** Indications for Initiation of Renal Replacement Therapy

- Refractory hyperkalemia
- Acute pericarditis
- Fluid overload or pulmonary edema refractory to diuretics
- Encephalopathy
- Severe peripheral neuropathy
- Hypertension refractory to antihypertensive medications
- Severe uremic bleeding; clinically significant bleeding diathesis attributable to uremia
- Intractable nausea and vomiting

the need for renal replacement therapy is imminent, and dialysis and/or transplantation becomes inevitable to sustain life (Box 64.4).

The indications for initiating renal replacement therapy include severe refractory abnormalities in biochemistry (severe hyperkalemia and acidosis), severe pulmonary edema, bleeding, metabolic encephalopathy, and the presence of pericarditis. More subtle but no less important indications include malnutrition and marked tiredness and lethargy.

Life expectancy for a 49-year-old patient with ESRD is, on average, approximately 7 years, lower than that for colon cancer and prostate cancer and one-quarter that of

the general population. This reduction in life expectancy is largely attributable to cardiovascular complications. Nearly 50% of all deaths in patients with ESRD are caused by cardiovascular causes. The risk is 17 times that of the general population. Remarkably, this gap is largest in young patients with ESRD. The risk factors for cardiovascular disease in individuals with chronic renal failure include the magnitude of the calcium-phosphorus product with its risk of coronary calcification, the presence of dyslipidemia, hypertension, hyperhomocysteinemia, and the presence of left ventricular hypertrophy (LVH). The clinical manifestations of cardiovascular disease in ESRD patients include LVH, left ventricular dilatation, diastolic dysfunction, macrovascular and microvascular disease, and abnormalities in autonomic function; increased sympathetic discharge; and increased circulating catecholamine levels. Vascular disease may involve calcification of coronary vessels and valve disease. Indeed, calcification of the mitral valve annulus and the aortic valve cusps is common among ESRD patients.

### KDOQI Action Plan by Stage of Chronic Kidney Disease

The NKF KDOQI group has released an action plan for management of patients with CKD as determined by stage of CKD. In stage 1 CKD, these guidelines suggest the diagnosis and treatment of CKD, treatment of comorbid conditions, prevention of progression of renal disease, and cardiovascular disease risk reduction. In stage 2, the issue of primary concern is that of estimating and managing renal disease progression. The focus in stage 3 disease is that of evaluating and treating complications, whereas stage 4 CKD, the immediate predialysis stage, consists of preparation for renal replacement therapy. The management of stage 5 CKD is that of initiation and maintenance of renal replacement therapy. Thus in addition to the task of diagnosing and treating the specific etiology of renal disease, the broad themes that govern early versus late

renal disease management are those of prevention of progression in the early stages of CKD, management of complications beginning in the early stages and continuing throughout the follow-up of patients, and preparation for renal replacement in the later predialysis phase (Figs. 64.4 and 64.5).

Declining kidney function is associated with altered clearance of many drugs (e.g., aminoglycosides), as well as increased toxicity (e.g., iodinated contrast agents and phosphate-based enemas). In addition, gadolinium exposure in patients with moderate-to-severe CKD may be associated with an increased risk of nephrogenic systemic fibrosis. Lastly, some drugs are contraindicated in patients with moderate-to-severe CKD (e.g., metformin, because of the risk of lactic acidosis).

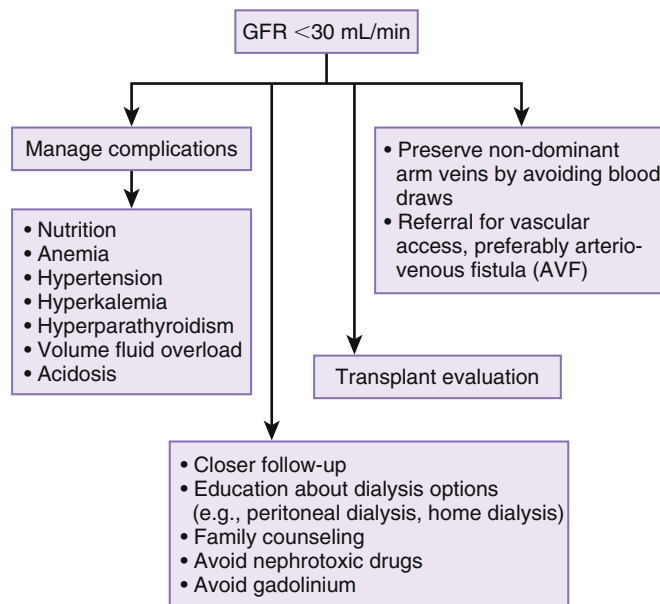

There are three important elements to the management of progression in CKD patients.

### Use of Angiotensin Blockers to Protect the Kidney

Both landmark studies in animals by Brenner et al. as well as studies in humans support an independent role for angiotensin blockade in renoprotection. Angiotensin-converting

• **Fig. 64.4** Schematic showing progression of patients through the stages of chronic kidney disease (CKD). *BUN*, Blood urea nitrogen; *ESRD*, end-stage renal disease; *GFR*, glomerular filtration rate.

• **Fig. 64.5** Management strategies for patients with more advanced chronic kidney disease. *GFR*, Glomerular filtration rate.

enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) can be used. The dose of ACE inhibitor or ARB should be titrated to maximal levels using reduction of proteinuria as the yardstick for efficacy. In addition, sodium restriction and diuretics in conjunction with ACE inhibitor/ARB therapy increase their antiproteinuric effects and should be used in an adjunctive fashion (ACE inhibitors and ARBs are contraindicated in patients who are pregnant and in patients with a history of angioedema). The use of dual blockade with both an ACE inhibitor and an ARB is not recommended because of a higher rate of adverse events.

### Control of Blood Pressure

The MDRD study demonstrated that patients targeted to mean arterial BP of 92 and 107 mm Hg had rates of decline of GFR of  $-3.56$  and  $-4.10$  mL/min/year, respectively, and that there was greater effect with increasing levels of albuminuria. This study, taken in conjunction with several other studies that have been published subsequently, all point to beneficial effects of controlling BP on kidney disease. On the other hand, the ACCORD (Action to Control Cardiovascular Risk in Diabetes) study has demonstrated that among diabetic patients, being assigned to the more aggressive control of BP ( $<120$  vs.  $<140$  mm Hg systolic pressure) is associated with a higher rate of adverse events (hypotension and bradycardia). Among a subset of patients with impaired kidney function who were enrolled in ACCORD, aggressive BP control was associated with higher number of renal complications (doubling of serum Cr or ESRD). Therefore the 2013 ADA now recommends a BP goal of  $<140/80$  mm Hg. The 2013 Eighth Joint National Committee guidelines recommend a target BP in CKD patients of  $<140/90$  mm Hg. The Kidney Disease Improving Global Outcomes (KDIGO) guideline recommends a target BP in CKD patients of  $<140/90$  mm Hg and among those patients with significant proteinuria  $<130/80$  mm Hg. The 2012 NKF-KDOQI clinical practice guidelines for the management of BP in CKD patients are shown in [Box 64.5](#). Based on the recent American College of Cardiology/American Heart Association 2017 guideline for high blood pressure in adults, it is recommended that for patients with CKD, the BP goal should be  $<130/80$  mm Hg. Further, in those with stage 3 or higher CKD or stage 1 or 2 CKD with albuminuria ( $>300$  mg/day), treatment with an ACE inhibitor is reasonable to slow progression of kidney disease. An ARB is reasonable if an ACE inhibitor is not tolerated. However, it is likely that in nondiabetic patients, the target systolic BP will be likely lowered to  $<120$  mm Hg. This is because of the remarkable findings that have emerged from the Systolic Blood Pressure Intervention Trial (SPRINT) and the subsequent analysis of a subset of SPRINT patients with CKD. [Cheung et al.](#) reported that in SPRINT CKD patients targeting a systolic BP of  $<120$  mm Hg reduced rates of major cardiovascular events by nearly 20% and all-cause death by nearly 30% without any significant effect on kidney outcome.

With regard to adjunctive antihypertensive agents, the KDIGO guidelines suggest diuretics followed by either beta-blockers or calcium channel blockers in diabetic kidney

disease as well as in nondiabetic albuminuric kidney disease. Among recipients of renal allografts, calcium channel blockade, diuretic therapy, beta blockade, ACE inhibitor, or ARB are recommended without any preference ([Table 64.3](#)).

### Adjunctive Strategies in Retarding Progression

#### Strict Glycemic Control

The Diabetes Control and Complication Trial (CCT) and the United Kingdom Prospective Diabetes (UKPDS) studies for type 1 and type 2 diabetics, respectively, have unequivocally demonstrated the benefits of tight glycemic control with a goal hemoglobin ( $HbA_{1c}$ ) of  $<7.0\%$ .

#### Protein Restriction

The KDOQI Guidelines for Nutrition in Chronic Renal Failure recommend restriction of protein intake to 0.8 g/kg/d in all patients with CKD, with further restriction to 0.6 g/kg/d in those with  $CrCl <25$  mL/min. The guidelines also recommend a caloric intake of 30 to 35 kcal/kg/d.

#### Smoking Cessation

Smoking has been implicated as a risk factor in the progression of kidney disease, particularly diabetic kidney disease. The postulated mechanisms of injury include a heightened risk of atherosclerosis, vascular occlusion, and reduction in renal blood flow. Smoking cessation is recommended in all patients.

#### Management of Obesity

Obesity may result in an acquired resistance to the beneficial effects of inhibition of the renin-angiotensin system axis. Further, weight loss may facilitate the actions of ACE inhibition and/or angiotensin receptor blockade. In addition, obesity may induce certain renal diseases, such as focal segmental glomerulosclerosis, postulated to be due to a mechanism of hyperfiltration. Weight loss is recommended in CKD patients with a goal body mass index of  $<25$ .

**TABLE 64.3 National Kidney Foundation Kidney Disease Outcomes Quality Initiative Antihypertensive Guidelines for CKD Patients**

Type of Kidney Disease	Target BP (mm Hg)	Preferred Agents for CKD With or Without Hypertension	Other Agents to Reduce CVD Risk and Reach BP Target
Diabetic kidney disease	<130/80	ACE inhibitor or ARB	Diuretics preferred, then BB or CCB
Nondiabetic kidney disease with spot $U_p/U_{cr}$ ratio $\geq 200$ mg/g	<130/80	ACE inhibitor	Diuretics preferred, then BB or CCB
Nondiabetic kidney disease with spot $U_p/U_{cr}$ ratio <200 mg/g	<130/80	No preference	Diuretics preferred, then ACE inhibitor, ARB, BB, CCB
Disease in the kidney transplant recipient	<130/80	No preference	CCB, diuretic, BB, ACE inhibitor, ARB

## Complications of Chronic Kidney Disease

### Anemia

Anemia is a common complication in patients with CKD. The majority of patients with advanced CKD (stages 3 and 4) develop anemia, and by stage 5 CKD (ESRD) anemia is observed in over 95% of patients. The workup of anemia in CKD relies on both a thorough clinical evaluation and laboratory testing. Screening for anemia should occur annually in patients with stage 3 CKD and at least twice per year in patients with stage 4 or 5 CKD. Testing should include a complete blood count, reticulocyte count, iron stores (transferrin saturation and serum ferritin), folate and B<sub>12</sub> measurement, and screening for fecal occult blood (Fig. 64.6). Clinical evaluation should focus on whether the patient has complaints of tiredness, fatigue, and reduced exercise tolerance, as well as physical features such as pale mucous membranes and nail changes (e.g., koilonychia seen with iron deficiency anemia). The three most important causes of anemia in CKD patients are erythropoietin deficiency, because the kidney is the exclusive producer of erythropoietin; iron deficiency, because CKD is associated with reduced iron absorption and some degree of blood loss; and inflammation from the effects of uremia and the underlying cause of kidney disease.

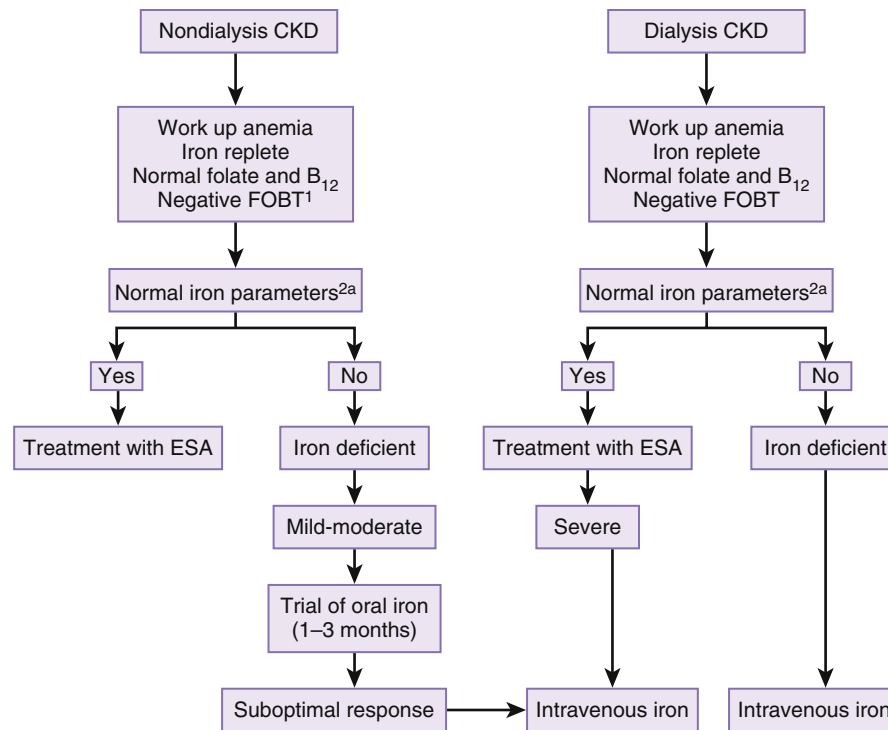

Various Hb criteria have been used to assess anemia in CKD patients. There is consensus that patients with anemia should be treated when the Hb level is <10 g/dL; however, patients may develop symptoms of anemia before the 10 g/dL Hb threshold, and workup of patients should begin when patients develop mild anemia (Hb 10–12 g/dL), and treatment should be individualized.

Assessment of iron stores in an anemic CKD patient is critical because iron deficiency is common in patients with CKD. Furthermore, treatment with an erythropoiesis stimulating agents (ESA) exacerbates iron deficiency that may lead to a state of iron-restricted erythropoiesis. Although a bone marrow biopsy may represent the gold standard in

assessing iron stores, it is clinically impractical, and measurement of serum ferritin and transferrin saturation provide the best indication of iron stores. The serum ferritin is an “acute phase reactant” and is affected by inflammation. Thus ferritin values are of greatest predictive value when low (<100 ng/mL) but of limited value when elevated. The transferrin saturation (TSAT; serum iron  $\times$  100 divided by total iron binding capacity) measures circulating iron that is available for erythropoiesis but also provides information on body iron stores. A TSAT of <20% is consistent with iron deficiency.

### Erythropoiesis Stimulating Agents

In the era before ESAs (i.e., before 1989) the treatment of CKD anemia consisted of blood transfusions, iron therapy, and anabolic steroid. In 1989 the introduction of epoetin-alfa had a transformative effect on the management of CKD anemia. By the 1990s almost all patients on dialysis were receiving epoetin-alfa therapy, and the numbers of nondialysis anemic patients on ESA treatment also increased dramatically. At least initially, normalization of the Hb level in CKD patients was recommended because observational studies dating back to the 1990s suggested that higher levels of Hb were associated with better outcomes including a lower rate of cardiovascular complications, lower mortality risk, and higher health-related quality of life. In 1998 the publication of the Normal Hematocrit trial in hemodialysis patients and, in 2006 and 2009, the publication of the Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) and the Trial to Reduce cardiovascular Events with Anaresp Therapy (TREAT) studies in nondialysis patients, respectively, changed the recommendations about management of anemia in CKD patients. It became clear from these randomized controlled studies that treatment of mild anemia with normalization of the Hb was not associated with clinically meaningful benefits but rather an increased risk of cardiovascular complications without any meaningful improvement in quality of life. Because

• **Fig. 64.6** Approach for treating anemia in chronic kidney disease (CKD) patients. ESA, Erythropoiesis stimulating agent. <sup>1</sup>If folate, B<sub>12</sub>, or FOBT abnormal, treat accordingly.

correction of anemia requires epoetin therapy, it remains unclear whether the normalization of the Hb per se or exposure to epoetin, especially at high doses, explains the increased risk observed in the randomized trials. The current recommendation from the US Food and Drug Administration (FDA) is an Hb target <11 g/dL. The 2012 KDIGO Anemia guidelines also recommend against normalization of the Hb concentration and advocate for a target Hb of 9.0 to 11.5 g/dL. The KDIGO guidelines emphasize that ESAs should be used cautiously, if at all, in patients with a prior history of a stroke or a history of cancer. Anemia treatment in CKD patients should be individualized based on a patient's symptoms, the rate of fall of Hb concentration, prior response to iron therapy, the risk of needing a transfusion, and the risks related to ESA therapy.

An approach that the author favors in treating CKD anemia is to identify an individualized Hb concentration at which to intervene—the “Hb trigger.” This Hb trigger could represent an Hb level at which the patient becomes symptomatic. For a young patient, this might be an Hb of 8 or 9 g/dL, whereas for an older patient the Hb trigger might be 10 or 11 g/dL. Iron therapy, ESA, and treatment of underlying inflammation are then used to maintain the patient above his or her individualized Hb trigger. For some patients, individualization may involve trying to use ESAs sparingly—for example, in a patient with a history of a stroke or an active malignancy (in these patients, but not generally because of the risk of allosensitization, blood transfusion might be considered). The response to ESA could also vary according to the individual; indeed, studies suggest that poor responders to ESA therapy are more likely to be

female, have a history of cardiovascular disease, have signs of iron deficiency and inflammation, and be overweight.

There are many ESAs currently in the market. Available ESAs can be broadly divided into short- and long-acting agents. The very first ESA was epoetin- $\alpha$  (Epo, marketed in the United States as Epogen) and approved in 1989 by the FDA as short acting (half-life of approximately 8.5 hours). Epo can be administered subcutaneously or intravenously. Epo is the only short-acting ESA available currently in the United States. There are three other short-acting ESAs available in non-US markets: epoetin- $\beta$ , epoetin- $\omega$  (Repotin, South Africa), and epoetin- $\theta$  (Biopoin, Eporatio, Ratloepo, Europe). There are differences that exist in dose, safety, tolerability, and immunogenicity among these forms of epoetin. In addition to different classes of short-acting epoetins, epoetin- $\alpha$  biosimilars are also widely available. Biosimilars are “copy-cat” agents to the innovator or originally developed ESA. Currently, no Epo biosimilar has received approval from the FDA. The most commonly used long-acting epoetin is darbepoetin- $\alpha$  (Aranesp, Amgen, Thousand Oaks, CA, USA). Darbepoetin- $\alpha$  is a hyperglycosylated epoetin analogue designed for prolonged survival in the circulation and with consequently greater bioavailability than the shorter acting epoetins (Darbe has a 3-fold longer half-life than Epo—25.3 vs. 8.5 hours), darbepoetin- $\alpha$  was approved by the FDA and the European Medicines Agency (EMA) in 2001. The terminal half-life of intravenous darbepoetin- $\alpha$  was estimated to be nearly 70 hours, and the time to peak concentration after subcutaneous administration is more than double with darbepoetin- $\alpha$  compared with epoetin- $\alpha$  (54 vs. 16–24 hours) in dialysis patients. The optimal administration dosing schedule for darbepoetin- $\alpha$  is

once weekly or every 2 weeks in a stable CKD patient. The dose does not change if given by intravenous route or subcutaneous route. The other long-acting epoetin that is approved is Continuous Erythropoietin Receptor Activator (CERA; Mir-cera, Roche, Basel, Switzerland). CERA is a molecule that has a water-soluble polyethylene glycol moiety added to the epoetin-beta molecule. The half-life after intravenous administration is approximately 134 hours and 139 hours after subcutaneous administration, and the dose is the same by either route. CERA is recommended to be administered every 2 weeks for correction of anemia and once a month during the maintenance phase. Because of patent infringement issues, CERA is currently not marketed in the United States but is widely available elsewhere in the world. Prolyl hydroxylase inhibitors are currently undergoing phase 3 trials. These agents stabilize hypoxia-inducible factor (HIF). HIF is a transcription factor that activates endogenous erythropoietin production in both the kidney and the liver. It is likely that these agents, once approved, will become an alternative to ESAs.

### **Iron Supplementation to Treat Chronic Kidney Disease Anemia**

Iron deficiency is a common finding in patients with CKD. Absolute iron deficiency reflects no stores of iron and occurs when both transferrin saturation and ferritin levels are both low (<20% and 100 ng/mL, respectively). Functional iron deficiency is the inadequate release of iron to support erythropoiesis, despite the presence of adequate store of iron. ESA therapy can be associated with functional iron deficiency when patients are inflamed (e.g., with a coexisting smoldering infection or a failed kidney allograft still in place). Functional iron deficiency should be suspected when the serum ferritin is high but transferrin saturation is low. Iron deficiency can lead to decreased effectiveness of ESA therapy, and iron therapy without ESA therapy is usually unsuccessful in patients with CKD. Untreated iron deficiency is a major cause of hyporesponsiveness to ESA treatment.

Iron deficiency is treated with iron administered either by the oral or intravenous route. Oral iron therapy is the preferred method of treating nondialysis CKD patients. However, certain foods and drugs affect oral iron therapy absorption. Absorption of ferrous sulfate, an iron salt, can be influenced by a variety of amino acids, therefore it should be taken on an empty stomach. Proton pump inhibitors may affect the duodenal pH and the conversion of iron from  $Fe^{2+}$  to  $Fe^{3+}$  and interfere with iron absorption. Calcium acetate, lanthanum carbonate, and aluminum-containing antacids also impair iron storage.

Intravenous iron is recommended in nondialysis CKD patients with severe iron deficiency or patients unresponsive or those intolerant of oral iron. In general, intravenous iron is recommended as first-line therapy in all dialysis CKD patients, because oral iron is generally not well absorbed in dialysis patients (attributed to a hepcidin-mediated functional block in absorption of iron at the level of the enterocyte iron channel). Three intravenous agents currently in the market in the United States are iron dextran, ferrous gluconate, and iron sucrose. These agents are of low molecular weight and

safer than high-molecular-weight iron dextran that preceded them and was associated with a high risk of anaphylaxis.

The 2012 KDIGO Anemia Clinical Practice Guidelines make several recommendations about the use of iron. Most of these recommendations are based on opinion rather than evidence derived from randomized trials. In nondialysis CKD anemic patients not on ESA therapy, KDIGO recommends an initial trial of oral iron therapy for 1 to 3 months. The KDIGO guidelines recommend that decision making around the route of iron therapy should be governed by the severity of iron deficiency, availability of venous access, response to prior oral or intravenous iron therapy and tolerance of side effects, patient compliance, and cost. Furthermore, KDIGO suggests that decisions to continue iron therapy may be based on recent patient responses to iron therapy, TSAT and ferritin, Hb concentration, ESA responsiveness, ESA dose, ongoing blood losses, and patient's clinical status.

When oral iron is being considered, it is important to dose iron adequately. In general, 200 mg of elemental iron is necessary (ferrous sulfate 325 mg three times daily). If iron supplementation with oral iron after a 1- to 3-month trial is ineffective (measured by no rise in Hb level and/or no fall in ESA requirement), then it is appropriate to consider intravenous iron. Intravenous iron can be administered as a single large dose or repeated smaller doses depending on the specific intravenous iron preparation used. The initial course of intravenous iron is approximately 1000 mg in divided doses, which may be repeated if there is no effect on Hb level and/or decreased ESA dose.

Iron status should be monitored every 3 months with TSAT and ferritin while on ESA therapy. When initiating or increasing ESA dose, in the setting of ongoing blood loss, or in circumstances where iron store may become depleted, it is also appropriate to monitor TSAT and ferritin more frequently. A common setting in which to monitor iron status more frequently is infection or inflammation.

### **Sexual Dysfunction**

Abnormalities in sexual function are common in both men and women with CKD and become more apparent as kidney disease progresses and is most commonly manifest among patients on dialysis. Sexual disturbances include, in women, abnormalities in their menstrual cycle; in men, erectile dysfunction (ED); and in both genders, decreased libido and infertility. Abnormalities in sexual function are now recognized as important factors in determining health-related quality of life among CKD patients, especially those on chronic hemodialysis. To date, sexual dysfunction in CKD patients has focused mostly on the issue of ED in men on dialysis, and sexual dysfunction in women has been quite underappreciated.

### **Male Sexual Dysfunction**

Data from multiple studies indicate that ED is common among men on dialysis. ED is estimated to be present in approximately 80% of men on dialysis and is severe in approximately 45%. ED is associated with impairments

in multiple domains of quality of life, including lower physical and mental well-being. The underlying pathophysiological pathways for ED are still not fully elucidated; however, abnormalities along the neurovascular pathway, the hypothalamic-pituitary-gonadal axis, vascular supply, and penile tissue damage from either infections or trauma are all regarded as being contributory. Key hormonal abnormalities important in causing ED in ESRD patients include the loss of pulsatile release of gonadotrophin-releasing hormone, low plasma testosterone levels, and increased levels of luteinizing hormone and follicle-stimulating hormone. Hyperprolactinemia has also been reported in 25% to 57% of male ESRD patients and has been implicated in impotence, hypogonadism, and reduced desire. Other factors include arterial disease, venous leakage, psychologic factors, neurogenic factors, endocrine factors, and drugs.

In addition to correcting anemia with ESA treatment, there are several specific treatments now available for ED. In particular, phosphodiesterase-5 inhibitors are now established agents for the treatment of ED in patients without kidney disease and also work well in patients with CKD.

### Female Sexual Dysfunction

Sexual dysfunction is highly prevalent among women on chronic hemodialysis; 80% of women on dialysis report sexual dysfunction. Female sexual dysfunction is more common among women without partners and independently associated with age, history of education, level of education, comorbidities such as depression and diabetes, and the menopause. In a recent study, 95% of women who were not waitlisted for a kidney transplant and were not cohabiting with a partner reported sexual dysfunction. Abnormalities of gonadal function are multifactorial in CKD patients, with both physiologic and psychologic factors playing a role. CKD women have a number of sexual abnormalities. Menstrual cycle irregularity and infertility are common among women with renal failure. This is caused by irregular bleeding time along with ovulation failure or maintaining normal corpus luteum function.

### Amenorrhea in Women With Chronic Kidney Disease

Amenorrhea is common in ESRD patients. Advanced kidney failure results in quite marked perturbations in the menstrual cycle. In ESRD patients, menstruation is typically irregular and with scanty flow. In a minority of patients, menorrhagia develops sometimes leading to significant blood loss and increased transfusion requirements.

Hyperprolactinemia is common in women with chronic renal failure due to increased secretion and decreased metabolic clearance of this hormone. Elevated prolactin levels may impair hypothalamic-pituitary function and contribute to sexual dysfunction and galactorrhea.

Women with CKD are likely to experience premature menopause, on average 4.5 years ahead of their healthy counterparts. Consequently, most women with CKD are postmenopausal. Short-term effects of hypogonadism in

women include skin wrinkling, urinary incontinence, hypoactive sexual functions, hot flashes, sleep disorders, and depression. Long-term effects include osteoporosis, disorders of cognitive function, and cardiovascular disease.

Options available for the treatment of sexual dysfunction in CKD women include generalized strategies such as correction of anemia, ensuring sufficient dialysis delivery, and treatment of underlying depression. More specific pharmacologic therapy includes estrogen/progesterone and androgens. It is not known whether unopposed estrogen stimulation of the endometrium (due to anovulatory cycles) might lead to endometrial hyperplasia or endometrial cancer. It is recommended that patients be seen by a gynecologist, and some women may benefit from the use of a progestational agent several times per year to diminish the estrogen effect on the endometrium. Patients who are experiencing vaginal atrophy and dyspareunia can use topical estrogen cream and vaginal lubricants. Transdermal hormone replacement therapy (HRT) allows sustained physiologic serum estradiol concentrations in premenopausal women with estrogen deficiency on hemodialysis, with the restoration of regular menses and a marked improvement in sexual function. HRT with estrogens may positively affect sexual desire and may prevent loss of bone mass in postmenopausal women with ESRD.

### Metabolic Bone Disease

Disturbances in calcium and phosphorus metabolism are common in CKD patients. The spectrum of disorders observed in CKD patients has been defined by the KDIGO guideline group (Box 64.6).

#### • BOX 64.6 Definitions of Chronic Kidney Disease Mineral and Bone Disorder (CKD-MBD) and Renal Osteodystrophy

##### Definition of CKD-MBD

A systemic disorder of mineral and bone metabolism caused by chronic kidney disease (CKD) manifested by either one or a combination of the following:

- Abnormalities of calcium, phosphorus, parathyroid hormone, or vitamin D metabolism
- Abnormalities in bone turnover, mineralization, volume, linear growth, or strength
- Vascular or other soft tissue calcification

##### Definition of Renal Osteodystrophy

- Renal osteodystrophy is an alteration of bone morphology in patients with CKD.
- It is one measure of the skeletal component of the systemic disorder of CKD-MBD that is quantifiable by histomorphometry of bone biopsy.

From Kidney Disease: Improving Global Outcomes (KDIGO) CKD-MBD Work Group. KDIGO clinical practice guideline for the diagnosis, evaluation, prevention, and treatment of chronic kidney disease mineral and bone disorder (CKD-MBD). *Kidney Int Suppl.* 2009;(113):S1–S130.

As GFR declines, the kidney's ability to excrete phosphorus decreases as a result of lower nephron mass, and the serum phosphate level rises. To maintain normophosphatemia, there is increased secretion of fibroblast growth factor 23 (FGF23), the main hormonal regulator of phosphorus homeostasis. FGF23 is made by osteocytes and directly decreases renal phosphate absorption as well as downregulating conversion of inactive vitamin D to active vitamin D, thereby decreasing intestinal phosphate absorption. Not surprisingly, FGF23 levels are elevated in patients with CKD, and high levels of this hormone are associated with increased cardiovascular morbidity and mortality.

In patients with early CKD, FGF23 stimulates increased phosphate excretion to maintain phosphorus homeostasis. However, in patients with more advanced CKD, FGF23 levels are unable to enhance renal phosphate excretion and results in hyperphosphatemia. In addition to its effects on phosphate excretion, FGF23 stimulates parathyroid hormone (PTH) production by the parathyroid glands and reduces  $1,25(\text{OH})_2\text{D}_3$  levels through inhibition of 1- $\alpha$ -hydroxylase, an enzyme produced in the kidney. Reduced  $1,25(\text{OH})_2\text{D}_3$  levels results in reduced gastrointestinal calcium absorption and hypocalcemia. Decreased absorption of calcium from the intestine is further compounded by the low calcium content in the diet of patients with CKD, particularly in those who are on low phosphorus diets. Low levels of active vitamin D also contribute to the development of secondary hyperparathyroidism because this hormone normally exerts a direct inhibitory effect on the release of PTH from the parathyroid gland. Increased PTH levels results in increased phosphate excretion in remaining functional nephrons. High PTH results in osteoclast-mediated bone demineralization and in the long-term renal osteodystrophy.

### Hyperphosphatemia

In most patients with CKD, the focus of management is to prevent metabolic bone disease by maintaining the serum phosphorus level within normal limits. This is accomplished by controlling the serum phosphorus and PTH to normal or near-normal levels. In stage 3 or 4 CKD patients, the serum level of phosphorus should be managed to between 2.7 and 4.6 mg/dL and, in patients with stage 5 CKD, the serum level of phosphorus between 3.5 and 5.5 mg/dL. To achieve these levels, a phosphate-restricted diet (800 to 1000 mg/d) and treatment with a phosphate binder to decrease dietary absorption of phosphate are necessary.

In many patients with advanced CKD or those on dialysis, it is necessary to use both a calcium-containing and noncalcium-containing phosphate binder. Calcium-containing phosphate binders are available as the calcium salts of carbonate, acetate, and citrate. Calcium citrate increases aluminum absorption and should be avoided. Calcium acetate is the most potent phosphate binder in this class. There are two types of noncalcium-containing phosphorus

binders: sevelamer or lanthanum. Sevelamer is available as sevelamer hydrochloride (RenaGel) or sevelamer carbonate (Renvela). Both are calcium- and aluminum-free phosphate binders that control serum phosphorus and reduce PTH levels without inducing hypercalcemia. In addition, both lower serum cholesterol levels. Sevelamer hydrochloride is an exchange resin that releases chloride in exchange for phosphate. The subsequent formation of hydrochloric acid creates an acid load and may cause metabolic acidosis; sevelamer carbonate is less likely to cause acidosis. Lanthanum carbonate (Fosrenol) is another calcium- and aluminum-free binder that is approved for the treatment of hyperphosphatemia in patients with ESRD. The initial clinical experience has shown the drug to be both effective and well tolerated. Oral bioavailability of lanthanum is very low, and the drug is excreted largely unabsorbed in the feces. There has been concern about the long-term safety of lanthanum because of reports of tissue deposition of lanthanum in the liver, lung, and kidney in animal models exposed to lanthanum. However, no long-term toxicity has been reported in humans.

Aluminum is a powerful phosphate binder because it forms a very strong ionic bond with phosphorus. However, because of concerns about long-term toxicity, including dementia and aluminum bone disease, aluminum-containing binders have largely fallen from favor. In patients with severe hyperphosphatemia refractory to treatment, aluminum-containing compounds such as aluminum hydroxide and aluminum carbonate may be used as a short-term therapy (for up to 1 month); thereafter, they should be replaced with either lanthanum or sevelamer. Although calcium-containing binders provide an effective means of controlling phosphorus, their use may not be without risk. Calcium excess induced by the prescription of large doses of calcium-containing phosphate binders has been associated with calcifications of the aorta and the carotid and coronary arteries; calcium-containing phosphate binders have been implicated in the acceleration of vascular disease that accompanies advancing CKD. Widespread use of these drugs may also play a contributory role in the development of calciphylaxis.

### Renal Bone Disease

The most common abnormalities in bone in CKD patients are from the effect of secondary and tertiary hyperparathyroidism. The clinical effect of hyperparathyroidism in the majority of patients is high-turnover bone disease osteitis fibrosa. However, in a minority of patients, adynamic bone disease characterized by extremely low bone turnover may occur. When PTH levels remain persistently elevated, secondary hyperparathyroidism develops. Left untreated, secondary hyperparathyroidism can progress to tertiary hyperparathyroidism, a condition in which the parathyroid glands become autonomous and releases high amounts of PTH out of proportion to a patient's hypocalcemia or hyperphosphatemia; this may occur in late-stage CKD or in ESRD. Secondary hyperparathyroidism is associated with

effects on bone and osteitis fibrosis, where osteoclasts stimulated by chronically elevated concentrations of PTH cause severe bone loss, and predispose patients to fractures and bone cysts.

The mainstay for treatment of hyperparathyroidism is vitamin D therapy. Several therapeutic options are available: vitamin D sterols such as calcitriol, the vitamin D prohormones alfacalcidol and doxercalciferol, and the vitamin D analogue paricalcitol. The least expensive option is the native hormone calcitriol, which is available orally and intravenously. It is effective but has a moderately narrow therapeutic window and may be associated with hypercalcemia. Other vitamin D sterols, such as the vitamin D prohormones, are also available and work similarly to calcitriol but seem to cause less hypercalcemia. Vitamin D analogues such as paricalcitol are now widely used. Vitamin D analogues have structural alterations in the vitamin D molecule to selectively suppress PTH while minimizing the effects on calcium and phosphorus. Paricalcitol is available both in an intravenous and oral form. Some observational evidence supports a survival benefit with the use of paricalcitol over calcitriol, but the explanation for this benefit remains elusive.

Cinacalcet is now also widely used in managing patients in combination with active vitamin D and one or more phosphate binders. Cinacalcet is a calcimimetic allosteric activator of the calcium-sensing receptor in the parathyroid gland and inhibits PTH release. As with active vitamin D therapy, cinacalcet effectively lowers the circulating levels of PTH; however, it does not cause the increased gastrointestinal absorption of calcium and phosphorus associated with vitamin D therapy. Hypocalcemia can occur in a small percentage of patients. In patients with ESRD, combination therapy with cinacalcet and active vitamin D is advantageous, but the optimal mix has not yet been determined.

Monitoring of plasma levels of intact PTH may help prevent the development of secondary hyperparathyroidism. There is debate about whether recommendations from KDOQI guidelines or the KDIGO bone guidelines should be applied to patients. The target PTH levels from both guideline groups are listed in Table 64.4. For patients with PTH values above the target range, 25-(OH)D levels should be obtained at first encounter; if the serum level is normal, the test should be repeated annually. If the serum level of 25-(OH)D is <30 ng/mL, supplementation with vitamin D<sub>2</sub> (ergocalciferol) should be initiated, typically at a dose of 50,000 IU weekly and rechecked after 8 to 12 weeks. Once vitamin D levels are replenished, the patient should be maintained on a multivitamin containing vitamin D or 1000 to 2000 IU of vitamin D<sub>3</sub> (cholecalciferol) daily. Some patients may require more than one course of therapy with ergocalciferol.

Serum levels of calcium and phosphorus need to be monitored every 3 months after starting therapy with high-dose ergocalciferol. If the total corrected serum calcium level exceeds 10.2 mg/dL, vitamin D therapy should

**TABLE 64.4**

**Parathyroid Hormone Targets in CKD Patients**

CKD Stage	Treatment Target
3	KDIGO: upper limit of normal <sup>a</sup> (2C) KDOQI: 3570 pg/mL
4	KDIGO: upper limit of normal <sup>a</sup> (2C) KDOQI: 70110 pg/mL
5	KDIGO: upper limit of normal <sup>a</sup> (2C) KDOQI: 150–300 pg/mL
5D	KDIGO: 2–9 times upper limit of normal <sup>a</sup> (2C) KDOQI: 150–300 pg/mL

<sup>a</sup>In patients with CKD stages 3 to 5 not on dialysis, in whom serum parathyroid hormone is progressively rising and remains persistently above the upper limit of normal for the assay despite correction of modifiable factors, treatment with calcitriol or vitamin D analogues is suggested. (2C) CKD; Chronic kidney disease; KDIGO, Kidney Disease: Improving Global Outcomes; KDOQI, Kidney Disease Outcomes Quality Initiative. From Kidney Disease: Improving Global Outcomes (KDIGO) CKD-MBD Work Group. KDIGO clinical practice guideline for the diagnosis, evaluation, prevention, and treatment of chronic kidney disease mineral and bone disorder (CKD-MBD). *Kidney Int Suppl.* 2009;(113):S1–S130; National Kidney Foundation. K/DOQI clinical practice guidelines for chronic kidney disease: evaluation, classification and stratification. *Am J Kidney Dis.* 2002;39(suppl 1):S1.

be discontinued. If the serum phosphorus level exceeds 4.6 mg/dL, phosphate binders should be initiated or the dose increased. Persistently increased serum phosphorus levels should prompt discontinuation of vitamin D therapy. Plasma levels of PTH should be monitored during therapy when the active form of vitamin D is being used. The target values for PTH in patients with CKD are higher than normal because of evidence that higher levels are required for normal bone remodeling, presumably as a result of the end-organ resistance to PTH in patients with uremia. Suppression of PTH to normal nonuremic values is not desirable, because such low PTH levels are associated with a higher prevalence of adynamic bone disease. After the initiation of therapy with vitamin D, plasma PTH levels should be measured every 3 months. Vitamin D should be decreased or withheld when PTH values fall below the target range.

Once patients reach stage 5 CKD, levels of PTH are almost always elevated, and use of active vitamin D therapy is usually required, with the goal of reducing PTH levels to a target range of 150 to 300 pg/dL. As with earlier stages of CKD, close monitoring of serum calcium and phosphorus levels is required. In these patients, treatment with ergocalciferol is controversial; on the one hand, it is believed that there is inadequate renal mass to convert 25-(OH)D to the active vitamin D sterol, although ongoing studies are examining the benefit of ergocalciferol in late-stage CKD and ESRD.

## Chapter Review

### Questions

- A 78-year-old African-American man is referred to the CKD clinic because of an apparently reduced eGFR. He is otherwise healthy. Medical history is notable for hypertension diagnosed by his primary care physician about 15 years ago. He has a mildly elevated cholesterol treated with atorvastatin. His BP has been quite stable; in the 150 to 160/80 to 90 mm Hg range. He had a recent hip replacement that went well. He has no allergies. Medications include hydrochlorothiazide 50 mg/d and atorvastatin 10 mg once daily. He is a former smoker. On physical examination, he is a healthy-looking obese man. His BP is 152/68 mm Hg, heart rate is 72 beats per minute, weight is 244 lbs, and jugular venous pressure is 8 cm. The rest of the examination is negative. The urinalysis reveals a specific gravity of 1015, a pH 5.0, and 3+ albumin and is otherwise negative. The urine sediment is bland. His BUN and Cr are 28 and 1.1 mg/dL, respectively.

Which of the following statements is not true?

  - Estimating his GFR using the CG equation will result in a gross overestimation of his actual GFR.
  - Evidence indicates that elderly African-American patients do not benefit from angiotensin blockade.
  - Management of his hypertension should include workup for the possibility of sleep apnea syndrome.
  - His African-American race and the presence of albuminuria place this patient at a higher risk of progression regardless of his eGFR.
  - His eGFR will be approximately 20% higher than that of a similar white patient.
- A 44-year-old man is seen in follow-up for management for his presumed ibuprofen-associated gastritis. Two weeks previously, he was told to discontinue his ibuprofen, and the cimetidine was begun. He feels much better. Laboratory testing reveals that his serum Cr is now 1.4 mg/dL, up from a baseline from 6 months previously of 0.9 mg/dL. The patient's urinalysis on dipstick is negative, and the urine microscopy is bland. The most likely reason for the bump in serum Cr is:

  - Ibuprofen-associated acute interstitial nephritis
  - Renal vasoconstriction from ibuprofen therapy
  - Ibuprofen-precipitated minimal change disease
  - Cimetidine-associated interstitial nephritis
  - Cimetidine-mediated inhibition of tubular Cr secretion
- A 44-year-old patient with type 2 DM develops microalbuminuria (80 mg albumin/g Cr) on two separate measurements. Her BP is 138/77 mm Hg. At this point you should:

  - Start the patient on hydrochlorothiazide.
  - Start the patient on lisinopril.
  - Start the patient on lifestyle modifications; include a DASH (dietary approach to stop hypertension) diet and salt restriction.
  - Begin the patient on a calcium channel blocker.
  - Observe the patient and schedule a follow-up appointment in 3 months.
- You are asked to consult on a 62-year-old African-American male diabetic with nephropathy. Routine chemistry laboratory data show a potassium level of 6.2 mEq/L. All of the following would be changes seen on the electrocardiogram compatible with hyperkalemia, except:

  - Peaked T waves
  - Prolonged QRS
  - Flattened P wave
  - Sine-wave-appearing QRS complex
  - U wave
- A 52-year-old African-American female presents to the emergency department with unstable angina. She is noted to have a medical history of CKD (serum Cr of 1.8 mg/dL). She is transferred to the coronary care unit, and therapy for her unstable angina is initiated. A cardiac catheterization is planned for the next day. Her cardiologist asks you for an estimate of her risk of developing contrast nephrotoxicity. Which one of the following would be the closest estimate?

  - 60%
  - <5%
  - 20%
  - >80%
  - >95%

## Essential and Secondary Hypertension

KARANDEEP SINGH, ANIKA T. SINGH, AND AJAY K. SINGH

Hypertension is one of the most common chronic diseases confronting humanity. The worldwide prevalence is estimated to be approximately 26%, or approximately 1 billion individuals. The World Health Organization estimates that high blood pressure (BP) causes one in every eight deaths, making hypertension the third leading source of mortality in the world. In the United States, the National Health and Nutrition Educational Survey reports an incidence of approximately 30% in individuals 18 years and older. The prevalence is higher in older individuals, non-Hispanic blacks, and women. Essential hypertension is the most prevalent hypertension type, affecting 90% to 95% of hypertensive patients.

### Definition of Hypertension

The definition of hypertension has recently been updated by a consortium that includes the American College of Cardiology (ACC) and the American Heart Association (AHA). Normal BP is defined as <120/<80 mm Hg; elevated BP 120–129/<80 mm Hg; hypertension stage 1 is 130–139 or 80–89 mm Hg, and hypertension stage 2 is  $\geq 140$  or  $\geq 90$  mm Hg. The update recommends that prior to labeling a person with hypertension, it is important to use an average based on  $\geq 2$  readings obtained on  $\geq 2$  occasions to estimate the individual's level of BP. This latest update contrasts with the long-standing definition (both in the seventh and eighth

Joint National Committee [JNC7 and JNC8]) guidelines where hypertension is defined as systolic and diastolic hypertension in the general population as a BP of  $\geq 140/90$  mm Hg measured on at least three separate occasions. The rationale for why these guidelines differ is discussed in more detail by [Kovell et al.](#)

The target BP and strategies to manage BP have changed with the recent publication of the JNC8 guidelines. The new BP targets from JNC8 are summarized in [Table 65.1](#). JNC8 departs from the previous JNC7 guidelines in several key areas ([Box 65.1A](#)). JNC8 recommends a less aggressive BP target than JNC7 in patients under age 60 years with diabetes and kidney disease. Also,

### • BOX 65.1A Changes in Hypertension Management in JNC8 Compared to JNC7

- First-line treatments are limited to four classes of medications: thiazide-type diuretics, CCBs, ACE inhibitors, and ARBs.
- Later-line treatments include beta-blockers, alpha-blockers, alpha1/beta-blockers (e.g., carvedilol), vasodilating beta-blockers (e.g., nebivolol), central alpha2/-adrenergic agonists (e.g., clonidine), direct vasodilators (e.g., hydralazine), loop diuretics (e.g., furosemide), aldosterone antagonists (e.g., spironolactone), and peripherally acting adrenergic antagonists (e.g., reserpine).
- When initiating therapy, patients of African descent without CKD should use CCBs and thiazides instead of ACE inhibitors.
- Use of ACE inhibitors and ARBs is recommended in all patients with CKD regardless of ethnic background, either as first-line therapy or in addition to first-line therapy.
- ACE inhibitors and ARBs should not be used in the same patient simultaneously.
- CCBs and thiazide-type diuretics should be used instead of ACE inhibitors and ARBs in patients age >75 years with impaired kidney function because of the risk of hyperkalemia, increased creatinine, and further renal impairment.

**TABLE 65.1** JNC8 Target Blood Pressures

Patient Population	Target BP (mm Hg)
$\geq 60$ years	<150/90
<60 years	<140/90
>18 years with CKD	<140/90
>18 years with diabetes	<140/90

BP, Blood pressure; CKD, chronic kidney disease; JNC8, Eighth Joint National Committee.

From James PA, Oparil S, Carter BL, et al. 2014 Evidence-based guideline for the management of high blood pressure in adults: report from the panel members appointed to the Eighth Joint National Committee (JNC8). *JAMA*. 2014;311(5):507-520.

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CCB, calcium channel blocker; CKD, chronic kidney disease.

From James PA, Oparil S, Carter BL, et al. 2014 Evidence-based guideline for the management of high blood pressure in adults: report from the panel members appointed to the Eighth Joint National Committee (JNC8). *JAMA*. 2014; 311(5):507-520.

the new JNC8 guidelines do not make an aggressive recommendation about the use of thiazide-type diuretics as initial therapy in most patients but instead recommend that first-line therapy could include an angiotensin-converting enzyme (ACE) inhibitor, an angiotensin receptor blocker (ARB), a calcium channel blocker (CCB), or a thiazide-type diuretic as options. In contrast, the AHA/ACC update takes a different approach to JNC8. Key recommendations from this update are summarized in [Box 65.1B](#).

Although the prevalence of hypertension is high, many people are unaware of their BP. Fifty-three percent of patients with hypertension are being treated with medications.

#### • BOX 65.1B ACC/AHA 2017 Guideline for High Blood Pressure in Adults

- Chlorthalidone (12.5–25 mg) is the preferred diuretic because of its long half-life and proven reduction of CVD risk.
- Initial first-line therapy for stage 1 hypertension should include thiazide diuretics, CCBs, and ACE inhibitors or ARBs. Two first-line drugs of different classes are recommended with stage 2 hypertension and average BP of 20/10 mm Hg above the BP target.
- For adults with confirmed hypertension and known stable CVD or  $\geq 10\%$  10-year ASCVD risk, a BP target of  $< 130/80$  mm Hg is recommended.
- For patients with CKD, the BP goal should be  $< 130/80$  mm Hg. In those with stage 3 or higher CKD or stage 1 or 2 CKD with albuminuria ( $> 300$  mg/day), treatment with an ACE inhibitor is reasonable to slow progression of kidney disease. An ARB is reasonable if an ACE inhibitor is not tolerated.
- For patients with DM and hypertension, antihypertensive drug treatment should be initiated at a BP  $\geq 130/80$  mm Hg with a treatment goal of  $< 130/80$  mm Hg.
- In African-American adults with hypertension but without CHF or CKD, including those with DM, initial antihypertensive treatment should include a thiazide-type diuretic or CCB. Two or more antihypertensive medications are recommended to achieve a BP target of  $< 130/80$  mm Hg in most adults, especially in African-American adults, with hypertension.
- Treatment of hypertension is recommended for noninstitutionalized ambulatory community-dwelling adults ( $\geq 65$  years of age), with an average SBP  $\geq 130$  mm Hg with an SBP treatment goal of  $< 130$  mm Hg. For older adults ( $\geq 65$  years of age) with hypertension and a high burden of comorbidity and/or limited life expectancy, clinical judgment, patient preference, and a team-based approach to assess risk/benefit is reasonable for decisions regarding intensity of BP lowering and choice of antihypertensive drugs.

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ASCVD, atherosclerotic cardiovascular disease; BP, blood pressure; CCB, calcium channel blocker; CHF, congestive heart failure; CKD, chronic kidney disease; CVD, cardiovascular disease; DM, diabetes mellitus; SBP, systolic blood pressure.

Derived from content in Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APha/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *J Am Coll Cardiol*. 2017 Nov 7. [Epub ahead of print]

Of those treated, 29% are able to achieve a BP  $< 140/90$  mm Hg. Data from several studies indicate that increasing awareness improves BP control.

## Primary Hypertension

Primary or essential hypertension is defined as high BP for which no medical cause can be found. About 90% to 95% of cases are termed *primary hypertension*. The etio-pathogenesis of primary hypertension remains obscure, although various factors have been implicated including increased sympathetic nervous activity, genetic factors, mineralocorticoid excess, increased angiotensin II activity, reduced renal mass, race, salt sensitivity, and the presence of insulin resistance.

Hypertension is a major risk factor for cardiovascular disease, heart failure, stroke, left ventricular hypertrophy, and chronic kidney disease. For example, among 347,978 men screened for participation in the Multiple Risk Factor Intervention Trial, the risk of fatal stroke for those with systolic BP (SBP) over 180 mm Hg was about 15 times as high and the risk of fatal ischemic heart disease 7 times as high as the rates among those with optimal BP. The optimal interval for screening for hypertension is not known. The 2007 US Preventive Services Task Force guidelines on screening for high BP recommend screening every 2 years for persons with systolic and diastolic pressures below 120 mm Hg and 80 mm Hg, respectively, and yearly for persons with a systolic pressure of 120 to 139 mm Hg or a diastolic pressure of 80 to 89 mm Hg.

Workup of hypertension should include a thorough history and physical examination and laboratory workup ([Box 65.2](#)). Common and uncommon causes of secondary hypertension and clues to secondary causes of hypertension are shown in [Box 65.3](#).

## Management of Hypertension

Treatment of hypertension should follow the broad outlines recommended by JNC8 and the ACC/AHA 2017 guideline ([Fig. 65.1](#)). Key recommendations derived from JNC8 and the ACC/AHA 2017 guideline are listed (see [Boxes 65.1A and 65.1B](#)).

#### Uncommon

Pheochromocytoma  
Glucocorticoid excess/Cushing disease  
Coarctation of aorta  
Hyperthyroidism/hypothyroidism

#### Clinical Clues for Secondary Hypertension

Young age  
Family history of renal disease  
Evidence of renal disease  
Hypertension caused by drugs  
Episodes of sweating, headache, anxiety  
(pheochromocytoma)  
Episodes of muscle weakness and tetany  
(hyperaldosteronism)

### Lifestyle Modifications

A recommended initial step is lifestyle modification. Components of lifestyle modification that have demonstrated effectiveness in reducing BP include weight reduction in patients who are obese to achieve a body mass index of 18.5 to 24.9, a decrease in daily sodium intake to <2.4 g, regular aerobic physical activity of 30 minutes daily on most days of the week, moderation of alcohol consumption, and smoking cessation.

In addition, patients should be encouraged to adopt a diet rich in fruits, vegetables, and low-fat dairy products, with reduced content of total and saturated fat modeled on the Dietary Approaches to Stop Hypertension (DASH) diet. The DASH diet has been demonstrated to be beneficial in reducing elevated BP levels, particularly when combined with low sodium intake.

### Pharmacotherapy

Another way the latest recommendations from the JNC8 depart from the previous iteration of these guidelines (JNC7) is by deemphasizing the use of a thiazide-type diuretic as treatment in hypertensive patients. In JNC7, thiazide-type diuretics were recommended as initial drug therapy for patients without a compelling condition. The use of CCBs, ACE inhibitors, ARBs, and beta-blockers is considered as an alternate but not first-line therapy. In JNC8 the options for first-line therapy are broadened to four classes for nonblack patients and two classes for black patients. First-line therapy for black patients consists of a thiazide-type diuretic, ACE inhibitor, ARB, or CCB. Notably, the 2010 International Society on Hypertension in Blacks (ISHIB) guidelines recommend an ACE inhibitor (or ARB)/CCB

combination as an attractive option for black patients when BP is >15/10 mm Hg above the treatment threshold (e.g., systolic BP of 141 mm Hg in a black patient with diabetes). In JNC8, beta-blockers are no longer recommended as first-line therapy because they seem to provide less protection against stroke. Furthermore, JNC8 essentially abandons the concept of defining compelling conditions such as diabetes mellitus or chronic kidney disease in guiding antihypertensive therapy but incorporates black race in guiding treatment choice (see Fig. 65.1).

The treatment threshold also changes in JNC8. Whereas JNC7 recommended a treatment threshold of 140/90 mm Hg regardless of age, JNC8 raises the systolic threshold to 150 mm Hg at age 60 years. In addition, JNC7 recommended a lower treatment threshold (130/80 mm Hg) for patients with diabetes or chronic kidney disease, but JNC8, informed by the publication of recent randomized trials showing increased adverse risk associated with a lower target BP, abandons the lower BP threshold of 130/80 mm Hg. Because of lack of supportive evidence from randomized trials, JNC8 elected to not support the more aggressive BP targets proposed in the 2010 ISHIB guidelines, which recommended a treatment target of 135/85 mm Hg for most black hypertensive individuals and <130/80 mm Hg for those with additional comorbidity and/or target-organ disease.

The Systolic Blood Pressure Intervention Trial (SPRINT) published in 2015 is very likely to change the JNC guidelines. In SPRINT, 9361 nondiabetic subjects aged >50 years were randomized to either intensive treatment (SBP <120 mm Hg) or standard treatment (SBP <140 mm Hg). The trial reported a significant reduction in the intensive arm of the primary composite endpoint of myocardial infarction, other acute coronary syndromes, stroke, heart failure, or death from cardiovascular causes. Remarkably, there was also a significant 25% reduction in all-cause mortality in the intensive-treatment group.

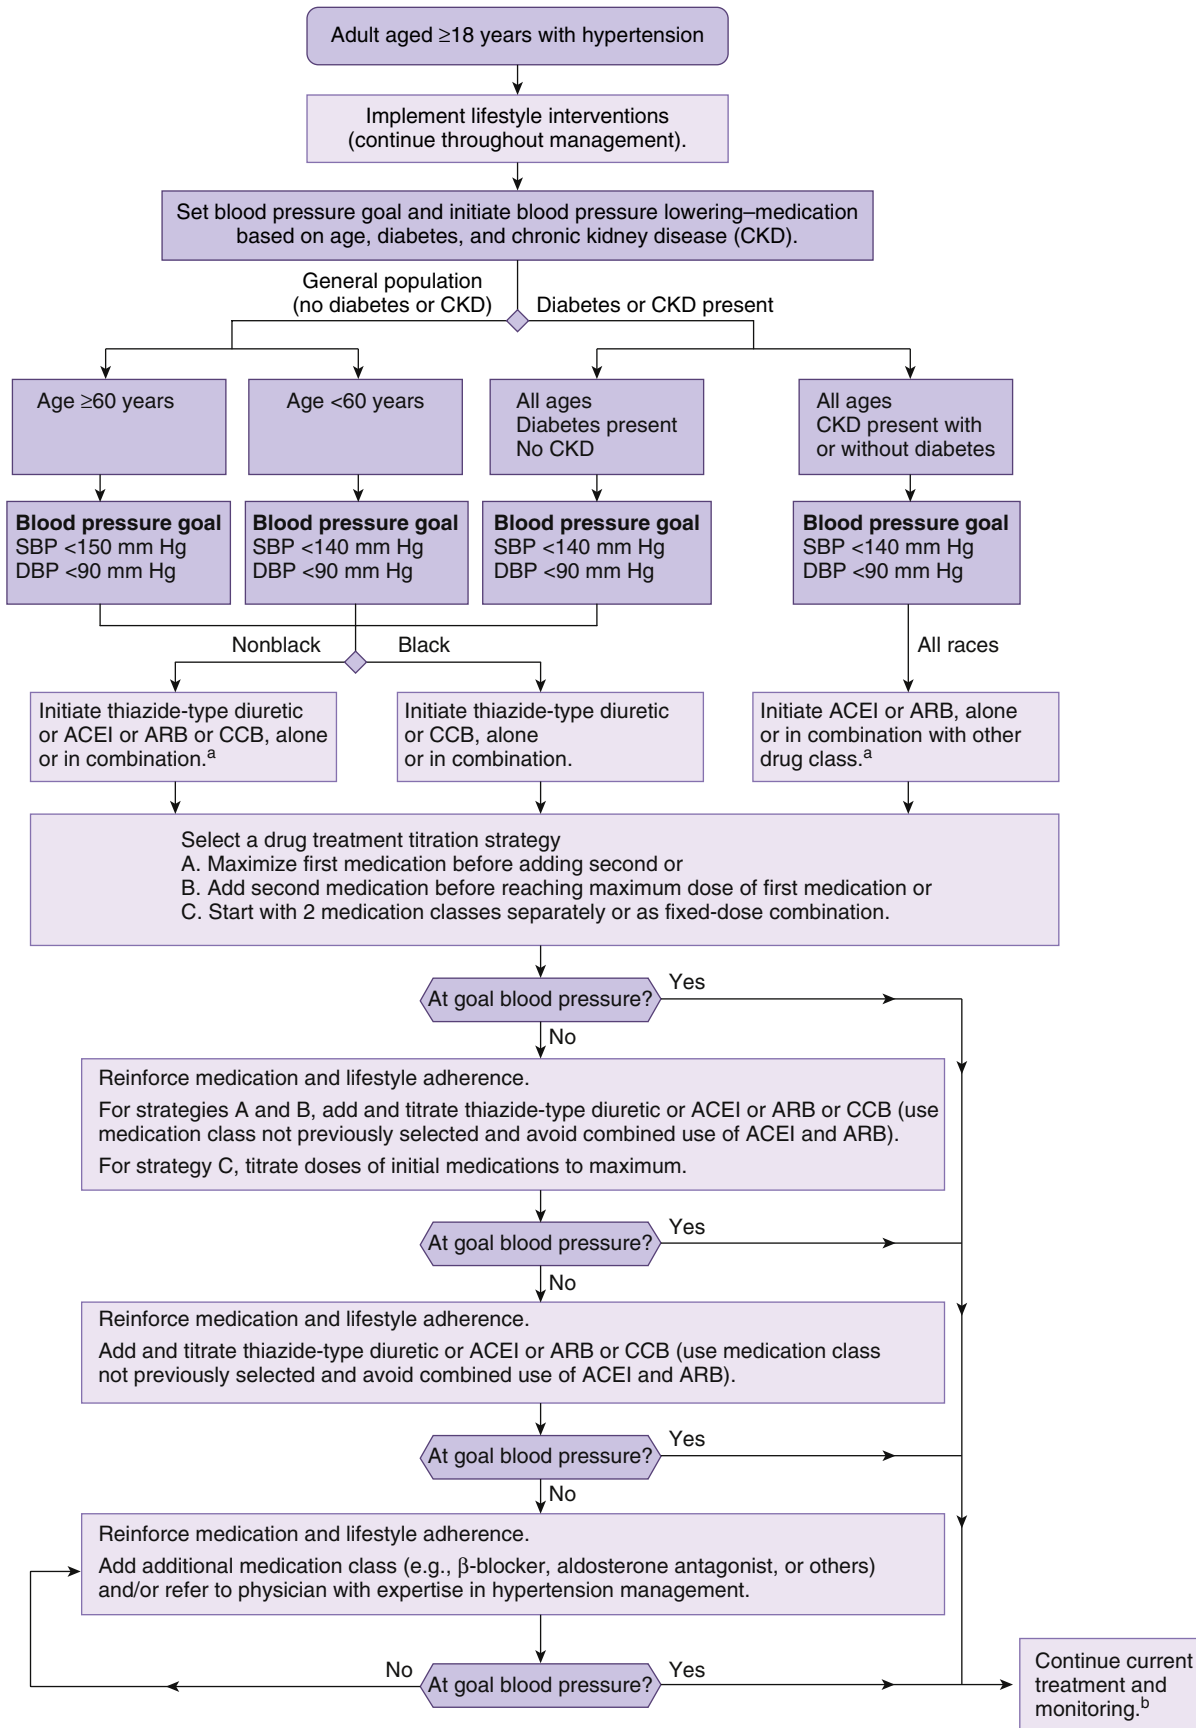

## Hypertension Syndromes

### Hypertension Emergencies

A hypertensive emergency is a condition in which elevated BP results in target organ damage to one or more of the following: the cardiovascular system, the kidneys, and/or the central nervous system. Hypertensive emergencies are potentially life threatening and usually associated with BP  $\geq$ 180/120 mm Hg. Hypertensive urgency is defined as severely elevated BP (i.e., systolic >220 mm Hg or diastolic >120 mm Hg) with no evidence of target organ damage. A hypertensive emergency requires immediate intervention and acute reduction in BP to either reverse or attenuate further target organ damage. In contrast, the treatment of hypertensive urgency can be more deliberate.

### Malignant Hypertension

Fewer than 1% of patients with essential hypertension develop malignant hypertension. The average age at diagnosis is 40 years, and men are affected more often than

• **Fig. 65.1** Algorithm for the Eighth Joint National Committee recommended first-line treatment of hypertension. <sup>a</sup>ACEIs and ARBs should not be used in combination. <sup>b</sup>If blood pressure fails to be maintained at goal, reenter the algorithm where appropriate based on the current individual therapeutic plan. *ACEI*, Angiotensin-converting enzyme inhibitor; *ARB*, angiotensin receptor blocker; *CCB*, calcium channel blocker; *DBP*, diastolic blood pressure; *SBP*, systolic blood pressure.

• **Fig. 65.2** Fundoscopic appearance of hypertensive retinopathy. The picture shows extensive flame-shaped hemorrhages.

• **Fig. 65.3** Typical appearance of a red cell cast in a patient with malignant hypertension with renal thrombotic microangiopathy.

women. Risk factors for malignant hypertension include cigarette smoking, black race, medication nonadherence, and individuals with secondary hypertension. Before effective therapy, life expectancy was <2 years, with most deaths resulting from stroke, renal failure, or heart failure. With current therapy, including dialysis, the survival rate at 1 year is >90% and at 5 years is >80%. Malignant hypertension is characterized by severe hypertension with associated ophthalmologic findings of retinal hemorrhages, exudates, and/or papilledema (Fig. 65.2). Renal involvement manifests clinically with azotemia and an abnormal urinalysis—presence of hematuria, proteinuria, and red cell casts (Fig. 65.3). Renal biopsy (if one is performed) usually demonstrates arteriosclerosis and fibrinoid necrosis. Neurologic presentations include occipital headaches, cerebral infarct,

#### • **BOX 65.4** Keith-Wagener Classification for Hypertensive Retinopathy

- Grade 1: Mild arteriolar narrowing, tortuosity, irregular caliber with copper/silver wiring
- Grade 2: Focal narrowing and arteriovenous nicking
- Grade 3: Retinal hemorrhages (flame-shaped and blot hemorrhages), cotton wool spots, and hard exudates
- Grade 4: Severe grade 3 plus papilledema

cerebral hemorrhage, or hypertensive encephalopathy. Hypertensive encephalopathy is a symptom complex comprising severe hypertension, headache, vomiting, visual disturbance, mental status changes, seizure, and retinopathy with papilledema. Focal signs and symptoms are uncommon and may indicate another process, such as cerebral infarct or hemorrhage. Gastrointestinal symptoms are nausea and vomiting. Diffuse arteriolar damage can result in microangiopathic hemolytic anemia.

Patients with malignant hypertension are usually admitted to an intensive care unit for continuous cardiac monitoring and frequent assessment of neurologic status and urine output. BP measurements should be taken in both arms. A rapid assessment for target organ damage is performed, both clinically and by a laboratory workup. The clinical workup must include a complete cardiac, neurologic, and ophthalmoscopic examination. Hypertensive retinopathy is graded using the Keith-Wagner classification (Box 65.4). Examination of the urine is also essential (see Fig. 65.3). Proteinuria and hematuria are common. Red cell casts may be seen on urine sediment examination. An intravenous line is essential for medications. The initial goal of therapy should be to reduce the mean arterial pressure by approximately 20% to 25% over the first 24 to 48 hours or to 110 to 120 mm Hg, whichever is higher. An intraarterial line is helpful for continuous titration of BP. Use of short-acting antihypertensive agents administered intravenously is recommended (Table 65.2). The most widely used intravenous medications are nitroprusside, nitroglycerin, labetalol, and fenoldopam.

Hypertensive urgencies do not mandate admission to a hospital. The goal of therapy is to reduce BP within 24 hours, and this can be achieved as an outpatient, frequently with orally administered medications.

### Resistant Hypertension

The JNC7 defines resistant hypertension as failure to achieve goal BP (<140/90 mm Hg for the overall population and <130/80 mm Hg for those with diabetes mellitus or chronic kidney disease) when a patient adheres to maximum tolerated doses of three antihypertensive drugs including a diuretic. Resistant hypertension is present in 5% of patients with hypertension in a general practice setting, but it is much more common in specialty settings such as a renal clinic.

TABLE  
65.2

Drugs Commonly Used for the Treatment of Hypertensive Emergency

Drug	Dosage	Onset/Duration of Action	Potential Adverse Effects
Nitroprusside	0.25–10 µg/kg/min	Instant/1–2 min	Thiocyanate cyanide poisoning
Nitroglycerin	5–400 µg/min	1–5 min/3–5 min	Flushing, headache, methemoglobinemia
Nicardipine	5–15 mg/h	5–10 min/1–4 h	Tachycardia, flushing
Hydralazine	10–20 mg	5–15 min/3–8 h	Flushing, tachycardia
Enalaprilat	1.25–5 mg IV every 6 h	20–30 min/6 h	Hypotension, hyperkalemia
Fenoldopam	0.1–1.6 µg/kg/min	5 min/10–15 min	Flushing, headache, tachycardia
Labetalol	10–80 mg IV bolus every 10 min, 0.5–2 mg/min IV infusion	5–10 min/3–6 h	Heart block, orthostatic hypotension
Esmolol	500 µg/kg/min for 1 min, then 50–300 µg/kg/min	1–2 min/10–20 min	Hypotension
Phentolamine (α1 blocker)	1–5 mg IV bolus then 1–40 mg/h continuous infusion	1–2 min/3–10 min	Tachycardia, flushing, headache

IV, Intravenously.

Treatment of resistant hypertension usually requires multiple agents (by definition) and is commonly associated with treatment failure. An approach to resistant hypertension is shown in [Box 65.5](#). Because a suboptimal dosing regimen or inappropriate antihypertensive drug combination is the most common cause of resistant hypertension, the first step in management is to review the medication regimen. One of the most important interventions is to target subtle or clinically apparent extracellular volume expansion by either adding a diuretic agent or increasing the dose of diuretic, or by changing the diuretic class based on kidney function. A thiazide diuretic is preferred if the patient's estimated glomerular filtration rate (eGFR) is  $>50$  mL/min/1.73 m<sup>2</sup>. Switching to a loop diuretic such as furosemide or bumetanide is recommended once the eGFR falls to  $<50$  mL/min/1.73 m<sup>2</sup>. In addition, the patient should be treated with renin-angiotensin-aldosterone system blockade along with a CCB. Options for a fourth agent include a vasodilator, beta-blocker, or peripheral alpha-blocker. Adding a complementary CCB (e.g., adding diltiazem to nifedipine XL) has also been recommended. On the other hand, dual blockade with an ARB and ACE inhibitor does not result in additive BP reduction and may be harmful.

Renal denervation became an attractive option for resistant hypertension after the publication of the Symplicity 1 and 2 studies. These studies reported significant improvement in office BPs 6 months following the procedure. European regulatory approval followed, but the US Food and Drug Administration required further studies to overcome limitations in the design of both Symplicity 1 and 2 (the lack of a true control group and inadequate blinding). The Symplicity 3 trial ([Bhatt et al., 2014](#)) included sham (renal angiography alone without renal denervation) and active

intervention arms, and patients were blinded to the intervention. Symplicity 3 failed to demonstrate a significant difference between the control and active intervention arms groups, although BP was lower in both arms as compared with baseline, and there was no safety signal associated with the intervention.

### Endocrine Hypertension Syndromes

Endocrine hypertension includes the following disorders.

#### Primary Aldosteronism

Primary hyperaldosteronism is the most common form of endocrine hypertension. It affects 5% to 10% of all patients with hypertension. The two most common forms of primary aldosteronism are Conn syndrome, in which a single adrenal tumor produces excessive aldosterone, and bilateral adrenal hyperplasia, in which both adrenal glands are enlarged, causing hyperaldosteronism. Adrenal carcinoma is an extremely rare cause of primary hyperaldosteronism. Excessive aldosterone production by the adrenal glands leads to fluid retention, potassium loss that manifests as mild-to-moderate hypokalemia, metabolic alkalosis, and hypertension. Initial workup should include electrolytes, serum aldosterone, and plasma renin activity (PRA). A significant elevation of the plasma aldosterone-to-renin ratio to  $>30$  may be found (normal ratio is 4–10). If the plasma aldosterone concentration is  $>20$  ng/dL and the ratio is  $>30$ , the sensitivity and specificity for primary aldosteronism are  $>90\%$ . Confirmatory testing should include either measurement of the serum aldosterone level after 3 days of an unrestricted sodium diet and 1 hour of full recumbency, or measurement of 24-hour urinary aldosterone excretion, or an oral or intravenous salt-loading test with measurement

of serum aldosterone and PRA. Additional testing includes high-resolution, thin-slice (2–2.5 mm) adrenal CT scanning with contrast and adrenal venous sampling. Adrenal venous sampling probably has its greatest utility in the setting of either totally normal adrenal imaging despite biochemical evidence for primary aldosteronism or settings in which bilateral adrenal pathology is present on imaging. MRI is not superior to contrast-enhanced CT scanning for adrenal visualization. Bilateral adrenal hyperplasia is best treated with medications such as spironolactone or eplerenone. Surgery is the treatment of choice for the lateralizable variants of primary hyperaldosteronism.

### Cushing Syndrome

Cushing syndrome is caused by prolonged exposure to elevated levels of either endogenous or exogenous glucocorticoids. Cushing syndrome can be caused by direct adrenal

#### • BOX 65.5 Approach to Patient With Resistant Hypertension

##### Measure Blood Pressure (BP) Accurately

- “Persons should be seated quietly for 5 minutes with feet on the floor and the arm supported at heart level.”
- Cuff must be appropriately sized (cuff bladder must encircle 80% of the arm)
- Check both arms and a leg (or palpate pulses carefully)

##### Consider “White Coat Hypertension”

- Home and ambulatory BP monitoring

##### Consider Pseudoresistance

- Pseudohypertension (calcification of the arteries resulting in failure of the BP cuff to compress and occlude flow)
- Nonadherence (may account for up to 50% of resistant cases)
- Inadequate regimen
- Interfering medicines and substances also need to be considered
  - Nonsteroidal antiinflammatory drugs
  - Excessive alcohol, caffeine, or tobacco
  - Excessive salt intake
  - Oral contraceptives
  - Sympathomimetic agents (nasal decongestants, anorectic pills, cocaine, amphetamine-like stimulants)
  - Glucocorticoids
  - Anabolic steroids
  - Erythropoietin
  - Cyclosporine
  - Black licorice
  - Herbal supplements (e.g., ma huang and ginseng)

##### Consider Secondary Causes

- Obstructive sleep apnea
- Obesity (metabolic syndrome)
- Endocrinopathies
  - Hyperaldosteronism, thyroid problems, pheochromocytoma
- Kidney disease
  - Renal insufficiency and renal artery stenosis

involvement (adrenal Cushing) or independent of adrenocorticotrophic hormone (ACTH) secretion (i.e., ACTH independent). ACTH-dependent Cushing disease is either secondary to an anterior pituitary tumor (in approximately 80%) or to ectopic ACTH production (Box 65.6). Nonpituitary ectopic sources of ACTH include oat cell carcinoma, small cell lung carcinoma, or carcinoid tumor. A more detailed discussion is provided in the endocrinology section of this book (see Section 5).

### Pheochromocytoma

This is a syndrome caused by tumors of the adrenal glands. Pheochromocytoma is rare. These tumors produce excessive amounts of epinephrine, norepinephrine, or other catecholamines. The classic triad of symptoms in patients with a pheochromocytoma consists of episodic headache, sweating, and tachycardia. Patients with a pheochromocytoma have episodic or sustained hypertension. About 10% of these tumors are located outside the adrenal glands (extraadrenal) in various locations in the body. Extraadrenal pheochromocytomas are also known as *paragangliomas*. About 10% of the tumors are malignant. Pheochromocytomas may present as a part of multiple endocrine neoplasia (MEN) syndromes (Table 65.3). MEN syndromes can involve endocrine organs such as the parathyroid glands, pituitary, and thyroid, as well as other organs such as the kidney, pancreas, or stomach. The MEN 2A and 2B syndromes, which are autosomally inherited, have been traced to germline mutations in the *RET* protooncogene. The *RET* protooncogene, located on chromosome 10, encodes a tyrosine kinase receptor involved in the regulation of cell growth and differentiation. Pheochromocytomas occur bilaterally in the MEN syndromes in as many as 70% of cases.

Other types of endocrine hypertension are shown in Table 65.4.

#### • BOX 65.6 Causes of Cushing Syndrome

##### ACTH Dependent

- Pituitary tumor (Cushing disease pituitary hypersecretion of ACTH)
- Nonpituitary tumors (ectopic secretion of ACTH)
- Nonhypothalamic tumors (ectopic secretion of corticotropin-releasing hormone causing ACTH secretion)
- Administration of exogenous ACTH (iatrogenic or factitious Cushing syndrome)

##### ACTH Independent

- Exogenous administration of glucocorticoids (iatrogenic or factitious Cushing syndrome)
- Adrenocortical adenomas and carcinomas
- Primary pigmented nodular adrenocortical disease (bilateral adrenal micronodular hyperplasia)
- Bilateral ACTH-independent macronodular hyperplasia

ACTH, Adrenocorticotrophic hormone.

**TABLE 65.3** Pheochromocytoma Syndromes

Syndrome	Key Characteristics
MEN 2A (Sipple syndrome)	Medullary thyroid carcinoma, hyperparathyroidism, pheochromocytomas, and Hirschsprung disease >95% of cases of MEN 2A have mutations in the <i>RET</i> protooncogene
MEN 2B	Medullary thyroid carcinoma, pheochromocytoma, mucosal neurofibromatosis, intestinal ganglioneuromatosis, Hirschsprung disease, and a marfanoid body habitus; a germline missense mutation in the tyrosine kinase domain of the <i>RET</i> protooncogene
VHL disease	Pheochromocytoma, cerebellar hemangioblastoma, renal cell carcinoma, renal and pancreatic cysts, and epididymal cystadenomas; >75 germline mutations in a <i>VHL</i> suppressor gene on chromosome 3.8
Neurofibromatosis or von Recklinghausen disease	Congenital anomalies (often benign tumors) of the skin, nervous system, bones, and endocrine glands; only 1% of patients with neurofibromatosis have been found to have pheochromocytomas, but as many as 5% of patients with pheochromocytomas have been found to have neurofibromatosis

*MEN*, Multiple endocrine neoplasia; *VHL*, von Hippel-Lindau.

## Hypertension in the Elderly

Hypertension is quite common in the elderly. Primary hypertension is the most common type, but common identifiable causes (e.g., renovascular hypertension) should be considered. In the elderly, SBP appears to be a better predictor of cardiovascular events than diastolic BP (DBP). However, pseudohypertension and “white-coat hypertension” are common, and readings outside the office should be emphasized. Therapy should begin with lifestyle modifications. Starting doses for drug therapy should be lower than those used in younger adults. The importance of managing BP in the elderly has solid support in the literature.

In 2008 the Hypertension in the Very Elderly Trial (HYVET) found that active treatment with perindopril was associated with a 30% reduction in the rate of fatal or non-fatal stroke, 39% reduction in the rate of death from stroke, 21% reduction in the rate of death from any cause, 23% reduction in the rate of death from cardiovascular causes, and 64% reduction in the rate of heart failure. However, in a major break from long-standing practice, the JNC8 guidelines relaxed the target BP for the general population aged  $\geq 60$  years to  $<150/90$  mm Hg as compared with the previous BP target in JNC7 of  $<140/90$  mm Hg. The JNC8 panel’s decision to relax the BP target in the elderly seems to be driven by a lack of additional benefit in the elderly of targeting a systolic BP of  $<140$  mm Hg coupled with evidence from observational analyses that suggest greater adverse effects of a lower BP target (cognitive effects and a high rate of falls).

**TABLE 65.4** Endocrine Syndromes of Hypertension

Type of Syndrome	Key Characteristics
Familial hyperaldosteronism type I (also known as <i>glucocorticoid-remediable aldosteronism</i> )	Clinical: About 1% of cases of primary hyperaldosteronism may be detected in asymptomatic individuals when screening offspring of affected individuals, or patients may present in infancy with hypertension, weakness, and failure to thrive due to hypokalemia. Genetics: Autosomal dominant with low frequency of new mutations. Presence of a hybrid or chimeric gene on chromosome 8q consisting of the regulatory region of the 11-beta-hydroxylase gene coupled to the coding sequence of the aldosterone synthase gene.
Familial hyperaldosteronism type II (FH-II, also known as <i>pseudo-hypoaldosteronism type 2</i> or <i>Gordon syndrome</i> )	Clinical: Rare familial renal tubular defect characterized by hypertension and hyperkalemic metabolic acidosis in the presence of low renin and aldosterone levels. Genetics: Autosomal dominant. It is caused by absent WNK1 or WNK4 kinase function in the distal nephron.
Liddle syndrome	Clinical: Early-onset severe hypertension, hypokalemia, metabolic alkalosis in the setting of low plasma renin and aldosterone, low rates of urinary aldosterone excretion, and a family history of hypertension. Genetics: Autosomal dominant disorder caused by hyperactivity of the amiloride-sensitive sodium channel (ENaC) of the principal cell of the cortical collecting tubule.
Apparent mineralocorticoid excess	Clinical: Presents with hypertension and hypokalemia. Genetics: Autosomal recessive disorder. Results from mutations in the <i>HSD11B2</i> gene, which encodes the kidney isozyme of 11-beta-hydroxysteroid dehydrogenase type 2.
Licorice ingestion	Clinical: Presents with hypertension and hypokalemia. Pathophysiology: Pseudoaldosteronism due to ingestion of certain types of licorice (usually black licorice).

Key recommendations in treating hypertension in elderly patients from the European Society of Hypertension are summarized below:

1. In elderly hypertensive patients with an SBP  $\geq 160$  mm Hg, the systolic target should be between 140 and 150 mm Hg.
2. In fit elderly patients age  $< 80$  years, treatment may be considered at a systolic level  $\geq 140$  mm Hg with a target SBP  $< 140$  mm Hg if treatment is well tolerated.
3. In frail elderly patients, treatment decisions should be governed by comorbidity. Treatment effects should be carefully monitored.
4. Hypertensive patients age  $> 80$  years should have their treatment continued if the antihypertensive regimen is well tolerated.

## Hypertension in Diabetics

The prevalence of hypertension is greater among patients with diabetes mellitus than nondiabetics. The combination of diabetes and hypertension may have a compounding effect on cardiovascular and kidney disease. The JNC8 guidelines recommend a BP goal of  $< 140/90$  mm Hg in diabetics. Many randomized controlled trials with large populations of diabetics, including the UK Prospective Diabetes Study (UKPDS), Hypertension Optimal Treatment (HOT), Systolic Hypertension in the Elderly Program (SHEP), Syst-EUR, Heart Outcomes Prevention Evaluation (HOPE), Losartan Intervention for Endpoint Reduction in Hypertension (LIFE), and Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), have demonstrated improved cardiovascular outcomes when BP is adequately controlled. Although the optimal BP goal for diabetics remains controversial, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) hypertension trial has been influential in relaxing the BP threshold recommendation from  $< 130/80$  mm Hg in JNC7 to  $< 140/90$  mm Hg in JNC8, respectively. ACCORD compared a strategy of lowering the BP to  $< 120$  mm Hg (intensive therapy) versus  $< 140$  mm Hg (standard therapy) and found no difference in overall mortality and deaths from cardiovascular causes between the two arms. However, there was a lower risk of total and nonfatal strokes in the intensive therapy arm but a higher risk of serious adverse events.

## Hypertension in Pregnancy

Hypertension is the most common medical problem encountered during pregnancy, complicating 2% to 3% of pregnancies. Hypertension during pregnancy is an important cause of both maternal and fetal morbidity and of maternal mortality, especially in the developing world. Hypertensive disorders during pregnancy are classified into four categories by the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy: (1) chronic hypertension; (2) preeclampsia/eclampsia; (3) preeclampsia superimposed on chronic hypertension; and (4) gestational hypertension (Table 65.5).

**TABLE 65.5** Classification of Hypertension in Pregnancy

Disorder	Key Characteristics
Chronic hypertension	BP $\geq 140/90$ mm Hg before pregnancy or diagnosed before 20 weeks of gestation not attributable to gestational trophoblastic disease, or hypertension first diagnosed after 20 weeks of gestation and persistent after 12 weeks postpartum.
Preeclampsia/eclampsia	BP $\geq 140/90$ mm Hg after 20 weeks of gestation in a woman with previously normal BP and with proteinuria ( $\geq 0.3$ g protein in 24-h urine specimen). Eclampsia is defined as seizures that cannot be attributable to other causes in a woman with preeclampsia.
Superimposed preeclampsia (on chronic hypertension)	New-onset proteinuria ( $\geq 300$ mg/24 h) in a woman with hypertension but no proteinuria $< 20$ weeks of gestation. A sudden increase in proteinuria or BP, or platelet count $< 100,000$ , in a woman with hypertension and proteinuria $< 20$ weeks of gestation.
Gestational hypertension	BP $\geq 140/90$ mm Hg for the first time during pregnancy. No proteinuria. BP returns to normal $< 12$ weeks postpartum. Final diagnosis made only postpartum.

BP, Blood pressure.

From National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy Hypertension.

## Chronic Hypertension

Chronic hypertension may be either essential or secondary. About 20% to 25% of women with chronic hypertension develop preeclampsia during pregnancy. In normal pregnancy, women's mean arterial pressure drops 10 to 15 mm Hg over the first half of pregnancy. Most women with mild chronic hypertension (i.e., SBP 140–160 mm Hg, DBP 90–100 mm Hg) have a similar decrease in BPs and may not require any medication during this period. If maternal BP rises to  $\geq 160/100$  mm Hg, however, drug treatment is recommended. The goal of pharmacologic treatment should be a DBP of  $< 100$  to 105 mm Hg and an SBP  $< 160$  mm Hg. Women with preexisting end-organ damage from chronic hypertension should have a lower threshold for starting antihypertensive medication (i.e.,  $\geq 140/90$  mm Hg) and a lower target BP ( $< 140/90$  mm Hg).

## Preeclampsia

The incidence of preeclampsia in the United States is estimated to range from 2% to 6% in healthy nulliparous women. Preeclampsia can be classified into mild, severe, and HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome (Table 65.6). Most cases (75%) are

**TABLE 65.6 Preeclampsia Syndromes**

Preeclampsia Syndrome	Key Features
Mild pre-eclampsia	BP $\geq$ 140/90 mm Hg on two occasions, at least 6 h apart Proteinuria $\geq$ 1+ protein on random dipstick or $\geq$ 300 mg of protein in a 24-h urine collection, or urine protein-creatinine ratio $\geq$ 0.3 as a criterion for proteinuria
Severe pre-eclampsia	Presence of preeclampsia plus >1 of following: Systolic BP $\geq$ 160 mm Hg, diastolic BP $\geq$ 110 mm Hg (on two occasions at least 6 h apart) Proteinuria $\geq$ 5 g/24 h Pulmonary edema Oliguria (<400 mL in 24 h) Persistent headaches Epigastric pain and/or impaired liver function Thrombocytopenia Intrauterine growth restriction
HELLP syndrome	Form of severe preeclampsia Hemolysis Abnormal peripheral smear Indirect bilirubin >1.2 mg/dL Lactate dehydrogenase >600 U/L Elevated liver enzymes (serum AST >70 U/L) Low platelets/coagulopathy (platelet count <100,000/mm <sup>3</sup> , elevated PT or aPTT, decreased fibrinogen, increased D-dimer)

*aPTT*, Activated partial thromboplastin time; *AST*, aspartate aminotransferase; *BP*, blood pressure; *HELLP*; hemolysis, elevated liver enzyme, low platelets; *PT*, prothrombin time.  
From National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy Hypertension.

mild; 10% occur in pregnancies of <34 weeks' gestation. Risk factors for preeclampsia include nulliparity, age >40 years, a family history of preeclampsia, multiple gestations, chronic hypertension, antiphospholipid antibody syndrome, underlying renal disease, obesity, diabetes, and thrombophilia. Clues to differentiate preeclampsia from chronic hypertension include the presence of visual disturbances such as scintillations and scotomata; the presence of new-onset headache described as frontal, throbbing, or similar to a migraine headache; new-onset epigastric pain; and rapidly increasing or nondependent edema (edema is no longer included among the criteria for diagnosis of preeclampsia).

Glomerular endothelial injury in the kidneys is the mechanistic explanation for proteinuria, extracellular volume expansion, and hypertension. This kidney lesion originates in response to the production and release into the maternal

circulation of placental antiangiogenic factors, specifically soluble fms-related tyrosine kinase 1 and soluble endoglin that are upregulated in preeclampsia. Other factors, including hypoxia and perturbations in the renin-angiotensin-aldosterone system, among other factors, also seem to be important (Wang et al., 2009).

Magnesium sulfate is the drug of choice for seizure prophylaxis in women with preeclampsia. Therapy is started at the beginning of labor or before cesarean section and continued 24 hours postpartum in most cases. The duration of postpartum therapy may be modified depending on the severity of the disease. Treatment is started by administering an intravenous loading dose of 4 to 6 g magnesium sulfate, followed by a maintenance dose of 1 to 2 g per hour. Management of hypertension in patients with preeclampsia is shown in Table 65.7. SBP of  $\geq$ 160 mm Hg and/or diastolic pressure of  $\geq$ 110 mm Hg must be treated. The goal is to maintain the BP around 140/90 mm Hg.

### Management of Mild Preeclampsia

Delivery is the only cure for a pregnancy complicated by mild preeclampsia; if the mother is >37 weeks, the fetus should be delivered. Vaginal delivery is the first choice but with induction of labor regardless of cervical status; cesarean section should be performed based on standard obstetric criteria. If the mother is <37 weeks' gestation then the optimal management depends on gestational age and severity of the disease. The mother should be hospitalized and monitored carefully, and antepartum testing (nonstress test [NST] and biophysical profile) should be performed at admission and twice per week until delivery.

### Management of Severe Preeclampsia

For severe preeclampsia diagnosed >34 weeks' gestation, delivery is most appropriate. Vaginal delivery is the first choice, and cesarean section should be based on routine obstetric indications. Women with severe preeclampsia who have nonreassuring fetal status, ruptured membranes, labor, or maternal distress should be delivered regardless of gestational age. For women <34 weeks' gestation, corticosteroids for fetal lung maturity should be administered. If a woman with severe preeclampsia is >32 weeks' gestation and has received a course of steroids, she should be delivered as well. Fetal monitoring should include daily NST and ultrasonography performed to monitor for the development of oligohydramnios and decreased fetal movement. In addition, daily blood tests should be performed for liver function tests (LFTs), complete blood count, uric acid, and lactate dehydrogenase. Patients should be instructed to report any headache, visual changes, epigastric pain, or decreased fetal movement.

### Eclampsia

Eclampsia is defined as new onset of grand mal seizure activity and/or unexplained coma during pregnancy or

**TABLE 65.7** Management of Hypertension in Preeclampsia

Medication	Key Issues
Hydralazine	Hydralazine is a direct peripheral arteriolar vasodilator, and, in the past, it was widely used as the first-line treatment for acute hypertension in pregnancy. Hydralazine has a slow onset of action (10–20 min) and peaks approximately 20 min after administration. Hydralazine should be given as an IV bolus at a dose of 5–10 mg, depending on the severity of hypertension. It may be administered every 20 min up to a total dose of 20 mg. The side effects of hydralazine are headache, nausea, and vomiting. Importantly, hydralazine may result in maternal hypotension, which may subsequently result in a nonreassuring fetal heart rate tracing in the fetus.
Labetalol	Labetalol is a selective alpha-blocker and nonselective beta-blocker that produces vasodilatation and results in a decrease in systemic vascular resistance. The dosage for labetalol is 20 mg IV with repeat doses (40, 80, 80, and 80 mg) every 10 min up to a total dose of 300 mg. Decreases in BP are observed after 5 min (in contrast to the slower onset of action of hydralazine) and results in less overshoot hypertension than hydralazine. Labetalol decreases supraventricular rhythm and slows the heart rate, reducing myocardial oxygen consumption. No change in afterload is observed after treatment with labetalol. The side effects of labetalol are dizziness, nausea, and headaches. After achieving satisfactory control with IV administration, an oral maintenance dose can begin.
Calcium channel blockers (CCBs)	CCBs act on arteriolar smooth muscle and induce vasodilatation by blocking calcium entry into the cells. Nifedipine is the oral CCB that is used in the management of hypertension in pregnancy. The dosage of nifedipine is 10 mg orally every 15–30 min with a maximum of 3 doses. The side effects of CCBs include tachycardia, palpitations, and headaches. Concomitant use of CCBs and magnesium sulfate is to be avoided. Nifedipine is commonly used postpartum in patients with preeclampsia for BP control.
Sodium nitroprusside	Used in a severe hypertensive emergency, nitroprusside results in the release of nitric oxide, which subsequently results in significant vasodilation. Preload and afterload are then greatly decreased. The onset of action is rapid, and severe rebound hypertension may result. Cyanide poisoning may occur subsequent to its use in the fetus. Therefore its use should be reserved for postpartum care or just before the delivery of the fetus.

*BP*, Blood pressure; *IV*, intravenously.

postpartum in a woman with preeclampsia. Eclampsia and preeclampsia account for >60,000 maternal deaths each year worldwide. In developed countries, the maternal death rate has been reported as up to 1.8%.

### Management of Eclampsia

The most important goals are to stabilize the patient, deliver the fetus after the patient has been stabilized, and prevent further seizure activity. Stabilization of the patient involves protection of the airway, oxygen therapy, and establishing intravenous access. Once the patient has been stabilized (i.e., seizure activity has abated or the comatose state is resolved) the fetus should be delivered. The patient and fetus should be very closely monitored, and the patient is induced. Delivery by the vaginal route is preferred. However, if vaginal delivery is associated with delay and/or fetal or maternal distress, then immediate cesarean section is preferred. Intrapartum complications include fetal growth retardation, nonreassuring fetal heart rate patterns, and placental abruption. Preeclamptic/eclamptic pregnancies of <28 weeks' gestation are associated with a high rate of maternal mortality. Further seizure activity is possible but is generally prevented by administration of magnesium sulfate (4–6 g over 20 minutes as a loading dose followed by a maintenance dose of 1–2 g per hour as a continuous intravenous infusion); 90% of women will not have a recurrent seizure after treatment with magnesium sulfate, but if a second or recurrent seizures occur, then control with lorazepam or diazepam should be considered.

### Gestational Hypertension

*Gestational hypertension* refers to hypertension with onset in the latter part of pregnancy (>20 weeks' gestation) without any other features of preeclampsia and followed by normalization of the BP postpartum. Of women who initially present with apparent gestational hypertension, about one-third develop the syndrome of preeclampsia. The main goal in working up patients with gestational hypertension is to exclude the possibility of preeclampsia. The pathophysiology of gestational hypertension is unknown, but in the absence of features of preeclampsia the maternal and fetal outcomes are usually normal. Patient workup should include measurement of urine protein excretion, laboratory evaluation (for uric acid, LFTs, platelets, coagulation factors, and kidney function), and fetal assessment. Unless BP is >160/90 mm Hg, no pharmacologic treatment is indicated. No steroids need to be administered, and the pregnancy can proceed to term. Gestational hypertension may, however, be a harbinger of chronic hypertension later in life, and follow-up with a primary care physician is reasonable.

### Renovascular Hypertension

Renovascular hypertension (RVHT) denotes nonessential hypertension in which a causal relationship exists between anatomically evident arterial occlusive disease and elevated BP. Pathophysiologically, RVHT reflects

### • BOX 65.7 Causes of Renovascular Hypertension

#### Major Causes

Atherosclerosis  
Fibromuscular dysplasia

#### Minor Causes

Vasculitis (Takayasu arteritis)  
Dissection of the renal artery  
Thromboembolic disease  
Renal artery aneurysm  
Renal artery coarctation  
Extrinsic compression  
Radiation injury

### • BOX 65.8 Risk Factors Associated With Renovascular Disease

Carotid artery disease  
Coronary artery disease  
Diabetes mellitus  
Hypertension  
Obesity  
Old age  
Peripheral vascular disease (vascular disease in the extremities, e.g., the legs)  
Smoking  
Familial history of atherosclerotic disease or renal artery stenosis

renin-angiotensin-aldosterone activation as a result of renal ischemia. RVHT is the most common type of secondary hypertension, accounting for 1% to 5% of patients with hypertension. Renal artery stenosis (RAS) is also being increasingly recognized as an important cause of chronic renal insufficiency and end-stage renal disease. Studies suggest that ischemic nephropathy from RAS may be responsible for 5% to 22% of advanced renal disease in all patients older than 50 years in the United States. The incidence of renovascular disease is bimodal: It is common in younger women and older men, and it is twice as common in white individuals as in black individuals. Causes of RVHT are shown in [Box 65.7](#).

Major complications of RVHT include end-organ damage caused by chronically uncontrolled hypertension (coronary artery disease, stroke, and progressive renal insufficiency).

Risk factors for RVHT are shown in [Box 65.8](#). RVHT should be suspected in patients younger than 30 years or older than 50 years, those patients with symptoms of atherosclerotic disease elsewhere, and those with a negative family history of hypertension. Other clinical clues are shown in [Box 65.9](#).

Once patients are identified as being at higher risk of RAS, the choice of the best test for diagnosis is controversial. Options for the workup of RVHT are shown in [Box 65.10](#). Accurate identification of patients with correctable RVHT can be difficult with the use of standard noninvasive techniques because they provide only indirect

### • BOX 65.9 Clinical Clues Suggesting the Possibility of Renal Artery Stenosis

- Difficult-to-control hypertension despite adequate medical treatment
- Hypertension with renal failure or progressive renal insufficiency
- Accelerated or malignant hypertension
- Severe hypertension (diastolic blood pressure >120 mm Hg) or resistant hypertension
- Hypertension with an asymmetric kidney
- Paradoxical worsening of hypertension with diuretic therapy

### • BOX 65.10 Workup of Renovascular Disease

- Serum creatinine and creatinine clearance
- 24-hour urine protein
- Urinalysis
- Measurement of plasma renin activity
- Ultrasound/duplex ultrasound
- Captopril renography
- CT angiography (spiral CT)
- MR angiography
- Renal arteriography/intraarterial digital subtraction angiography or carbon dioxide angiography

evidence of the presence of renal artery lesions (e.g., sonography, CT angiography, MR angiography [MRA]). On the other hand, invasive techniques with more accurate diagnostic potential can produce a worsening of renal function because of contrast toxicity and complications related to the procedure itself (e.g., arterial puncture, catheter-induced atheroembolism). When the history is highly suggestive and there is minimal risk for radiocontrast-mediated renal injury, conventional angiography or digital subtraction angiography is the appropriate initial test. In patients at risk of contrast nephropathy, a carbon dioxide angiogram should be considered. Alternatives to angiography include an MRA or duplex ultrasonography. However, in patients with chronic kidney disease and an estimated GFR of <30 mL/min/1.73 m<sup>2</sup>, MRA with gadolinium is contraindicated because of the potential risk for nephrogenic systemic fibrosis/nephrogenic fibrosing dermopathy.

Treatment of RVHT is still debated. All patients need medical therapy: treatment with antihypertensive drugs to optimize BP control and risk factor management including smoking cessation and hyperlipidemia treatment. In many patients, BP can be well controlled with CCBs, beta-blockers, and many other classes of drugs. ACE inhibitors should be avoided in patients with bilateral renovascular disease. However, in some patients, BP may be particularly difficult to control or may require multiple antihypertensive agents. The decision to persist with medical therapy versus recommending percutaneous renal angioplasty or surgical revascularization continues to

be debated. The recent publication of the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) study points to a lack of benefit of percutaneous renal angioplasty in reducing hard clinical events. In CORAL, 947 patients with renal artery atherosclerosis (stenosis >60%) who had either systolic hypertension and were taking two or more BP-lowering drugs or chronic kidney disease were randomized to either medical therapy alone or medical therapy plus renal artery stenting. At a median follow-up of 43 months, the rate of the primary composite endpoint (death from cardiovascular or renal causes, myocardial infarction, stroke, hospitalization for congestive heart failure, progressive renal insufficiency, or need for renal replacement therapy) was no different between the two arms. Although BP was a little lower (−2.3 mm Hg) in the stented patients, these patients also had a higher rate of arterial dissection. The study overcame a key criticism of earlier studies (e.g., ASTRAL [Angioplasty and Stenting for Renal Artery Lesions] and STAR [Stent Placement in Patients With Atherosclerotic Renal Artery Stenosis and Impaired Renal Function]) by strictly controlling for crossover between the randomized arms. However, whether the study findings are generalizable for all patients with renal artery stenosis (e.g., patients who fail intensive medical therapy or have cardiovascular complications such as flash pulmonary edema) will continue to be debated. In general, however, CORAL reinforces prior data to support the use of medical therapy for most patients with renal artery disease.

In those patients in whom intervention is necessary, angioplasty has become the procedure of choice. The patency rate after angioplasty is strongly dependent on

the size of the vessel treated and the quality of inflow and outflow through that vessel. Previously, a solitary or transplanted kidney was considered a contraindication for renal angioplasty; however, this is no longer the case, and angioplasty is now considered the procedure of choice for treatment of RAS in these patients. Technical success is achieved in >90% of patients, and patency rates are 90% to 95% at 2 years for fibromuscular disease and 80% to 85% for atherosclerosis. Restenosis requiring repeat angioplasty has been reported in fewer than 10% of patients with fibromuscular disease and in 8% to 30% with atherosclerotic stenosis. Improvement in BP control with fewer antihypertensive medications is achieved in 30% to 35% of fibromuscular lesions and in 50% to 60% of atherosclerotic lesions. Surgical revascularization is reserved for patients in whom the main renal artery appears completely occluded and in whom the surviving renal parenchyma is vascularized by collaterals. Surgical revascularization might also be used when an ostial stenosis is present with a buttressing atheroma on either side of the ostium. Several surgical options are available. The stenotic segment may be excised and the artery resutured directly onto either the aorta or surviving stump. A vein graft may be transplanted, or the kidney resected and reimplanted in the iliac fossa with the renal artery anastomosed to the iliac artery.

## Acknowledgment

The authors and editors gratefully acknowledge the contributions of Dr. Ajay K. Singh for an earlier version of the chapter published in the 2nd edition.

## Chapter Review

### Questions

- An anxious 39-year-old white male is seen in the clinic for a routine physical. He is noted to have a BP of 160/95 mm Hg and a heart rate of 72 beats per minute, but his examination is otherwise unremarkable. What should you do next?
  - Work him up for renovascular disease.
  - Check urine catecholamines.
  - Start him on losartan 50 mg/d.
  - Check serum aldosterone level.
  - Measure his BP again on two more occasions.
- A 52-year-old man presents with BP consistently >150/90 mm Hg and a history of chronic kidney disease. He does not have diabetes. You recommend to your patient:
  - An endocrine consultation
  - Hydrochlorothiazide (HCTZ) 12.5 mg daily, dosed orally
  - HCTZ 50 mg daily, dosed orally
  - Lisinopril 20 mg daily, dosed orally
  - Metoprolol 25 mg twice daily, dosed orally
- A 40-year-old woman who is G3/P2 and is at 34 weeks of gestation presents with a BP of 210/110 mm Hg and a seizure. What is the best way to control her seizure?
  - A loading dose of phenytoin
  - Treatment with diazepam
  - Treatment with amobarbital sodium
  - A loading dose of magnesium sulfate
- A 42-year-old man presents to you for management of his newly diagnosed hypertension. On several measurements in the clinic and at home, his BP has been documented in the 150–155/90–95 mm Hg range. He is not on any medications except for tadalafil (Cialis) for erectile dysfunction (ED). His physical examination is normal. Considering his ED, which one of the following drugs would be least likely to cause ED?
  - HCTZ
  - Metoprolol
  - Clonidine
  - Lisinopril

5. A 25-year-old white female is diagnosed with fibromuscular disease as the cause for her hypertension. The most likely finding on her angiogram corresponding to this diagnosis will be:
- An ostial lesion of her right renal artery
  - A string-of-beads appearance unilaterally in the proximal one-third of the right renal artery
  - A string-of-beads appearance bilaterally in the distal one-third of her renal arteries
  - Distal arterial disease in smaller intrarenal branch vessels

## Urinalysis

KENNETH LIM, THEODORE I. STEINMAN, AND LI-LI HSIAO

Urinalysis is an integral part of the initial evaluation of renal and urinary tract disease. It may also provide an indication of the presence of systemic disease affecting the kidneys. Analysis of the urine should consist of three parts: (1) examination of the physical properties of urine; (2) examination of the chemical properties by dipstick urinalysis; and (3) microscopic examination of the sediment.

### Practical Aspects to Specimen Collection

Techniques used in the collection and laboratory handling of urine are crucial to the accurate interpretation of urinalysis findings. A midstream specimen is required in both men and women. In addition, to avoid contamination with vaginal secretions in women, it is usually recommended that the external genitalia should first be cleaned; however, this has no proven benefit, and one study has found that contamination rates were similar in specimens collected with and without prior cleansing (32% vs. 29%). Urine may also be collected via a bladder catheter or suprapubic bladder puncture, and in both circumstances a fresh sample should be obtained where possible.

In certain situations, a 24-hour urine collection can be helpful diagnostically, particularly in the assessment of proteinuria in both preeclampsia and in various proteinuric renal disease. A 24-hour urine collection can be performed to assess for daily total protein or albumin excretion, as well as to assess urine electrolytes. A benefit of this collection is the estimation of the glomerular filtration rate from the creatinine clearance if creatinine is measured. The 24-hour urine collection is begun when the patient wakes up in the morning. At that time, the first void is discarded, and all subsequent urine voids are collected. The last void is collected in the morning 24 hours after the first void was collected. Usually, no preservatives are needed for this type of urine collection, and the sample can be kept at room temperature for no longer than 48 hours. The adequacy of the collection can be assessed by quantifying the 24-hour urine creatinine excretion, which is a function of muscle mass. In females, the 24-hour urine creatinine excretion should be between 15 and 20 mg/kg using prepregnancy body weight. In males,

the 24-hour urine creatinine excretion should be between 20 and 25 mg/kg.

Examination of the urine should occur within 2 hours after collection. Delays of >2 hours result in the accumulation of ammonia from the breakdown of urea; the higher pH dissolves casts and promotes cell lysis causing inaccurate sediment examination. Refrigeration of specimens at +2°C to +8°C can preserve urine for up to 8 hours; however, this may allow precipitation of phosphates or urates. When storage of urine is necessary, preservatives can be used to fix the formed elements of urine and include formaldehyde, glutaraldehyde, “cellFIX,” and lyophilized borate-formate sorbitol powder.

### Physical Properties of Urine

Important diagnostic information can be gained by the physical appearance of urine with the naked eye (Tables 66.1 and 66.2).

### Chemical Properties of Urine

#### Specific Gravity

Specific gravity defines the number and weight of dissolved particles and can be measured using an ionic reagent strip. The urine specific gravity provides an indication of the amount of free water present in relation to the amount of solute. Normal urine specific gravity can range from 1.003 to 1.030. A low specific gravity may be observed in diabetes insipidus or following heavy water ingestion; a high specific gravity can occur with excess solute excretion (i.e., in some cases of glycosuria) and volume contraction/dehydration. Abnormally high values can occur in the presence of hyperosmolar osmotic agents (i.e., contrast agents).

#### Urine pH

Urine pH can be evaluated using a dipstick with a mixed pH indicator that detects urine pH between 5 and 8.5. A pH meter with a glass electrode can provide a more accurate measurement and can detect a wider range of pH values.

**TABLE 66.1** Physical Properties of Urine: Clarity and Color

	Pathologic Causes	Other Causes
Cloudy/turbid	In presence of amorphous calcium phosphate crystals (occurs only in alkaline urine), pyuria, chyluria, lipiduria, hyperoxaluria	Purine-rich foods (hyperuricosuria)
<b>Discoloration</b>		
Red	Hematuria, hemoglobinuria, myoglobinuria, porphyria	Beets, blackberries, rhubarb, phenolphthalein, rifampin (Rifadin)
Green or blue	Pseudomonas UTI, biliverdin	Amitriptyline, indigo carmine, IV cimetidine, IV promethazine, methylene blue, triamterene, propofol, motorcycle accident, intragastric balloon placement
Orange	Bile pigments	Phenothiazines, phenazopyridine
Brown or black	Bile pigments, melanin, methemoglobin	Cascara, levodopa, methylodopa, senna, blackwater fever, malaria infection from <i>plasmodium falciparum</i> .
Yellow	Concentrated urine	Carrots, cascara

IV, Intravenous; UTI, urinary tract infection.

**TABLE 66.2** Physical Properties of Urine: Odor

Odor	Pathologic Causes
Pungent	Bacterial urinary tract infections caused by production of ammonia
Fruity or sweet	Diabetic ketoacidosis
Musty or mousy	Phenylketonuria
Sweaty feet	Isovaleric acidemia
Rancid butter or fishy	Hypermethioninemia
Fecal	Gastrointestinal-bladder fistulas
Sulfuric	Cystine decomposition
Other	Medications (e.g., penicillin) and diet (e.g., asparagus, coffee) may also cause different odors to urine

Urine is usually in the pH range of 4.5 to 7.8, but because of metabolic activity, it is normally slightly acidic (i.e., 5.5–6.5). Urine pH generally reflects serum pH, except in patients with renal tubular acidosis (RTA). A hallmark of RTA is the inability to acidify urine pH to <5.5 despite administration of an acid load or an overnight fast. Patients with metabolic acidosis, volume depletion, or those who consume large quantities of protein may present with more acidic urine. Patients with RTA as mentioned earlier (particularly of the distal segment), those infected with urea-splitting organisms (e.g., *Proteus*), and those consuming vegetarian diets may

present with more alkaline urine. Prolonged storage of urine with accumulation of ammonia from urea will also cause a high urine pH.

### Glucose

Glycosuria occurs when the filtered load of glucose exceeds the reabsorbing capacity of the tubules (i.e., 180–200 mg/dL). The dipstick test for glucose is dependent on the oxidation of glucose to gluconic acid and hydrogen peroxide by glucose oxidase. Hydrogen peroxide reacts with a chromogen such as potassium iodide to produce a colored product. Glycosuria can be observed in a number of conditions, including diabetes mellitus, Cushing syndrome, liver and pancreatic disease, and Fanconi syndrome. However, false-positive results can occur in the presence of levodopa, following ingestion of sodium hypochlorite (bleach; this is an example of an oxidizing detergent), and hydrochloric acid. False-negative results can occur in the presence of excess excretion of uric acid and ascorbic acid.

### Ketones

Ketone bodies are products of fatty acid metabolism that are normally not found in the urine. Acetic acid is detected using a sodium nitroprusside or nitroferricyanide and glycine reaction. Ketones are most commonly detected in diabetic and alcoholic ketoacidosis. They can also be observed in pregnancy, carbohydrate-free diets, starvation, vomiting, and strenuous exercise. False-positive results can occur when levodopa metabolites, free sulfhydryl groups, or highly pigmented urine is present.

**TABLE 66.3 Interpretation of Results of Urine Dipstick Test for Proteinuria**

0	Negative
Trace	15–30 mg/dL
1+	30–100 mg/dL
2+	100–300 mg/dL
3+	300–1000 mg/dL
4+	>1000 mg/dL

## Protein

Proteinuria is defined as urinary protein excretion of more than 150 mg per day. Microalbuminuria is defined as the excretion of 30 to 150 mg of albumin per day and is associated with an increased risk of progression to overt proteinuria (macroalbuminuria) and renal failure, particularly in diabetic patients, as well as an increased risk for all-cause and cardiovascular mortality, cardiac abnormalities, and cerebrovascular disease. In health, the glomerular capillary wall is permeable only to substances with a molecular weight <20,000 Da. Low-molecular-weight proteins once filtered are reabsorbed and metabolized by the proximal tubule cells. Urine dipstick tests provide an approximate quantification of urinary protein concentration on a scale of 0 to 4+ (Table 66.3). The urine dipstick test is sensitive to albumin but less sensitive to low-molecular-weight proteins such as beta-2-microglobulins and immunoglobulin light chains. Detection of protein by urine dipstick uses tetrabromophenol blue dye impregnated on paper as a pH indicator. Urine dipsticks do not detect positively charged light chains of immunoglobulins, and detection of these proteins requires the addition of sulfosalicylic acid. False-positive results may occur in the presence of highly alkaline urine that cannot be compensated by the dye's buffer.

Remember that the dipstick allows only a semiquantitative measurement of urinary protein concentration. Quantitative methods such as 24-hour urine protein collection, spot urine protein-to-creatinine ratio, urinary albumin evaluation, or albumin-to-creatinine ratio are required for further evaluation of persistent proteinuria. Evaluation for renal injury regardless of renal function should be made in patients with persistent proteinuria >2 to 3 g per day.

Proteinuria can be broadly classified as *selective* versus *nonselective* proteinuria, and a table of differential diagnoses is provided in Table 66.4. Orthostatic proteinuria generally occurs in patients age <30 years where proteinuria is typically <1 g per day. In suspected cases, an 8-hour overnight, supine urinary protein measurement should be <50 mg. The clinical approach to proteinuria identified on screening dipstick test should be tailored to identify existing renal damage and the potential for future injury to the kidney. A 24-hour urine protein collection together with serum creatinine should be obtained, along with microscopic examination of the urinary sediment.

## Summary of Key Points in Proteinuria

- Proteinuria is defined as >150 mg per day of urinary protein, and microalbuminuria is defined as the excretion of 30 to 150 mg of protein per day.
- Urine dipstick test is most sensitive to albumin and less sensitive to low-molecular-weight proteins.
- False-positive results may occur in highly alkaline urine.
- Quantitative methods such as 24-hour urine protein collection, protein-to-creatinine ratio or albumin-to-creatinine ratio should be considered for further evaluation of proteinuria.
- Random spot urine protein-to-creatinine ratio accurately estimates 24-hour total protein measurement. Sulfosalicylic acid can be used for dipstick-negative proteinuria to detect positively charged light chains of immunoglobulins.
- Presence of proteinuria indicates renal injury (see Table 66.4).
- In orthostatic proteinuria, suspected cases should be confirmed by an 8-hour overnight urinary measurement demonstrating <50 mg per day.

## Blood

Hematuria is defined by three or more red blood cells (RBCs) per high-power field. The presence of hematuria is always an abnormal finding and may result from renal or extrarenal causes (Fig. 66.1). The most benign form of hematuria is its appearance after vigorous exercise (in marathon runners), which disappears in 24 to 48 hours. The urine dipstick test detects the pseudoperoxidase activity of hemoglobin. The dipstick test has a sensitivity range of approximately 91% to 100% with specificity ranging from 65% to 99%. It is more sensitive to free hemoglobin and myoglobin than to intact erythrocytes. Hemoglobin detected on dipstick may occur as a result of hematuria, intravascular hemolysis, or myoglobinuria that can be secondary to conditions such as rhabdomyolysis. A positive result may also occur with lysis of erythrocytes on standing, an alkaline pH, or a low relative density (especially <1.010). When the dipstick test for hemoglobin is positive, microscopic sediment examination should be performed to distinguish hematuria from other causes, which is discussed in further detail later in this chapter.

## Summary of Key Points on Positive Dipstick for Blood

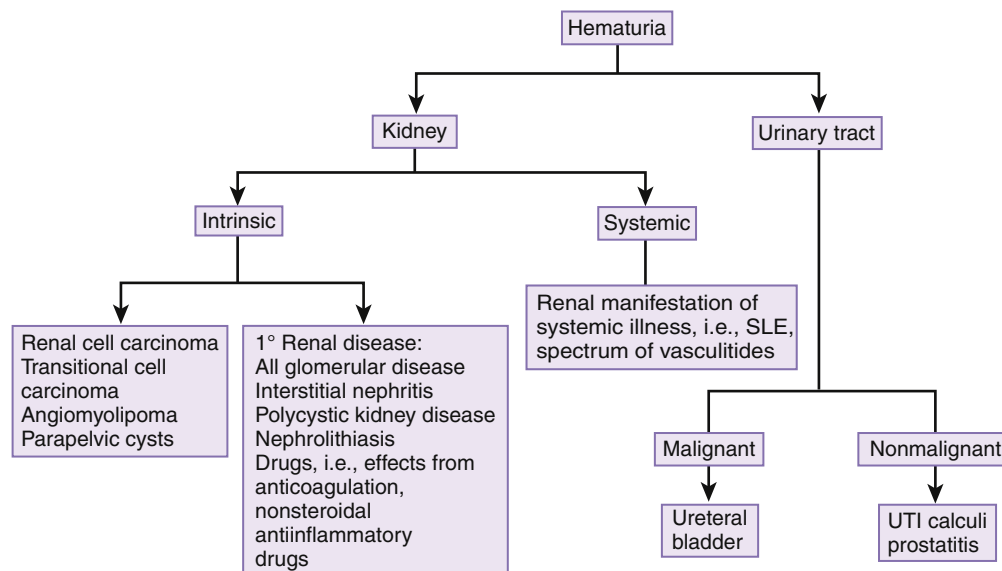

- Dipstick test is dependent on the pseudoperoxidase activity of hemoglobin.
- Dipstick test is more sensitive to free hemoglobin and myoglobin than to intact erythrocytes.
- It has sensitivity of 91% to 100% and specificity of 65% to 99%.
- Microscopic sediment examination should be performed in positive cases.

**TABLE 66.4** Differential Diagnoses of Proteinuria

	Glomerular Lesions		
	Selective	Nonselective	Other Causes
Differential diagnoses	MCD	FSGS, IgA nephritis, lupus nephritis, diabetic nephropathy	Polycystic kidney disease, pyelonephritis, rhabdomyolysis, hemoglobinuria, obstruction, vesicoureteral reflux, orthostatic, medications (i.e., chronic lithium exposure, analgesics, aminoglycosides), metabolic defects (i.e., oxalosis, cystinosis, hypercalcemia), trace metals (i.e., lead, mercury, cadmium)
Pathology	<ul style="list-style-type: none"> <li>• Predominantly albumin excretion, which is relatively innocuous</li> <li>• Interstitial infiltrates seldom develop despite heavy proteinuria</li> </ul>	<ul style="list-style-type: none"> <li>• Variety of proteins found in urine, including immunoglobulins (i.e., IgG) and complement components C5 to 9</li> <li>• Complement proteins enter tubular fluid and cause complement-mediated injury resulting in tubulointerstitial inflammation</li> </ul>

• **Fig. 66.1** Common differential diagnoses for hematuria. SLE, Systemic lupus erythematosus; UTI, urinary tract infection.

- Positive dipstick test may occur in hematuria, intravascular hemolysis, or myoglobinuria such as in rhabdomyolysis.
- Hematuria is defined as three or more RBCs per high-power field and is indicative of renal or extrarenal pathologies.

**Leukocyte Esterase and Nitrites**

The urine dipstick detects leukocyte esterase released from lysed neutrophils and is suggestive of pyuria associated with glomerular and/or interstitial inflammation or a urinary

tract infection. To accurately detect significant pyuria, the dipstick reagent strip should be allowed to sit for several minutes to allow a change in color. False-positive results can occur with granulocyte lysis in long-standing urine or glomerular epithelial cells that can contaminate the specimen. False-negative results may occur with hyperglycemia, albuminuria, tetracycline, cephalosporins, and oxaluria.

Bacteria produce nitrites by the reduction of urinary nitrates that can be detected by urine dipstick. This process occurs in the presence of many gram-negative and some gram-positive organisms. False-negative results can occur in the presence of ascorbic acid and high specific gravity. They

may also occur with low levels of urinary nitrate because of diet, prolonged storage of urine, and rapid transit of urine in the bladder. Urinary tract infection is more likely if both leukocyte esterase and nitrites are positive on dipstick examination. However, infection cannot be definitively ruled out if both tests are negative.

## Microscopic Examination

Microscopic examination of the urine sediment is a critical component of urinalysis. The identification of cells, casts, crystals, lipids, and organisms can yield important diagnostic information. Examination of urinary sediment provides clues to diagnosis and management of renal or urinary tract disease and to detection of metabolic or systemic disease not directly related to the kidney.

To prepare a urine specimen for microscopic analysis, this requires a fresh sample of urine to be collected as described previously. Ten milliliters of urine should be centrifuged at 1500 to 3000 rpm for approximately 5 minutes. The supernatant is then decanted and the sediment resuspended. A single drop is transferred to a clean glass slide, and a cover

slip is applied. All areas of the slide should first be scanned under brightfield low-power magnification for quantification of casts, crystals, and elements. High-power magnification under brightfield and phase-contrast microscopy can then be used to further delineate morphology and cellular structures.

## Cells

Erythrocytes, leukocytes, and epithelial cells are the three main types of cells found in urine in various pathologic conditions (Table 66.5; Figs. 66.2–66.4).

## Casts

The formation of casts occurs when proteins, predominantly Tamm-Horsfall protein secreted by cells of the thick ascending limb of the loop of Henle, trap cells, fat, bacteria, and other inclusions. These amalgamations are then excreted in urine (Table 66.6; Figs. 66.5–66.7). The predominant cellular elements determine the type of cast hyaline, granular, waxy, fatty, red cell, leukocyte, or epithelial (see Table 66.6).

• **Fig. 66.2** Erythrocytes in urinary sediments. (A) Isomorphic red blood cells (RBCs) are uniformly round, biconcave, and 7  $\mu\text{m}$  in diameter and have ample hemoglobin. These increased numbers are typically associated with lower urinary tract inflammation, 400 $\times$  magnification. (B) Dysmorphic RBCs in urine sediment; in glomerular hematuria, 4000 $\times$  magnification. (C) Erythrocytes under phase contrast; oil droplets.

• **Fig. 66.3** Leukocytes in urinary sediments. Polymorphonuclear leukocytes in which the lobed nuclei are readily evident (A, *arrow*, and B). These increased numbers may be associated with lower urinary tract infection or with renal disease affecting either tubules, interstitium, or the glomerulus, 400 $\times$  magnification.

• **Fig. 66.4** Epithelial cells in urinary sediments. (A) Squamous epithelial cells. (B) Transitional epithelial cells in the presence of bacteria (*arrow*).

## Crystals

Many crystals observed in urine are present as artifacts because of the precipitation of normally dissolved substances at room temperature. Several different types of crystals can be identified based on their morphology, appearance under polarized light, and measurement of urine pH (Table 66.7; Figs. 66.8–66.11).

## Lipids

Lipids may be identified free in the urine and within the cytoplasm of tubular epithelial cells or macrophages, where

they are known as oval fat bodies. Oval fat bodies are seen in nephrotic syndrome (Fig. 66.12).

## Organisms

When there is nonsterile handling of urine, bacteria can be observed in urine specimens (especially in females, representing genital contamination). When there is an inordinate delay of many hours before sediment examination, and an especially alkaline pH of the urine that has been sitting at room temperature, bacteria can begin to grow (Fig. 66.13). Gram-negative organisms, and gram-positive streptococci and staphylococci, can be distinguished by appearance

**TABLE 66.6** Microscopic Examination of Casts in Urine

Pathologic Causes and Description	
Hyaline (see Fig. 66.5A)	<ul style="list-style-type: none"> <li>• Can be observed under normal conditions, in concentrated acidic urine, and under various physiologic states, including strenuous exercise, dehydration, and febrile disease</li> <li>• Large numbers are frequently seen in congestive heart failure and minimal change disease nephrotic syndrome</li> </ul>
Granular (see Fig. 66.5B and C)	<ul style="list-style-type: none"> <li>• Formed from amalgamation of Tamm-Horsfall protein, debris of cells, and plasma proteins</li> <li>• Classification as finely or coarsely granular casts depends on how much digestion of debris has occurred within cast</li> <li>• Nonspecific causes and can be observed in a variety of glomerular or tubular diseases</li> <li>• In acute tubular necrosis, large numbers of muddy brown granular casts can be observed</li> </ul>
Waxy (see Fig. 66.6A and B)	<ul style="list-style-type: none"> <li>• Opaque, formed from degeneration of hyaline, granular, and cellular casts</li> <li>• Can be detected by light microscopy</li> <li>• Observed in CKD and have been reported as a frequent finding in rapidly progressive glomerulonephritis</li> </ul>
Fatty (see Fig. 66.6C)	<ul style="list-style-type: none"> <li>• Formed by lipid droplets</li> <li>• Frequently are doubly refractile (Maltese crosses)</li> <li>• Seen in nephrotic syndrome and mercury poisoning</li> </ul>
Red cell (see Fig. 66.7A)	<ul style="list-style-type: none"> <li>• Active glomerular injury and is a finding that signifies serious glomerular disease</li> <li>• Characteristic of proliferative extracapillary and endocapillary necrotizing glomerulonephritis</li> </ul>
Leukocyte (see Fig. 66.7B)	<ul style="list-style-type: none"> <li>• Reflects trapping of WBCs within a matrix of tubular proteins (must distinguish from WBCs appearing in clusters that have no distinct borders)</li> <li>• Observed in acute pyelonephritis, acute interstitial nephritis, and other interstitial inflammatory processes</li> <li>• More frequent observation in glomerulonephritis than RBC casts and reflect the degree of inflammation</li> </ul>
Renal tubular epithelial cell casts (see Fig. 66.7C)	<ul style="list-style-type: none"> <li>• Typically observed in acute tubular necrosis, acute interstitial nephritis, and less frequently in glomerular disorders</li> </ul>

CKD, Chronic kidney disease; RBC, red blood cell; WBC, white blood cell.

• **Fig. 66.10** Cystine, struvite, and amorphous crystalluria. (A) Cystine crystals are shaped like stop signs (hexagons). Cystine crystals are quite rare. (B) Struvite crystals (triple phosphate) look like rectangles, or coffin lids. (C) Amorphous phosphate crystals appear as aggregates of finely granular material without any defining shape.

under high-power magnification. Gram-staining, culture, and in vitro testing against antibiotics can help guide pharmacologic therapy in more complicated cases. Contaminants from genital secretions include organisms such as *Candida*, *Trichomonas vaginalis*, and *Enterobius vermicularis*.

### Urinalysis Patterns in Kidney Disease

Urinalysis findings are most diagnostically useful when results from individual components of the test are considered together. In many cases, certain combinations of urinary findings may be strongly suggestive of specific renal disorders.

#### Heavy Proteinuria With Fatty Casts or Bland Sediment

Nephrotic syndrome, which involves a urine protein excretion  $>3.5$  g per day, is of multiple etiologies, and

the urine sediment examination can provide clues to the underlying diagnosis. The terms *nephritic* and *nephrotic sediments* are used to define the factors causing the heavy proteinuria. Glomerulonephritis caused by an inflammatory reaction is characterized by numerous RBCs, white blood cells (WBCs) (often with one or both types of these cellular casts), other coarsely and finely granular casts, waxy casts, and renal tubular epithelial cells. The RBCs are often dysmorphic in appearance, and acanthocytes (which are glomerular in origin) can often be noted by careful examination of the dysmorphic RBCs (see later for further details). This active sediment is characterized as nephritic in origin. A paucity or absence of cells and/or cellular casts, but often with a large number of hyaline casts and lipid droplets (sometimes appearing as doubly refractile fat bodies), is denoted as a bland or nephrotic sediment and is a typical presentation of a noninflammatory glomerular disorder (i.e., idiopathic nephrotic syndrome).

• **Fig. 66.11** Microscopic appearance of drug-induced crystals. (A) Sulfonamide crystals are typically yellow in color and often resemble uric acid crystals. However, sulfa crystals are easily distinguished from uric acid by confirmatory tests. Sulfa crystals are readily soluble in acetone and exhibit a positive dextrine/sulfuric acid test (old yellow newspaper test). (B) Sulfadiazine crystals are a common finding with administration of trimethoprim-sulfadiazine. They are often seen as sheaves of wheat or radially striated spherules. (C) Indinavir crystalluria. (D) Indinavir crystals under polarized light.

• **Fig. 66.12** Lipids in urinary sediments. (A) Free fat in urine. (B) Oval fat body.

• **Fig. 66.13** Organisms present in urine. (A) Bacteria in the presence of transitional epithelial cells. (B) *Trichomonas* (arrow). (C) Budding yeast.

### Dysmorphic Red Blood Cells or Red Blood Cell Casts With Proteinuria

The constellation of dysmorphic RBCs and/or RBC casts with proteinuria is characteristic of nephritic syndrome. The presence of red cell casts is indicative of active glomerular injury and is a finding that signifies serious glomerular disease. However, it should be noted that the absence of these findings does not exclude glomerulonephritis. The presentation of RBC casts and/or dysmorphic red cells in any patient regardless of renal function or proteinuria should always be followed by an evaluation for glomerular disease. A large number of WBCs and WBC casts are often more common than RBCs/RBC casts in an active glomerulonephritis because it represents the intensity of the inflammatory reaction.

### Hematuria With Dysmorphic Red Blood Cells and Pyuria

Dysmorphic (varying in size and shape) RBCs, and with the presence of acanthocytes (RBCs with a spiked cell membrane, also known as spur cells following splenic modification), can indicate the severity of various renal pathologies. Differential diagnoses should include glomerular disease, tubulointerstitial nephritis, vasculitis, urinary obstruction, crystalluria, cholesterol embolization, and renal infarction.

### Isolated Hyaline Casts

Large numbers of isolated hyaline casts are almost always caused by a prerenal failure such as volume depletion or congestive heart failure (CHF). The greatest number of hyaline casts are most often seen in CHF. However, these casts can also be prominent in minimal change disease. A small number (no more than two or three per high-power field examination) can be seen in healthy individuals, especially in the face of a concentrated acidic urine, following strenuous exercise, and with a febrile illness. They are easily visualized under phase-contrast microscopy. Because hyaline casts are transparent, decrease the incident light on the microscope for best visualization of this type of cast. A very bright light on the stage of the microscope can wash out the transparent hyaline casts, and they can be missed in this circumstance.

### Isolated Hematuria With Monomorphic Red Blood Cells

This combination of urinary findings is usually suggestive of crystalluria, nephrolithiasis, or malignancies of the genitourinary tract. In rare cases, it may be suggestive of glomerular disease such as IgA nephropathy or thin basement membrane

disease. However, dysmorphic RBCs and the presence of RBC casts confirm the glomerular origin of the injury.

### Free Tubular Epithelial Cells, Epithelial Cell Casts, and Granular Casts

In the presence of acute renal failure, this constellation of urinary findings is indicative of acute tubular necrosis as a result of ischemia and/or administration of a nephrotoxin. In hyperbilirubinemia, these cells and casts can be found stained with bile in the urinary sediment, and a serum bilirubin >10 mg/dL will help confirm the diagnosis.

### Free White Blood Cells, White Blood Cell Casts, Granular Casts, and Mild Proteinuria

This constellation of urinary findings is indicative of tubulointerstitial disease, including pyelonephritis, drug-induced tubulointerstitial nephritis, and systemic disorders such as sarcoidosis. As mentioned earlier, a large amount of leukocytes and WBC casts can be seen in acute glomerulonephritis because the glomerular injury is an inflammatory reaction.

### Dipstick Urinalysis Screening

Chronic kidney disease (CKD) is a major public health problem. In 2004 approximately 500,000 Americans suffered from CKD stage 5, a number projected to reach 1.5 million by 2020. However, patient awareness of CKD remains extremely low; approximately 10% of patients with CKD stage 3 and 40% with CKD stage 4 are aware of their condition. Thus early detection of CKD is vital to help improve patient outcomes.

Studies have shown that fixed proteinuria is highly associated with CKD progression, and persistent proteinuria is associated with an accelerated risk of cardiovascular morbidity and mortality. Aggressive preventative measures should be used to reduce the extent of the proteinuria as much as possible because lowering protein excretion decreases the severity of the aforementioned complications. It is interesting to note that mandatory kidney disease screening with urine dipstick analysis has been conducted in Japan since the early 1970s. Despite its value, however, routine dipstick urinalysis for kidney disease screening is not currently used in the United States; this remains a controversial topic.

### Acknowledgments

The authors and editors acknowledge and express their deepest gratitude to Dr. Wendy Brown, Chief of Nephrology, at VA Hospital, Chicago, IL, and Dr. Robert Cohen at the Beth Israel and Deaconess Hospital, Boston, MA, for their generosity in providing the figures used in this chapter.

## Chapter Review

### Questions

- A 63-year-old female with a history of prior kidney stones and multiple episodes of urinary tract infections (UTIs) presents with dysuria, urinary frequency, urgency, and a complaint of foul-smelling urine. Urine culture results from her last UTI several months ago revealed *Morganella morganii*. On physical examination, her blood pressure (BP) is 120/80 mm Hg, heart rate is 60 beats per minute, temperature is 98°F, and cardiac and abdominal examination is benign. Her laboratory results reveal a creatinine of 1.2 mg/dL. Urinalysis reveals a pH of 7.2, WBCs 2+, positive leukocyte esterase, and no protein or hematuria. A CT scan revealed the presence of bilateral staghorn calculi. What is the most likely composition of her kidney stones?

  - Ammonium magnesium phosphate
  - Cystine
  - Calcium phosphate
  - Uric acid
- A 42-year-old woman presents to your office with a 4-week history of a petechial rash on her legs, gross hematuria, and edema. She relates a 2-year history of intermittent polyarthralgias. She is taking ibuprofen 600 mg twice daily for her joint pains. Physical examination is notable for mild periorbital edema, a BP of 164/88 mm Hg, heart rate 66 beats per minute, afebrile. Her lungs, cardiovascular examination, and abdominal examinations are normal. She has 3+ edema. Urinalysis shows a specific gravity of 1.020, pH 5.0, 4+ blood, 4+ proteinuria, and 1+ leukocytes, with the rest of the dipstick negative. Urine sediment examination shows 15 to 20 dysmorphic red cells. Her electrolytes are normal, blood urea nitrogen (BUN) 36 mg/dL, creatinine 1.8 mg/dL. The most likely finding diagnosis is:

  - A proliferative glomerulonephritis
  - A minimal change lesion
  - Acute interstitial nephritis from the ibuprofen
  - Kimmelstiel-Wilson lesions with nodular glomerulosclerosis
  - Analgesic nephropathy from exposure to ibuprofen
- A 67-year-old man presents with a 1-week history of anorexia, nausea, lassitude, and pedal edema. He provides a history of long-standing hypertension, well controlled with hydrochlorothiazide and amlodipine. Medications: fenoprofen for osteoarthritis of the hip for the past 3 months. On physical examination, the patient has a BP of 157/93 mm Hg, a heart rate of 72 beats per minute, and a temperature of 97.8°F. His jugular venous pressure is 8 cm, and he has normal cardiac and pulmonary examinations. He has 2+ pitting edema. Urinalysis shows a specific gravity of 1.017, protein 4+, 1+ blood, and negative for glucose. Microscopic examination of the sediment showed 2 to 4 erythrocytes and 15 to 20 leukocytes/hpf, and occasional granular casts. BUN 93 mg/dL, creatinine 7.8 mg/dL, sodium 137 mEq/L, potassium 4.4 mEq/L, chloride 95 mEq/L, carbon dioxide 21 mEq/L, calcium 9.2 mg/dL, phosphate 7.8 mg/dL, urinalysis 7.7 mg/dL, albumin 2.9 g/dL, hematocrit 29%. Antineutrophil cytoplasmic antibodies (–). Antinuclear (+) 1:40 titer, anti-double-stranded DNA antibody level 0. The 24-hour protein excretion 7.7 g. Renal ultrasound showed normal-sized kidneys bilaterally without obstruction. Three months previously his serum creatinine was 1.7 mg/dL. The nephrotic-range proteinuria and renal failure are most likely the result of which of the following?

  - Lupus nephritis
  - Multiple myeloma
  - Systemic small vessel vasculitis
  - Fenoprofen-induced nephrotic syndrome and interstitial nephritis
  - Renal vein thrombosis secondary to membranous nephropathy
- Match the type of urine structure with its corresponding appearance from Fig. 66.14:

  - Oval fat body
  - Red cell cast
  - Cystine crystal
  - Struvite crystal
  - Budding yeast

## Board Simulation: Nephrology and Hypertension

BRADLEY M. DENKER

### Questions

1. A 50-year-old white male with a history of essential hypertension suffered two transient ischemic attacks without permanent neurologic sequelae within the last 12 months. He is treated with lisinopril, 20 mg, and hydrochlorothiazide, 25 mg daily; office blood pressure (BP) is 140/85 mm Hg. A 24-hour ambulatory BP monitor is obtained. Which of the following statements about 24-hour BP monitoring is most accurate?
  - A. Cardiovascular risk correlates better with elevated office BP readings than with average 24-hour ambulatory BP results.
  - B. Normally there is a nocturnal dip in BP of at least 15%.
  - C. Higher ambulatory BP monitoring has not been associated with progressive renal disease and the development of end-stage kidney failure.
  - D. Dipping of nocturnal BP correlates with the day–night difference in heart rate.
  - E. Ambulatory BP monitoring can be used to distinguish true hypertension from “white-coat” hypertension.
2. A 55-year-old black male comes to the emergency department (ED) complaining of 2 days of blurred vision, headaches, and nausea. He has a history of hypertension but ran out of his medications about 2 weeks ago. He is awake and alert. BP is 220/120 mm Hg with no orthostatic changes. Fundoscopic examination shows bilateral hemorrhages and blurred optic disk margins. The remainder of the physical examination was notable only for an S4 gallop and the absence of edema. Laboratory studies revealed a creatinine of 2.5 mg/dL (was 1.2 6 months prior) and normal electrolytes. Which of the following therapies is most appropriate for initial management?
  - A. Sublingual nifedipine in the ED while awaiting an intensive care unit (ICU) bed
  - B. Intravenous (IV) enalaprilat
  - C. IV nitroglycerin
  - D. IV esmolol
  - E. Sodium nitroprusside
3. A 44-year-old white male with obesity (body mass index 32) and type II diabetes with hemoglobin A1c (HbA<sub>1c</sub>) 8.4% on oral agents is found to have urinary microalbumin/creatinine of 112 µg/g and is seen in your office for follow-up. His office BP is 160/100 mm Hg, but he is convinced that these elevations are secondary to white-coat hypertension. You ask him to obtain a home BP cuff and confirm its accuracy. He returns with home BP readings ranging from 135/85 to 160/90 mm Hg. In addition to lifestyle changes, which of the following anti-hypertensive strategies is recommended as initial therapy?
  - A. Hydrochlorothiazide 25 mg daily
  - B. Hydrochlorothiazide 50 mg daily with the addition of a beta-blocker within 2 weeks
  - C. Lisinopril 10 mg daily and then titrate up to 40 mg to maximize BP effects
  - D. Lisinopril 10 mg daily plus hydrochlorothiazide 25 mg and titrate to maximize BP effects
  - E. Calcium-channel blocker plus hydrochlorothiazide 25 mg
4. A 60-year-old black female is seen for the first time in many years. The family history is strongly positive for type 2 diabetes, and she is found to have a serum creatinine of 2.1 mg/dL, estimated glomerular filtration rate (eGFR) 29 mL/min/1.73m<sup>2</sup>, 1.5 g of protein/24 h, and HbA<sub>1c</sub> of 8%. A renal ultrasound shows 11-cm kidneys with echogenic cortex. Which of the following statements about the use of an angiotensin-converting enzyme (ACE) inhibitor in this patient is true?
  - A. Because her renal failure is advanced, there is no benefit in delaying progression of her chronic kidney disease.
  - B. Evaluate serum creatinine and serum potassium 1 month after initiating therapy.

- C. Evaluate serum creatinine and potassium 1 to 2 weeks after starting therapy, and discontinue the drug if creatinine increases by 10% over baseline.
- D. Evaluate serum creatinine and potassium 1 to 2 weeks after starting therapy, and discontinue the drug if creatinine increases by 10% over baseline or serum potassium is 5.0 mEq/L.
- E. Evaluate serum creatinine and potassium 1 to 2 weeks after starting therapy, and discontinue the drug if creatinine increases by >30% over baseline or hyperkalemia (>5.4 mEq/L) develops despite dietary counseling and the use of loop diuretics.
5. A 27-year-old male with AIDS is hospitalized with a cough, fever, and a pulmonary infiltrate on chest x-ray. Therapy is initiated with trimethoprim-sulfamethoxazole. On admission, the serum creatinine is 1.6 mg/dL, and blood urea nitrogen (BUN) is 21 mg/dL; on reexamination 3 days later, the serum creatinine is 2.2 mg/dL, and BUN is 23 mg/dL. Results of urinalysis both on admission and 3 days later are normal. Urine output on day 3 is 1350 mL. The most likely cause of the increased creatinine is:
- AIDS glomerulopathy
  - Trimethoprim-mediated decrease in creatinine secretion
  - Intratubular obstruction secondary to sulfonamide
  - Acute interstitial nephritis caused by trimethoprim-sulfamethoxazole therapy
  - Acute tubular necrosis secondary to sepsis
6. A previously healthy 42-year-old male becomes ill with fever (temperature 38°C), malaise, myalgias, and a sore throat. The next day, he describes gross hematuria and right flank pain. Urinalysis shows protein 3+ and red blood cells (RBC) casts. His BUN is 42 mg/dL, and serum creatinine is 1.8 mg/dL. Electrolytes are within normal limits. Serologic testing reveals normal complements, a normal immunoglobulin (Ig) A level, a 1:40 antinuclear antibodies, anti-DNA antibody level of 0, and negative antistreptolysin O, and antineutrophil cytoplasmic antibody titers. His antiglomerular basement membrane (anti-GBM) titers are also negative. Which of the following is the most likely diagnosis?
- World Health Organization class IV lupus nephritis
  - IgA nephropathy
  - Rapidly progressive glomerulonephritis secondary to granulomatosis with polyangiitis (Wegener granulomatosis)
  - Goodpasture syndrome
  - Poststreptococcal glomerulonephritis
7. Which of the following statements regarding torsemide is not true?
- Torsemide has a bioavailability higher than that of furosemide.
  - Similar to furosemide, torsemide is a loop diuretic.
  - Torsemide has a shorter half-life than furosemide.
  - Torsemide does not accumulate in renal failure.
  - Torsemide is less ototoxic than furosemide.
8. A 64-year-old female with coronary artery disease, multiple prior myocardial infarctions, and ischemic cardiomyopathy, with a left ventricular (LV) ejection fraction of 15%, presents to your office with 2 weeks of worsening dyspnea on exertion and paroxysmal nocturnal dyspnea. Her medications include aspirin, metoprolol, furosemide, spironolactone, digoxin, isosorbide dinitrate, and lisinopril. On examination, her BP is 97/54 mm Hg, pulse rate 85 beats per minute, jugular venous pressure (JVP) 9 cm, moist mucous membranes, lungs with diffuse inspiratory crackles, heart with an S3 gallop, and cool, clammy extremities with 1+ peripheral edema. Laboratories show serum sodium 128 mEq/L, potassium 3.6 mEq/L, chloride 87 mEq/L, bicarbonate 34 mEq/L, BUN 46 mg/dL, and creatinine 1.2 mg/dL. Serum osmolality is 262 mOsm/kg. Urine electrolytes (she last took her diuretic ~6 hours ago): urine sodium 15 mEq/L, urine chloride <5 mEq/L, and urine osmolality 220 mOsm/kg. Her hyponatremia is mostly explained by:
- Hypothyroidism
  - Excessive free water intake
  - Congestive heart failure
  - Renal failure
  - Addison disease
9. You are asked to consult on a 62-year-old black male with acute-on-chronic renal insufficiency secondary to diabetes mellitus ascribed to contrast nephrotoxicity. Routine chemistry laboratory data show a potassium level of 8.2 mg/dL. Which of the following electrocardiogram (EKG) changes is most likely to be observed before ventricular stand still (flat line)?
- Peaked T waves
  - Prolonged QRS
  - Flattened P wave
  - Sine-wave-appearing QRS complex
  - U wave
10. The most common type of kidney stone observed in the United States is:
- Cystine stone
  - Triple phosphate stone
  - Struvite stone
  - Calcium oxalate stone
  - Uric acid stone
11. A 48-year-old male with end-stage renal disease (ESRD) on hemodialysis for 8 years presents to the ED with a potassium count of 7.8 mEq/L and bicarbonate of 22 mEq/L. His EKG shows peaked T waves. Which of the following is the best next step for potassium elimination?
- Calcium gluconate 10 mL, IV
  - Kayexalate 30 g now and repeat in 4 hours

- C. IV hydrodiuril 500 mg followed by IV furosemide 200 mg
- D. IV bicarbonate 8.4%, 1 to 2 amps IV
- E. Emergent dialysis
12. A 42-year-old male 8 days post–bone marrow transplantation on treatment with FK506 (tacrolimus), among many other medications, is diagnosed with a type IV renal tubular acidosis (RTA). The feature that best distinguishes type IV RTA from other RTAs is:
- A. A urine pH of 5
- B. The presence of hyperkalemia
- C. A negative urine anion gap of 22
- D. A serum bicarbonate of 18 mEq/L
- E. A normal anion gap
13. The most common cause of mortality in patients in ESRD patients on chronic hemodialysis is:
- A. Hyperkalemia
- B. Infection
- C. Cardiac disease
- D. Severe acidosis
- E. Acute gastrointestinal bleeding
14. A 60-year-old male who has been previously in good health and on no medications develops nephrotic syndrome. No systemic causes are identified, and serologic workup is completely negative. The most likely histologic lesion on renal biopsy is:
- A. Light chain nephropathy
- B. Membranous glomerulopathy
- C. Myeloma kidney
- D. Membranoproliferative glomerulonephritis
- E. IgA nephropathy
15. A 26-year-old man is brought to the ED by paramedics after ingesting 200 tablets of 325 mg aspirin. On examination, he is tachypneic (respiratory rate 28 breaths per minute), heart rate 105 beats per minute, BP 130/74 mm Hg, and oxygen saturation 98% on room air. His salicylate concentration was 90.6 mg/dL. His initial arterial blood gases (ABGs) gave pH 7.49, partial carbon dioxide pressure (PCO<sub>2</sub>) 20 mm Hg, partial oxygen pressure (PO<sub>2</sub>) 95 mm Hg, and bicarbonate 16 mEq/L. His serum electrolytes initially are normal. He receives IV volume repletion with isotonic sodium bicarbonate and activated charcoal. However, within 1 hour of arrival to the ED the patient becomes delirious and has a generalized seizure. Two hours after arrival, salicylate concentration was 98.6 mg/dL. The next best step is:
- A. Oral *N*-acetylcysteine administration
- B. Hemodialysis
- C. Therapy with fomepizole
- D. Repeat the dose of activated charcoal, and induce vomiting with 30 mL of ipecac.
- E. Intubation and transfer to the ICU

### Answers

1. E. A 24-hour ambulatory BP monitoring will distinguish white-coat hypertension from true hypertension.

The definition of hypertension on ambulatory BP monitoring is defined based on the time of day:

A 24-hour average above 135/85 mm Hg

Awake average above 140/90 mm Hg

Asleep average above 125/75 mm Hg

Studies have confirmed elevated BP on 24-hour monitoring correlate with LV hypertrophy, progressive renal insufficiency, microalbuminuria, and cardiovascular and all-cause mortality. Similar associations are seen in patients who are nondippers (do not decrease asleep BP by at least 10%).

2. E. Sodium nitroprusside is the drug of choice in this patient with end-organ damage and hypertensive emergency. It should only be used as initial therapy because of the potential accumulation of cyanide, especially with reduced GFR. There is no role for sublingual therapy in this situation. IV esmolol is effective, especially in the setting of an aortic dissection, and IV nitrates are particularly useful in the setting of acute coronary ischemia but are less potent than sodium nitroprusside. IV enalaprilat should be avoided in this case because of the renal failure. It should also be avoided in acute myocardial ischemia. Labetalol is also an excellent therapy but should be avoided in patients with heart failure or bronchospasm.
3. D. The Eighth Joint National Committee (JNC 8) guidelines recommend an ACE inhibitor or an angiotensin receptor blocker (ARB). Because his BP is high, initiating him on two medications (but not with dual ACE inhibitor and ARB) when you see him would be reasonable. The BP goal, based on JNC 8, is <140/90 mm Hg.
4. E. There is no contraindication to initiating therapy with an ACE inhibitor or ARB in this case, and the literature supports benefit in delaying progression even with advanced renal disease. Inhibition of the renin-angiotensin system will lead to reduced glomerular capillary pressure and decreased GFR. This is the mechanism of lower proteinuria and less glomerulosclerosis over time. The expected decline in GFR is ≤30%, and if it remains stable, the therapy can be continued. If creatinine rises >30%, an investigation into bilateral renal artery stenosis should be considered. The effects on potassium are variable. The drugs should not be discontinued with mild hyperkalemia, especially before attempts are made to minimize the increase with dietary counseling and the use of loop diuretics.
5. B. Trimethoprim-sulfamethoxazole is associated with an elevation in serum creatinine, no change in BUN, and no other evidence of acute renal failure (ARF). Trimethoprim blocks tubular secretion of creatinine leading to elevated serum levels without a change in GFR. Clinical syndromes seen with trimethoprim-sulfamethoxazole include (1) allergic interstitial nephritis with fever, rash, and eosinophilia induced by the sulfamoiety; (2) hyperkalemia with salt wasting resulting

- from amiloride-like action of trimethoprim; and (3) rarely crystallization of sulfamethoxazole metabolite and intratubular obstruction or renal stone formation.
6. B. The presentation of this clinical syndrome of acute glomerulonephritis coupled with normal serologies highly suggests a diagnosis of IgA nephropathy, the most common glomerular disease worldwide. Poststreptococcal glomerulonephritis usually occurs approximately 2 weeks after the onset of a sore throat, and the negative serologies exclude the other potential causes.
  7. C. Torsemide is a loop diuretic. It has a higher bioavailability (80% vs. 50%) and longer half-life than furosemide (3 hours vs. 1 hour). Metabolism is mainly in the liver, unaffected by renal function. Torsemide does not accumulate in ARF, and consequently, in patients with renal failure, torsemide is less ototoxic than furosemide. In a healthy person, 15 to 20 mg torsemide = 40 mg furosemide. In ARF, give 100 mg torsemide. This is bioequivalent to 200 mg of furosemide.
  8. C. The initial approach to a patient with hyponatremia is to confirm hypoosmolar hyponatremia, and the low measured serum osmolality excludes pseudohyponatremia or osmotic pull of water out of cells (hyperglycemia). Next, volume status, determined as hypovolemia, is a stimulus for antidiuretic hormone (ADH) secretion although hyponatremia will not develop in the absence of dilute fluid intake. This patient is hypervolemic based on edema, elevated JVP, and rales. The low urine sodium and chloride could be seen with volume depletion but is also seen in conditions of underfilled arterial circulation (decreased effective circulating volume) from congestive heart failure or cirrhosis. This patient does not have the syndrome of inappropriate ADH secretion. This condition can only be diagnosed in euvolemic patients (based on clinical examination and urine sodium >40 mEq/L) (Hoorn EJ, Zietse R. Diagnosis and treatment of hyponatremia: compilation of the guidelines. *J Am Soc Nephrol.* 2017;28(5):1340–1349).
  9. D. Sine-wave-appearing QRS complex is the last finding seen on the EKG before cardiac standstill. A U wave is seen in patients with hypokalemia. The typical EKG progression in the setting of hyperkalemia is peaked T waves (earliest) with shortened QT interval. Next, the PR becomes prolonged, and the QRS widens.
  10. D. In the United States, 75% of all kidney stones are calcium oxalate stones; 10% to 15% are uric acid stones; 15% to 20% struvite stones; and 1% cystine stones.
  11. E. Dialysis is the only effective treatment for potassium removal in this setting. Calcium gluconate does not affect potassium excretion but is important for stabilizing cardiac membrane potential. Kayexalate may be effective, but the response is not predictable and will take several hours. IV furosemide is not effective in a long-time hemodialysis patient with little or no residual renal function. Bicarbonate would not be necessary because the patient is not significantly acidotic. Furthermore, IV bicarbonate takes several hours to have its effect and has been shown to be less effective in promoting intracellular shift of potassium in patients on dialysis.
- Although a survey of 63 nephrology program directors advocated bicarbonate as first-line therapy (Iqbal Z, Friedman EA. Preferred therapy for hyperkalemia in renal insufficiency: survey of nephrology training program directors. *N Engl J Med.* 1989;320(1):60–61), its role is in fact quite controversial. In animal studies, IV bicarbonate has variable impact, whereas in human studies, infusion of sodium bicarbonate 400–600 mEq/L over 16 to 24 hours resulted in a modest 0.6 mEq/L reduction in potassium at 4 to 6 hours and 1.6 mEq/L reduction at 16 to 24 hours. Elements in the acute treatment of severe hyperkalemia include:
- Profile risk in patient: absolute value of potassium, presence of EKG changes, rate of rise
  - Stabilize myocardium: calcium gluconate, 10% solution, 10 to 20 cc IV bolus
  - Shift potassium into cells: regular insulin, 10 units + 50 cc 50% dextrose, IV bolus; albuterol (5 mg/mL), 10 to 20 mg, nebulized over 10 minutes; sodium bicarbonate
  - Remove potassium from body: kayexalate; acute hemodialysis against a low-potassium bath
12. B. Type 4 RTA is characterized by a urine anion gap that is positive, and the urine pH is typically <5.5 with hyperkalemia. Type I (distal) is usually seen with hypokalemia, and type II (proximal) serum potassium may be normal or reduced but not elevated. The metabolic acidosis is typically nonanion gap. These patients usually have either aldosterone resistance or deficiency. For selective aldosterone deficiency:
    - With low renin: hyporeninemic hypoaldosteronism (e.g., diabetic nephropathy): prostaglandin synthesis inhibitors (nonsteroidal antiinflammatory drugs)
    - With normal or high renin: normoreninemic hypoaldosteronism or hyperreninemic hypoaldosteronism in critically ill patients: ACE inhibitor, heparin therapy, cyclosporine, or tacrolimus (FK506)
    - For aldosterone resistance: in pseudohypoaldosteronism type I (infant's), pseudohypoaldosteronism type II (Gordon syndrome), or adult aldosterone hyporesponsiveness and renal insufficiency: spironolactone administration
  13. C. Cardiac causes are the most common cause of death in ESRD patients on hemodialysis, accounting for approximately 50% of the all-cause mortality. Risk factors include LV hypertrophy (presumably from anemia vs. hypertension vs. volume overload) and presence of hypertension (because of renal disease vs. sympathetic overactivity vs. volume overload). Underlying vascular disease is caused by traditional risk factors including

hyperlipidemia, hypertension, diabetes, smoking, and family histories in addition to nontraditional risk factors associated with ESRD (secondary hyperparathyroidism, anemia, oxidative stress).

14. B. The most common cause of a primary glomerular process in adults is membranous glomerulopathy (followed closely by focal segmental glomerulosclerosis). In children, the most common cause is minimal change disease. In adults, age-specific cancer screening is recommended to exclude membranous nephropathy as a paraneoplastic syndrome that can be the initial clinical presentation (Floege J, Amann K. Primary glomerulonephritides. *Lancet*. 2016;387(10032):2036–2048).
15. B. Although this patient does not present with some of the common earliest signs and symptoms of aspirin toxicity (nausea, vomiting, diaphoresis, and tinnitus with or without hearing loss), he does manifest other central nervous system (CNS) presentations: hyperventilation, agitation, and delirium, followed by convulsions (lethargy, stupor, and coma). A marked elevation in temperature is a sign of severe toxicity and typically preterminal condition. The hyperventilation and resulting respiratory alkalosis are because

salicylates stimulate the respiratory center in the brainstem. The respiratory alkalosis predominates initially, but ABGs may also reveal a mixed respiratory alkalosis and metabolic acidosis. Keys to management are (1) gastric decontamination with activated charcoal; this has shown to reduce the amount of active salicylate by 50% to 80%; (2) fluid replacement because salicylate toxicity can induce major fluid losses through tachypnea, vomiting, hypermetabolic state, and insensible perspiration; (3) urinary alkalinization with sodium bicarbonate because this results in enhanced excretion of the ionized acid form of salicylate (urine pH must be maintained at 7.5–8.0); (4) hemodialysis or hemoperfusion. Extracorporeal therapy is indicated when patients manifest with renal failure, acute decompensated heart failure, CNS abnormalities, severe acid–base or electrolyte imbalance, hepatic compromise with coagulopathy, acute lung injury, and/or a salicylate concentration >100 mg/dL.

Dialysis can be used to treat overdoses of methanol, ethylene glycol, isopropanol, lithium, mannitol, theophylline, acetaminophen, and aspirin. Dialysis is not useful in treating benzodiazepines, digoxin, dilantin, phenothiazines, and tricyclics.

# 68

## Nephrology Summary

AJAY K. SINGH

This chapter comprises a potpourri of topics that are important for the boards.

### Diabetic Nephropathy

Diabetic nephropathy (DN) is the leading cause of end-stage renal disease (ESRD) in Western societies and accounts for approximately 50% of the patients on renal replacement therapy in North America. DN is responsible for approximately 20% of all deaths in patients age >40 years. The prevalence of microalbuminuria is around 30% to 35% in both types of diabetes mellitus (DM). The risk factors for the development of DN include hyperglycemia, systemic hypertension, glomerular hypertension and hyperfiltration, proteinuria, cigarette smoking, hyperlipidemia, and gene polymorphisms affecting the activity of the renin-angiotensin-aldosterone axis. Other key facts are summarized in [Box 68.1](#).

### Clinical Features

Preclinically, patients may have asymptomatic glomerular hypertension and hyperfiltration causing an enlargement of the kidneys seen on ultrasound. With approximately 5 years of insult from glomerular hypertension and hyperfiltration, the kidneys start to develop microalbuminuria as an initial manifestation of the disease. [Fig. 68.1](#) shows an approximate timeline for the progression of DN in predominantly untreated patients. The microalbuminuria is clinically undetectable to the conventional dipstick test. Nephrotic levels of proteinuria, hypertension, and progressive loss of renal function may develop after about 5 to 10 years of microalbuminuria. DN usually presents itself in patients 12 to 22 years after the clinical diagnosis of DM. The disease is progressive in nature and eventually leads to chronic renal failure and ESRD in a significant proportion of patients. The course of the patients with type 2 DM will vary depending on whether they present late or are diagnosed late.

Approximately 25% of type 2 diabetics have microalbuminuria at the time of diagnosis, and 3% of newly diagnosed type 2 DM have clinically apparent nephropathy. The

majority of patients with type 2 DM have evidence of cardiovascular and hypertensive complications.

### Pathology

Three cardinal features of renal pathology are basement membrane thickening, accumulation of mesangial matrix (with or without Kimmelstiel-Wilson nodules), and vascular disease ([Fig. 68.2](#) and [Box 68.2](#)). In addition, there is frequently associated evidence of vascular disease. The renal pathologic changes are very similar in patients with type 1 or type 2 DN. In approximately 20% of biopsies there is a superimposed glomerular lesion with diabetic kidney disease being present in the background.

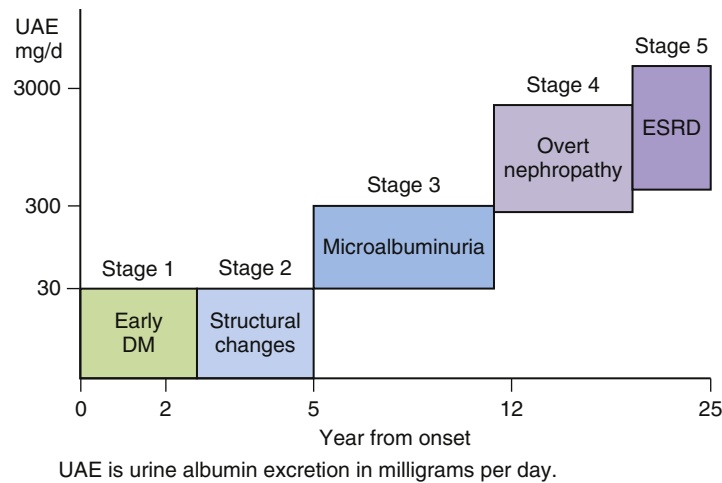

### Diagnosis

Patients with DN usually present with hyperglycemia, hypertension (systolic hypertension in particular), either microalbuminuria or proteinuria, and renal dysfunction. Microscopic hematuria may be seen but is unusual. In approximately 10% of patients, red cell casts in the urine sediment have been reported. Patients will frequently have evidence of other complications of DM, such as retinopathy, peripheral vascular disease, and a sensory neuropathy. Patients with more advanced DM may have the Charcot foot (increased warmth, erythema, swelling, absence of pain in the lower extremity or foot), diabetic ulcers, skin disease including acanthosis nigricans (darkening and thickening of certain areas of the skin especially in the skinfolds) or scleroderma diabeticorum (thickening of the skin on the back of the neck and upper back; [Fig. 68.3](#)).

#### • BOX 68.1 Key Facts on Diabetic Nephropathy

Most common cause of ESRD in West  
45% of all US patients with ESRD  
100,000 diabetics with ESRD in the United States  
Costs approximate \$10–16 billion/year  
Mortality of diabetic with ESRD is higher than nondiabetic  
Cardiovascular complications 4-fold to 8-fold higher in diabetic  
with renal disease than without renal disease

ESRD, End-stage renal disease.

• **Fig. 68.1** Approximate rates of progression in the different stages of diabetic nephropathy. *DM*, Diabetes mellitus; *ESRD*, end-stage renal disease; *UAE*, urine albumin excretion.

• **Fig. 68.2** Diabetic nephropathy. Picture shows the Kimmelstiel-Wilson lesions of nodular glomerulosclerosis, characteristic of diabetic renal disease. (From Helmut G. Rennke, MD.)

### • BOX 68.2 Pathologic Features of Diabetic Nephropathy

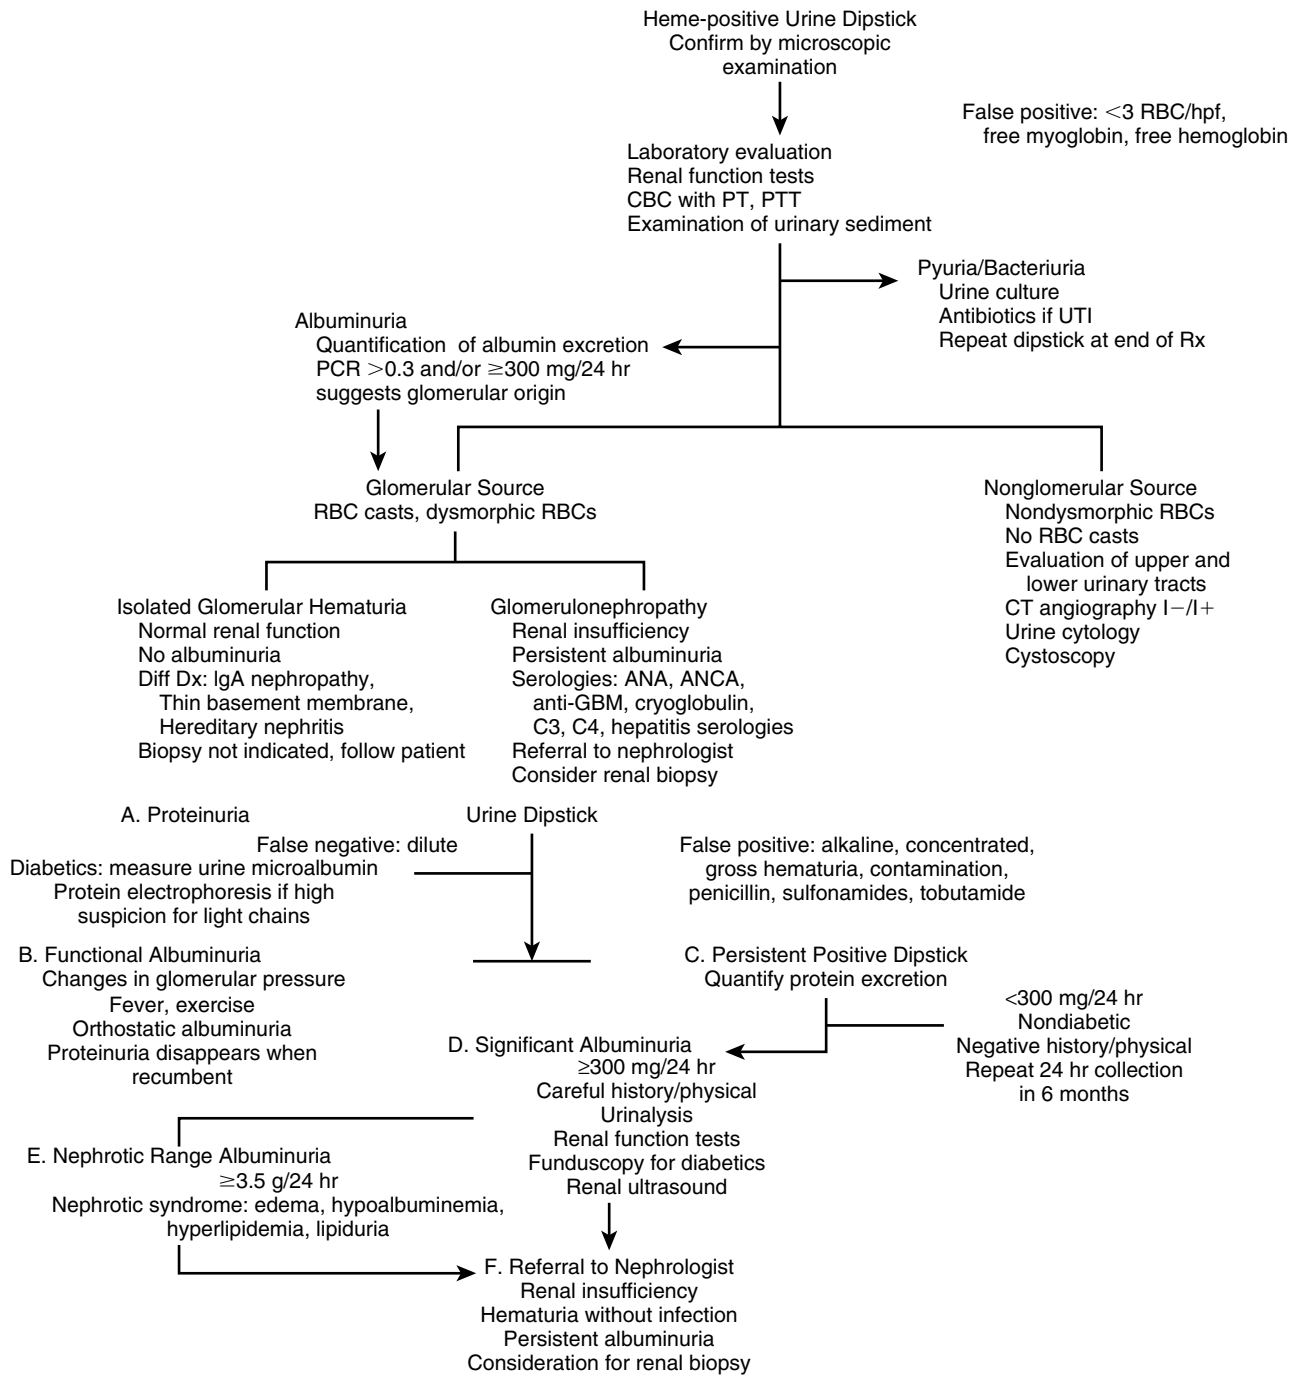

Expansion of mesangial matrix with diffuse and nodular glomerulosclerosis (Kimmelstiel-Wilson nodules)  
 Thickening of glomerular and tubular basement membranes  
 Arteriosclerosis and hyalinosis of afferent and efferent arterioles  
 Tubulointerstitial fibrosis

### Treatment and Prognosis

Treatment is summarized in [Box 68.3](#). Both the Diabetes Control and Complications Trial (DCCT) study for type 1 diabetics and the UK Prospective Diabetes Study (UKPDS) for type 2 diabetics demonstrate unequivocally that tight control of blood sugar (aiming for a hemoglobin A<sub>1c</sub> of <7%) is associated with reduced microvascular and macrovascular damage. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are drugs of choice because they control both systemic

hypertension and intraglomerular hypertension by inhibiting the actions of angiotensin II on the systemic vasculature and renal efferent arterioles. ACE or ARB inhibitors are effective in delaying the progression of the renal disease in patients with DM. Dual blockade (with both an ACE inhibitor [ACEi] and an ARB) should be avoided based on a higher rate of acute kidney injury and hyperkalemia reported in the NEPHRON-D study as well as results from the ONTARGET study.

The blood pressure target in patients with DN is evolving. The Joint National Committee 7 (JNC7) guidelines recommend a blood pressure target of <130/80 mm Hg using ACE inhibitors or ARBs as first-line therapy. However, these guidelines have now been replaced by JNC8, which recommends a blood pressure target of <140/90 mm Hg. The 2013 American Diabetes Association (ADA) guidelines reflecting results from the action to control cardiovascular risk in diabetes (ACCORD) study also recommends a less aggressive blood pressure target (<140/80 mm Hg) in diabetic patients (with or without kidney disease). In ACCORD, Cushman and colleagues randomized approximately 4700 subjects with type 2 DM at high risk for cardiovascular events, to a systolic blood pressure (SBP) of <120 mm Hg, as compared with <140 mm Hg. The study reported that there was no difference in the rate of a composite outcome of fatal and nonfatal major cardiovascular events, but the rate of adverse events such as electrolyte abnormalities, elevated creatinine, and hypotension was three times more common among those assigned to the lower blood pressure goal. However, the ADA guidelines note that a lower systolic target (<130 mm Hg) may be appropriate in certain patients if tolerated. Blood pressure control in patients with diabetic kidney disease frequently requires more than one drug to control blood pressure; consequently, diuretics, long-acting calcium channel blockers (CCBs), and beta-blockers are reasonable adjuncts. Other important interventions in DN that should be considered are dietary protein restriction (0.8 g/kg/d of protein) as

**Hypocomplementemia in Glomerular Disease**

### • BOX 68.3 Treatment Strategy for Diabetic Nephropathy

#### Lifestyle Changes

- Lose weight
- Stop smoking
- Low-salt diet for blood pressure control

#### Optimize Glycemic Control

- Benefit in both type 1 and type 2 patients
- Recommended:  $HbA_{1c} < 7\%$

#### Optimize Hypertension Management

- JNC8 recommends  $< 140/90$  mm Hg; 2013 ADA guidelines recommend  $< 140/80$  mm Hg
- Use ACE inhibitors or ARBs, even if normotensive
- If intolerant of ACE inhibitors use ARBs or vice versa

#### Low-Protein Diet (Controversial)

- Protein restriction to 0.8 mg/kg/d once CKD develops

ACE, Angiotensin-converting enzyme; ADA, American Diabetes Association; ARBs, angiotensin receptor blockers; CKD, chronic kidney disease;  $HbA_{1c}$ , hemoglobin A<sub>1c</sub>; JNC8, Eighth Joint National Committee.

recommended by the ADA, cessation of smoking, and control of lipids. A target low-density lipoprotein of 100 mg/dL is recommended by recent American Heart Association/American College of Cardiology guidelines. Incretin-based therapies, glucagon-like peptide (GLP-1) agonists and dipeptidyl peptidase 4 (DPP-4) inhibitors, and the sodium-glucose cotransporter 2 (SGLT2 inhibitors) have all emerged as important agents to consider in patients in the step-wise approach (metformin plus sulfonylurea and/or thiazolidinedione and/or DPP-4 and/or SGLT2 and/or GLP-1 inhibitor and/or insulin) to glycemic management recommended by the ADA ([American Diabetes Association, 2016](#)).

## Hypertensive Nephropathy/ Nephrosclerosis

Hypertension affects the majority of the US population. By the age of 60 years, over 50% of the US population will be hypertensive (defined as having a repeatedly elevated blood pressure of  $\geq 140/90$  mm Hg). The causes are many and include idiopathic or secondary factors. Secondary factors include renal disease, endocrine causes such as Cushing disease and hyperparathyroidism, hypercalcemia and pheochromocytoma, and primary hyperaldosteronism. Vascular causes include renovascular disease. Hypertension can result from renal failure; studies suggest that in stage 4 chronic kidney disease (CKD), over 75% of patients have evidence of hypertension. Less commonly, renal failure can result from hypertension.

Renal disease caused by chronic hypertension is seen primarily in the black population with a ratio of 8:1, but it can be observed in whites as well. Approximately 5% of patients

have accelerated or malignant hypertension (diastolic pressure  $> 120$  mm Hg), which may be associated with renal failure, retinal hemorrhages, and exudates, with or without papilledema.

### Clinical Features

Patients with renal disease secondary to hypertension usually describe a long antecedent history of hypertension that is evidenced by a slow rise in blood, urea, nitrogen (BUN), and creatinine. Retinopathy and left ventricular hypertrophy will be present in a majority of these patients. Depending on the severity of the renal damage, there may be either microalbuminuria or overt albuminuria. The risk for hypertensive renal disease is increased among individuals of black race, those with underlying renal disease, and those with chronically elevated blood pressure. Benign hypertensive nephrosclerosis is the most common clinical presentation.

### Pathogenesis

The vascular response to hypertension is intimal thickening with medial hypertrophy and resultant luminal narrowing. This response minimizes the pressure variations in the arterioles and capillaries. With chronicity, the autoregulatory mechanisms of the arterioles fail, and vascular damage ensues. This results in increased permeability, platelet deposition, and deposition of hyaline-like material in the damaged vessels, leading to a permanent lesion of fibroelastic hyperplasia and fibrinoid necrosis. Often hyaline arteriosclerosis accompanies these changes. Plasma renin, secreted by the kidney in the presence of vascular compromise, is markedly elevated. A self-perpetuating cycle of increasing angiotensin II/intrarenal vasoconstriction becomes established, leading to ischemia and renin secretion. The influence of increased levels of vasoconstrictors (e.g., endothelin) and decreased levels of vasodilators (nitric oxide) may also contribute to vasoconstriction. Aldosterone levels are also elevated, and salt retention undoubtedly contributes to the elevation of blood pressure. The increased incidence in the black population is attributed to poorly defined environmental and genetic factors. Often hypertension in blacks is not associated with high renin secretion.

### Pathology

Hypertensive nephropathy may involve the glomerulus, the vessels, and the tubulointerstitial tissue. In patients with advanced disease, there may be marked nephron loss in the injured portions of the kidney with hypertrophic enlargement of the remaining segments. The entire glomerular tuft may be involved in a focal segmental fashion or a global segmental fashion. Tubular atrophy may be similar to an ischemic type of renal injury. With severe disease, a chronic interstitial nephritis with hyperplastic arteriolitis (onion-skinning), fibrinoid necrosis of arterioles, and necrotizing glomerulitis is apparent.

## Diagnosis

A detailed history and the clinical presentation are usually sufficient for the diagnosis. In severe cases, patients may have papilledema, retinopathy, encephalopathy, and cardiovascular abnormalities. Urinalysis may show nonnephrotic-range proteinuria. A renal biopsy is rarely indicated.

## Treatment and Prognosis

Patients who present with hypertension should always be evaluated for reversible causes of hypertension. The goal of treatment is aimed at normalizing the blood pressure. The JNC8 guidelines published in 2014 made substantial changes to the JNC7 guidelines. Key recommendations include the following:

- For patients age >60 years, the SBP goal should be <150 mm Hg.
- For patients with hypertension and DM regardless of age, pharmacologic treatment should be initiated when blood pressure is >140/90 mm Hg.
- Initial antihypertensive treatment should include a thiazide diuretic, CCB, ACE inhibitor, or ARB in the general nonblack population or a thiazide diuretic or CCB in the general black population.
- If the target blood pressure is not reached within 1 month after initiating therapy, the dosage of the initial medication should be increased, or a second medication should be added.

It is likely that the systolic blood pressure intervention trial (SPRINT) published in 2015 will result in a change of the JNC8 guidelines. In SPRINT, 9361 subjects age >50 years were randomized to either intensive treatment (SBP <120 mm Hg) or standard treatment (SBP <140 mm Hg). The trial reported a significant reduction in the intensive arm of the primary composite endpoint of myocardial infarction, other acute coronary syndromes, stroke, heart failure, or death from cardiovascular causes. Remarkably, there was also a significant 25% reduction in all-cause mortality in the intensive-treatment group.

## Cystic Diseases of the Kidney

Simple renal cysts are common, occurring in 50% of patients age >50 years.

The widespread use of ultrasonography and CT scan has led to an increased detection of simple cysts. Ultrasound criteria for the classification of simple renal cyst include (1) spherical or ovoid shape; (2) absence of internal echoes; (3) presence of a thin, smooth wall that is separate from the surrounding parenchyma; and (4) enhancement of the posterior wall, indicating ultrasound transmission through the water-filled cyst. If these criteria are satisfied and the patient is asymptomatic, no further evaluation of the cyst is necessary because the likelihood of a malignancy is very small. Symptomatic patients with the same ultrasound findings should undergo CT scanning with contrast. The

gold standard for evaluating renal masses requires CT images <5 mm in thickness before and after contrast is given. The criteria for diagnosing a benign cyst on CT scan include (1) a homogeneous attenuation value near that of water, (2) no enhancement with intravenous contrast material, (3) no measurable thickness of the cyst wall, and (4) smooth interface with renal parenchyma. MRI is typically used to evaluate patients with indeterminate lesions. MRI does not detect calcifications. The suspicion for malignancy should be raised if the benign criteria are not met, calcification is present within a cyst, or repeat studies show an enlarging lesion. CT has a sensitivity of 94% for detection of renal parenchymal masses, but MRI is statistically superior to CT in the correct characterization of benign lesions. If a cyst meets the criteria for being benign, periodic reevaluation is the standard of care. If the lesion is not consistent with a simple cyst, surgical exploration is recommended.

Acquired renal cystic disease occurs in as many as 90% of patients who receive dialysis for 5 to 10 years. The cysts develop as a consequence of chronic renal insufficiency and may be clinically apparent long before dialysis is instituted. Malignancy and metastases can develop in a small percentage of cases. Screening of all dialysis patients by renal ultrasound is recommended after 3 years of dialysis at 1-year to 2-year intervals. Major clinical manifestations of acquired cystic disease include flank pain and hematuria in association with rupture of hemorrhagic cysts into the urinary tract or into the perinephric region. Cysts often resolve after successful renal transplantation.

## Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common renal hereditary disease and affects 1 in 400 to 1000 live births. ADPKD is usually recognized in adults between the third and fourth decades of life. Adult polycystic kidney disease (PKD) causes renal insufficiency in 50% of individuals by the age of 70 years, and it accounts for 10% of dialysis patients in the United States. ADPKD is caused by a defective *PKD1* gene on chromosome 16p in 85% of cases. A positive diagnosis requires (1) at least two cysts (unilateral or bilateral) in patients age <30 years; (2) at least two cysts in each kidney in patients age 30 to 59 years; or (3) four or more cysts in each kidney in patients age >60 years. These age-specific data have been developed in reference to PKD1 patients. Pathology of ADPKD is characterized by massive enlargement of the kidneys secondary to cyst growth and development. The liver also contains cysts in about 40% of patients with ADPKD. Arterial aneurysms of the circle of Willis are found in about 10% of patients. Diagnosis by ultrasound is straightforward in advanced disease, but it may be less reliable in the early stages. CT and MRI are more informative, and genetic testing may be required when greater certainty is needed for ADPKD diagnosis.

There has been substantial progress in the past 5 years on the approach to managing the progression of ADPKD. The target blood pressure in ADPKD patients has been explored in the HALT-PKD trial. In early ADPKD, Schrier and colleagues conducted a 2×2 factorial design trial of a standard blood pressure target of 120/70 to 130/80 mm Hg versus a low blood-pressure target of 95/60 to 110/75 mm Hg and lisinopril (ACEi) alone versus the combination of lisinopril and telmisartan (ACEi+ARB). They reported that intensive lowering of blood pressure (rather than the use of ACEi alone versus ACEi+ARB) was associated with a slower increase in total kidney volume, a greater decline in the left-ventricular-mass index, and greater reduction in urinary albumin excretion. However, intervention did not significantly alter the rate of increase in total kidney volume or result in an overall change in the estimated glomerular filtration rate (GFR). Torres and colleagues in studying patients with more advanced ADPKD (as a part of the HALT-PKD program) reported that there was no significant difference between the study groups in the incidence of the composite primary outcome of time to death, end-stage renal disease, or a 50% reduction from the baseline estimated GFR. Collectively, this suggests that more aggressive blood pressure treatment in patients with early ADPKD should be considered.

The vasopressin V2 receptor antagonist, tolvaptan, has also demonstrated much promise, although its use was associated with liver function abnormalities in treated patients. The European Renal Association–European Dialysis and Transplant Association (ERA-EDTA) Working Groups on Inherited Kidney Disorders and European Best Practice recommend treating ADPKD patients with early disease (CKD stages 1–3a) who have rapidly progressing disease.

### Medullary Cystic Kidney Disease

Medullary cystic kidney disease is a rare autosomal dominant cystic disease characterized by normal- to small-sized kidneys. When cysts are found, they are located at the corticomedullary junction and in the medulla. Diagnosis relies on clinical features with a thorough family history. CT is the most sensitive test for cyst detection. The first signs are inability to concentrate the urine and salt wasting, leading to polyuria and polydipsia. Medullary cystic disease progresses inevitably to ESRD by the age of 20 to 40 years. Transplantation is the treatment of choice.

### Medullary Sponge Kidney

Medullary sponge kidney is usually not diagnosed before the fourth or fifth decade of life, when patients have secondary calcifications with passage of urinary stones or frequent urinary tract infections. This is a benign disorder with incidence of 1 in 5000 in the general population. The diagnosis is made by intravenous urography, which shows irregular enlargement of the medullary and interpapillary collecting ducts bilaterally. There is no specific therapy for medullary sponge kidney disease. The patient should be able to excrete

over 2 L of urine a day and may benefit from a thiazide diuretic for hypercalciuria, allopurinol for hyperuricosuria, or potassium citrate for hypocitraturia.

### Renal Cell Cancer

Renal cell cancer occurs at a rate of 7.5 cases per 100,000 population annually. It accounts for >80% of renal malignancies in adults and occurs more frequently in men. Risk factors for renal cell carcinoma are smoking, chemicals such as cadmium and nitrosohydrocarbons, acquired cystic disease in ESRD, and von Hippel-Lindau disorder. Patients may present with hematuria, abdominal mass, flank pain, fever, weight loss, or varicocele, but many patients are asymptomatic until the disease is advanced. Laboratory findings include anemia or erythrocytosis, hepatic dysfunction, and hypercalcemia. CT with radiographic contrast is currently the most widely available, sensitive, and accurate nonoperative method available for making a presumptive diagnosis of renal cancer and its staging. MRI is used over CT when detecting tumors in regional lymph nodes and extension into the renal veins and inferior vena cava; in patients with radiographic contrast allergy; and when CT results are equivocal. For patients without distant metastases the treatment of choice is radical nephrectomy. The average survival of patients with metastases is only 6 to 9 months. Postoperative adjuvant radiation, hormonal therapy, and chemotherapy are not proven to prolong survival.

### Kidney Stones

Kidney stone disease is a common cause of morbidity in the Western world. It affects 10% to 20% of the population and leads to hospitalization in 1 in 1000 individuals each year. More than 80% of kidney stones occur in white males, who have a lifetime risk of stone formation approximating 20%. In contrast, the lifetime risk in white females is much lower—approximately 5% to 10%. There is also clear racial preponderance of stone disease among whites; blacks have an incidence rate of stone disease that is 25% that of whites. The peak age of onset for kidney stone formation is 20 to 30 years. However, there is a high recurrence rate—as high as 50% in 5 years among white males.

Kidney stones form in the renal tubule or collecting duct and arise when urine is supersaturated with insoluble materials. The nidus is usually a crystal or foreign object. Seventy-five percent of stones are primarily composed of calcium phosphate or calcium oxalate, 10% to 20% are struvite stones, 5% urate, and 1% to 2% cystine. Kidney stones can be found throughout the length of the urinary tract system. Symptoms depend on the type, location, and duration of kidney stones. Patients may be asymptomatic or have renal colic, hematuria, dysuria, frequency, or urinary tract infections. Symptoms associated with renal failure may arise when patients suffer from large staghorn calculi that impair renal function. The incidence and prevalence of kidney stones vary by region, age, sex, and race, but approximately 5% of American women and

12% of men will develop stones in their lifetime. The goals of management are to treat complications and symptoms, remove any stones, and prevent recurrences.

The clinical presentation varies depending on the location, size, and number of stones. The majority of kidney stones occur in the upper tracts. The most common presentation is renal colic—that is, the sudden onset of severe pain due to the presence of an obstructive renal or ureteral stone. Renal colic is typically spasmodic in character, lasting several minutes, typically localized to the flank, and often radiating down to the groin. Nausea and vomiting frequently accompany renal colic. Renal colic often occurs in the middle of the night or early morning while the patient is sedentary, and its severity has been described as akin to or worse than childbirth. The severity of pain is a common cause of patients coming to the emergency department. On the other hand, larger stones may present with painless obstruction or back pain. Stones that reach the ureterovesical junction often present with renal colic accompanied by urgency and frequency. Alternatively, stones located in the calyces may be completely asymptomatic. The general appearance of a patient with renal colic is of someone writhing in excruciating pain. Sometimes the patient presents with restlessness and pacing about the room. The presence of fever usually heralds an accompanying urinary tract infection. Otherwise the physical examination may be completely negative. The laboratory evaluation should comprise a complete blood count, blood chemistries including measurement of urea (BUN) and creatinine, and a urinalysis. The presence of a urinary tract infection, particularly with pyelonephritis, will be associated with a leukocytosis. An elevated BUN and creatinine would suggest dehydration and/or the presence of an obstructing stone in a patient with a single kidney or bilateral obstructing stones. The urine usually demonstrates hematuria and pyuria. Assessment of urine pH is critical because an acid urine with a radiolucent stone will suggest a uric acid

stone, whereas a very alkaline urine (pH >8) would suggest an infection with a urease-splitting organism (e.g., *Proteus*, *Pseudomonas*, and *Klebsiella* species). The initial radiologic workup should comprise of a kidney-ureter-bladder (KUB) radiograph and an ultrasound or a noncontrast CT scan.

## Management of Kidney Stones

The management of kidney stones can be divided into the management of the acute stone episode and, if the stone is nonobstructing, management of the prevalent stone medically and/or surgically and prevention of further stones. Management of the acute stone episode rests on optimal pain control using parenteral narcotic agents, hydration, and urologic consultation for potential removal of an obstructing stone. Medical management of a nonobstructing stone comprises increasing fluid intake to cause a urine output of >2 L/d, modification in diet, treatment targeted at changing urinary pH, and strategies to prevent further stones from forming. Surgical management depends on the size, location, and number of stones. Surgical options include extracorporeal shock wave lithotripsy (ESWL) and lithotripsy (percutaneous or transurethral). General rules of thumb are that cystine stones and calcium oxalate monohydrate stones are generally poorly broken up by ESWL, and percutaneous or transurethral lithotripsy for removal is favored. On the other hand, other calcium oxalate stones, struvite stones, and uric acid stones are generally amenable to ESWL, as well as to either percutaneous or transurethral routes for removal depending on the size and location of the stones.

## Acknowledgment

The author and editors gratefully acknowledge the contributions of Dr. Kuiylan Karai Subramanian for an earlier version of this chapter that was published in the 2nd edition.

## SECTION 7

# Digestive Diseases and Disorders of the Pancreas and Liver

# 69

## Esophageal Disorders

JOHN R. SALTZMAN AND KUNAL JAJOO

The diseases of the esophagus span a wide breadth of etiologies and symptoms at clinical presentation. Often, distinct etiologies can cause similar symptoms of esophageal dysfunction, thus complicating the diagnostic algorithm. A firm understanding of the anatomy and physiology of the esophagus and how symptoms correlate with pathophysiology will allow the clinician to effectively approach the diagnosis and treatment of patients with esophageal disorders.

### Esophageal Anatomy and Physiology

To understand the disorders of the esophagus, it is important to understand the basic anatomy and physiology of the esophagus. The esophagus is a tubular muscular structure that extends from the pharynx to the stomach. The esophagus serves as a passage for the transport of food, prevents the regurgitation of food and gastric contents from the stomach, and allows for the venting of ingested air to decrease bloating. At the proximal and distal ends of the esophagus are sphincter muscles that help control esophageal function and, in a coordinated manner, allow for swallowing. At the proximal margin is the upper esophageal sphincter that includes the inferior pharyngeal constrictor and cricopharyngeal muscles. The lower esophageal sphincter (LES) is a 2- to 4-cm-long, high-pressure segment of smooth muscle that is tonically contracted at the distal margin of the esophagus and is located within the diaphragmatic hiatus.

The primary muscle layer of the esophagus (*muscularis propria*) is comprised of both skeletal and smooth muscle, depending on the location. In the proximal third of the esophagus, the *muscularis propria* is skeletal; in the lower two-thirds it is primarily smooth muscle. Acetylcholine is the mediator released by excitatory neurons, which controls contraction of muscles and esophageal peristalsis. Nitric oxide is released by neurons predominantly in the distal esophagus and serves in an inhibitory capacity.

### The Symptoms of Esophageal Disease

Heartburn is the primary symptom of gastroesophageal reflux disease (GERD). Heartburn (also called *pyrosis*) is defined as a retrosternal burning discomfort that may radiate up toward the

neck. Heartburn typically occurs in the postprandial period, especially after a high-fat or a large-volume meal. Postural changes, such as bending over, will often exacerbate symptoms. Relief of heartburn occurs with an upright position, swallowing of water or saliva, and ingestion of antacids.

Regurgitation is the effortless appearance of gastric or esophageal contents in the mouth. In patients with severe GERD, regurgitation of bitter-tasting material occurs. This symptom may also occur in patients with esophageal obstruction from structural causes such as tumors or functional causes such as achalasia.

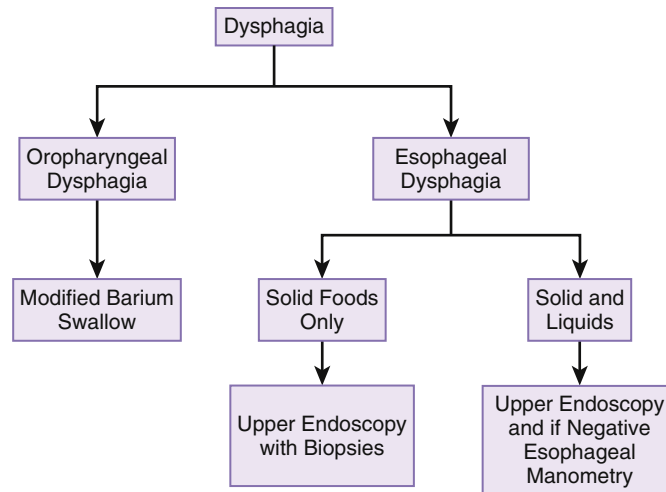

Water brash is a reflex induced by GERD that causes excessive salivation. Water brash is a distinct symptom that should not be confused with regurgitation.

Odynophagia is a sharp, substernal pain with swallowing and is usually caused by erosive esophagitis. This is typically from an infectious or pill-induced esophagitis. Odynophagia is an unusual symptom of uncomplicated GERD, although it can occur in severe GERD.

Globus is the sensation of a lump or fullness in the throat that persists following swallowing. This sensation may be a manifestation of GERD.

Dysphagia is defined as the sensation of a delay of food during its passage from the mouth to the stomach. Patients may perceive of food as sticking or getting caught after swallowing. Complications of dysphagia include aspiration pneumonia and weight loss. Dysphagia can be categorized as oropharyngeal dysphagia, which is due to difficulty in initiating a swallow (transferring a food bolus from the hypopharynx to the esophagus), or as esophageal dysphagia, which is due to difficulty in transferring a food bolus through the esophagus. Oropharyngeal dysphagia is due to disorders of the pharynx, upper esophageal sphincter, and striated upper esophagus, whereas esophageal dysphagia is due to a structural defect or a neuromuscular disorder of the esophageal smooth muscle. Fig. 69.1 shows the different types of dysphagia and the best tests to perform.

The most common cause of oropharyngeal dysphagia is neuromuscular dysfunction that disrupts the coordination of initial swallowing. Causes of oropharyngeal dysphagia include cerebrovascular accidents, Parkinson disease, amyotrophic lateral sclerosis, and myasthenia gravis. Rare structural disorders that can cause oropharyngeal dysphagia

• **Fig. 69.1** Algorithm for classification and evaluation of dysphagia.

include a Zenker diverticulum (see [Esophageal Structural Abnormalities](#)) and cervical osteophytes; these more commonly result in dysphagia to solids. The best test to detect an oropharyngeal source of dysphagia is a modified barium swallow with videofluoroscopy. This is often performed in collaboration with a speech pathologist at the time of the examination who can help identify abnormalities and direct specific swallow therapies.

The clinical history is important to distinguish the type and etiology of dysphagia. Oropharyngeal dysphagia is characterized by discoordination of swallowing, often accompanied by choking, gagging, nasal regurgitation, or coughing. These symptoms may be more prominent with liquids. Patients with dysphagia only to solids typically have esophageal dysphagia with a structural disorder of the esophagus such as a stricture (benign or malignant). These patients are best evaluated by an upper endoscopy to exclude structural lesions; if normal, biopsies from the mid and distal esophagus should be obtained to exclude eosinophilic esophagitis (see [Inflammatory and Infectious Disorders](#)), which can be present without an endoscopic abnormality. Patients with evidence of erosive esophagitis should be started on proton pump inhibitors (PPIs) because acid reflux can cause motility abnormalities. Esophageal rings, such as a Schatzki ring (see [Esophageal Structural Abnormalities](#)) in the lower esophagus, often cause intermittent dysphagia to solids. The site of where patients perceive food sticking is not entirely reliable, because when patients report an upper location, in about 30% of cases the site of obstruction is actually in the distal esophagus. Motility disorders of the esophagus, such as achalasia and scleroderma, are more likely to cause dysphagia to both solids and liquids. These conditions are best evaluated with an esophageal manometry study after an upper endoscopy has excluded a structural cause of dysphagia.

## Gastroesophageal Reflux Disease

GERD is the most common and expensive digestive disease. GERD accounts for at least 9 million office visits to

physicians in the United States each year, and annual direct costs for managing GERD exceed \$10 billion. GERD is a chronic disorder that occurs because of the retrograde flow of gastroduodenal contents into the esophagus, resulting in a variable spectrum of symptoms.

Transient inappropriate relaxation of the LES is the predominant pathophysiologic mechanism in the majority of patients (65%) with GERD. Relaxation of the LES occurs in response to swallowing or esophageal distension. Transient LES relaxation (TLESR) is a vagally mediated reflex that can be triggered by gastric distension. TLESR is the main mechanism for reflux of gastric contents in normal persons. A chronically low LES pressure is the predominant GERD mechanism in patients with severe reflux disease.

Anatomic disruption of the gastroesophageal junction, commonly associated with a hiatal hernia, is another mechanism that contributes to the pathogenesis of reflux disease, by impairing LES function and creating an intrathoracic reservoir of gastric contents. However, hiatal hernias are common and usually cause no symptoms.

Gastroparesis (delayed stomach emptying) is more common in patients with moderate-to-severe reflux disease and is an important factor in 10% to 15% of patients with GERD. Other gastric factors that contribute to GERD include increased gastric volume after meals and increased gastric pressure due to obesity. Increased gastric distention can cause an increase in TLESRs and volume of refluxate, particularly in GERD patients with large hiatal hernias. Reflux esophagitis is defined by esophageal mucosal lesions, whereas patients with GERD in the absence of mucosal damage have nonerosive or endoscopy-negative reflux disease.

## Epidemiology

There is a significant variability in GERD worldwide with a weekly prevalence of symptoms in Western countries of 10% to 20% compared with less than 5% in Asia. GERD is a common disorder, and the prevalence of GERD in the United States appears to be increasing. In Western

populations, 5% to 7% of healthy people describe having heartburn symptoms daily, 12% to 14% have symptoms at least once per week, and 15% to 25% report having heartburn at least once a month. Only one in four have discussed their symptoms with physicians. There appears to be no gender predominance of heartburn symptoms between men and women (except during pregnancy), although men tend to have more severe acid reflux (2–3:1) and Barrett esophagus (3–10:1). For women, the prevalence of daily heartburn during pregnancy is at least 25%, mostly in the third trimester. Familial clustering of GERD has also been reported. There is a positive association between increasing body mass index and reflux symptoms, and even moderate weight gain can cause or exacerbate symptoms of reflux. This is in part due to the fact that inappropriate TLESR can be induced by obesity.

## Clinical Findings

The typical manifestations of GERD are heartburn and regurgitation. Other symptoms of GERD include odynophagia, globus, and water brash. Symptoms can be aggravated by ingestion of direct irritants such as tomato sauce, spicy foods, coffee, tea, and alcohol. Certain foods, beverages, and behaviors will cause heartburn by reducing LES pressure. Fatty foods, peppermint, chocolate, caffeinated beverages, alcohol, and smoking can all lead to decreased LES pressure. Some medicines that can exacerbate GERD by lowering the LES pressure are listed in [Box 69.1](#).

Patients should be considered as having GERD if they have typical GERD symptoms twice a week or more, for at least 4 to 8 weeks. Alarm signs in GERD that mandate testing are anorexia, dysphagia, odynophagia, anemia, gastrointestinal blood loss, weight loss, advanced age, or a family history of upper gastrointestinal cancer.

Extraesophageal symptoms are atypical manifestations of GERD, including noncardiac chest pain, asthma, cough, aspiration pneumonia, and laryngitis. Pathologic GERD can be found in up to 80% of patients with asthma. Atypical manifestations can occur in patients with or without typical symptoms of GERD.

Complications of GERD include the development of a stricture, gastrointestinal bleeding, Barrett esophagus, and adenocarcinoma. Strictures represent the progression of ongoing reflux with mucosal damage and secondary fibrosis.

## Diagnosis

Classic GERD can be diagnosed by a history of characteristic symptoms and the absence of alarm symptoms that is confirmed by a complete response to medical therapy. A metaanalysis that assessed the accuracy of normal-dose or high-dose PPIs for 1 to 4 weeks in the diagnosis of GERD found a pooled sensitivity of 78% (95% confidence interval [CI] 66%–86%) and a specificity of 54% (44%–65%) when ambulatory esophageal pH was used as a gold standard. Diagnostic testing is typically reserved for patients who fail to respond to a trial of adequate medical therapy or for patients who have alarm symptoms of GERD. The current diagnostic tests for GERD in patients who fail medical therapy or have alarm signs include upper endoscopy, ambulatory pH studies, and impedance testing.

## Upper Endoscopy

Upper endoscopy involves the insertion of an endoscope through the mouth with direct inspection of the esophagus, stomach, and proximal duodenum. It can detect the extent and the severity of esophagitis, as well as exclude the presence of other diseases such as tumors and peptic ulcers. The identification of esophagitis by upper endoscopy is highly specific (90%–95%) for GERD but has a sensitivity of only around 50%. Two-thirds of GERD patients will have nonerosive reflux disease and thus negative findings of upper endoscopy. Upper endoscopy also allows evaluation for complications of GERD, such as strictures or Barrett esophagus. If a patient has dysphagia and a stricture is detected, dilation of the stricture can be performed during the same procedure. Upper endoscopy is the test of choice in patients with alarm signs.

## Intraesophageal Ambulatory pH Monitoring

Intraesophageal pH monitoring is the most accurate test to detect the presence of acid in the esophagus, with a sensitivity of about 85% and a specificity above 95%. It is most helpful in patients with difficult management problems or atypical presentations. Intraesophageal ambulatory pH monitoring is typically done by a probe that can record the distal esophageal pH continuously for 24 hours. The pH probe is passed transnasally to 5 cm above the manometrically determined LES. The data are collected by a battery-powered, beeper-sized device carried by the patient, who also records when meals are ingested and symptoms are experienced. This technique allows for correlation of symptoms with reflux episodes. Abnormal acid reflux episodes are defined as an esophageal pH below 4 for more than 4% of the total study duration. The discomfort associated with

nasal probe placement prompted the development of a wireless pH monitoring system that allows for a wireless, pill-sized capsule to be attached to the distal esophageal mucosa. The wireless pH system allows for 48 hours of monitoring, compared with 24 hours of monitoring with a conventional pH probe, which may detect GERD in patients with day-to-day variability. The capsule detaches and is spontaneously passed within 2 weeks.

Esophageal pH testing should be used in a select minority of GERD patients for whom the information will influence management. Ambulatory esophageal pH monitoring can be performed on acid-suppressing medications in patients who have typical GERD symptoms but are unresponsive to therapy, to determine if additional medical or surgical therapy is indicated. Ambulatory esophageal pH monitoring is also helpful off acid-suppressing medications to determine if GERD is present in patients with atypical GERD symptoms, such as asthma or chronic cough. In the prefundoplication operative evaluation of GERD patients, ambulatory esophageal pH monitoring is also important to document the presence and severity of GERD, especially if the patient has nonerosive reflux disease.

### Multichannel Intraluminal Impedance

The multichannel intraluminal impedance monitor measures both acidic and nonacidic refluxates. This device measures the intraluminal impedance of the esophagus (a measure of the total resistance to current flow between two electrodes) and is capable of detecting both liquid and gas consistencies. The combination of measuring both acid and nonacidic reflux in the esophagus has several advantages over traditional pH testing. This test can be helpful in patients with both typical and atypical GERD who are refractory to therapy for acid reflux by assessing nonacid and/or nonliquid reflux.

### Management

The goals of treatment for GERD are to eliminate symptoms, heal esophagitis, and prevent complications of GERD. Once a patient is in remission, the goal is to maintain symptom remission and prevent further tissue injury.

Lifestyle modifications are a cornerstone of the treatment of GERD, although not all are supported by clinical trials. Patients are instructed to avoid foods and beverages, such as high-fat and acidic foods, that can exacerbate symptoms of GERD. Avoidance of lying down for 3 hours after ingesting food may lessen reflux because during this time period, food may remain in the stomach and contribute to reflux. Smaller and more frequent meals may also be useful for patients with GERD. Elevation of the head of the bed 6 inches can also reduce reflux by using gravity to prevent reflux, although it is an unpopular intervention. The best position to reduce reflux when sleeping is to lie in the left lateral position because stomach contents are in a dependent location away from the gastroesophageal junction. Other useful recommendations

are to stop smoking and reduce weight, which can be critical to reducing or eliminating symptoms.

Medical treatment is with antacid and antisecretory agents. Over-the-counter antacids are taken at least twice a month by more than one-fourth of the US population. Antacids, alginic acid, and baking soda provide temporary symptom relief by neutralizing refluxed acid. These agents are most useful for treating mild and infrequent reflux symptoms, typically induced by indiscretions in lifestyle. Prokinetic drugs such as metoclopramide can relieve symptoms of heartburn but are most appropriate in patients with delayed gastric emptying. Unfortunately, these medications typically provide an incomplete response and have frequent side effects.

H<sub>2</sub>-receptor antagonists inhibit the secretion of gastric acid by competitively blocking gastric parietal cell H<sub>2</sub>-receptors. H<sub>2</sub>-blockers are approximately 75% effective in patients with mild-to-moderate degrees of esophagitis. However, in patients with moderate-to-severe esophagitis, these medications are only 50% effective in healing esophagitis. Patients with nonerosive GERD may paradoxically be more difficult to treat than those with erosive GERD. Thus H<sub>2</sub>-receptor antagonists are appropriate in mild-to-moderate GERD. Of note, chronic H<sub>2</sub>-blockers use may be associated with the loss of efficacy and the development of tachyphylaxis.

PPIs act by blocking the hydrogen potassium adenosine triphosphatase pump on the parietal cell apical surface. PPIs are more effective than H<sub>2</sub>-receptor antagonists because they act on the final common pathway of acid secretion rather than on just one of the three receptors (histamine, acetylcholine, and gastrin) responsible for acid secretion. PPIs are effective in patients with mild GERD and are indicated as initial therapy in patients with moderate-to-severe GERD and in patients with complications of GERD, such as bleeding and strictures. Some patients with persistent nocturnal GERD or regurgitation despite twice-daily PPIs benefit from H<sub>2</sub>-receptor antagonists taken at bedtime.

The timing of PPI use is important because PPIs are most effective when taken in a fasting state and are recommended to be ingested about 30 minutes before breakfast, when parietal cells have large numbers of active proton pumps. Side effects can occur in up to 3% of patients; the most common are headaches and diarrhea. There is potential for reduction of vitamin B<sub>12</sub> levels attributed to a decrease in protein-bound vitamin B<sub>12</sub> absorption with long-term PPI use, although this has not been seen clinically. Bacterial overgrowth of the small bowel can occur but is rarely significant unless there is also altered intestinal motility. Recently, the long-term use of PPIs has been possibly associated with increased rates of community-acquired pneumonia, *Clostridium difficile* infection, chronic kidney disease, dementia, and hip fracture.

Although most patients with GERD will be successfully managed with lifestyle modifications and medical therapy, some patients may have persistent symptoms despite treatment. Mechanical antireflux surgery can be used in

patients with a good clinical response to medical treatments who wish to discontinue medications or in patients with established GERD who have persistent symptoms despite medical therapy. The most widely performed procedure is a laparoscopic Nissen fundoplication, with a symptomatic response rate of up to 90%. Complications following fundoplication include dysphagia, chest pain, gas-bloat syndrome, postoperative flatulence, and vagal nerve injuries leading to gastroparesis and diarrhea. The prevalence of these postoperative complications ranges between 5% and 20%.

### Clinical Course and Prognosis

If a patient has responded to lifestyle changes and medical therapy with sustained symptom relief for 2 to 3 months, a trial of medication withdrawal should be attempted. If a patient is on a PPI, the dose can be reduced, it can be tapered to every other day, or the medication can be switched to an H<sub>2</sub>-blocker. Most patients who are treated with H<sub>2</sub>-blockers are on twice-daily medications and then can be tapered to a once-daily regimen. If a patient tolerates reduced medical therapy for 2 to 4 weeks without an increase in symptoms, the dosage can be further decreased, or the medication can be discontinued. The goal of long-term medical treatment is to provide the lowest level of medical therapy that effectively controls symptoms. However, if a patient experiences recurrent symptoms, the same medication that induces remission is usually required in the same dosage to maintain remission. For many patients, GERD is a chronic, relapsing disease with frequent symptom recurrence after medication withdrawal, thus requiring maintenance therapy. In non-erosive GERD, on-demand therapy can be a cost-effective alternative to maintenance treatment.

### Barrett Esophagus

The most important risk factor for the development of esophageal adenocarcinoma is Barrett esophagus. It is estimated that patients with Barrett esophagus have a 30- to 40-fold greater risk of esophageal adenocarcinoma than the general population. The development of a specialized columnar epithelium that replaces the normal squamous epithelium of the distal esophagus defines Barrett esophagus. The pathophysiology of Barrett esophagus involves GERD leading to reflux esophagitis with injury of the squamous epithelium. The injured epithelium heals with specialized columnar epithelium and intestinal metaplasia (required to diagnose Barrett epithelium).

At the time of the initial diagnosis of Barrett esophagus, approximately 8% of patients have adenocarcinoma. It is estimated that the risk of esophageal cancer is 0.12% to 0.63% per year in patients with known Barrett esophagus. Barrett esophagus shows a male to female ratio of 3 to 10:1, with an average age at the time of diagnosis of 55 years. Barrett esophagus is more likely to be found in patients with more severe GERD. It is estimated that 20% of patients with erosive esophagitis will develop Barrett metaplasia,

• **Fig. 69.2** Endoscopic view of Barrett esophagus showing the normal squamous epithelium of the esophagus that appears white and the Barrett mucosa that has a salmon color (arrow).

compared with 1% or less in unselected patients undergoing upper endoscopy.

There are no specific symptoms of Barrett esophagus. Upper endoscopy with biopsy of the gastroesophageal junction is needed for the diagnosis of Barrett esophagus. On upper endoscopy, Barrett esophagus appears as tongues of salmon-colored mucosa (Fig. 69.2), and biopsies confirm the diagnosis. Current recommendations include one-time screening upper endoscopy in patients who have longstanding GERD (5–10 years) and who are age >50 years with GERD. However, it is more cost effective to perform screening in patients with multiple risk factors for adenocarcinoma including chronic GERD, hiatal hernia, age ≥50, male gender, Caucasian race, elevated body mass index, and intraabdominal body fat distribution. The 2016 American College of Gastroenterology recommendations include:

- Screening for Barrett esophagus may be considered in men with chronic (>5 years) and/or frequent (weekly or more) symptoms of gastroesophageal reflux (heartburn or acid regurgitation) and two or more risk factors for Barrett esophagus or esophageal adenocarcinoma. These risk factors include age >50 years, Caucasian race, presence of central obesity (waist circumference >102 cm or waist–hip ratio >0.9), current or past history of smoking, and a confirmed family history of Barrett esophagus or esophageal adenocarcinoma (in a first-degree relative).
- Given the substantially lower risk of esophageal adenocarcinoma in females with chronic GERD symptoms (when compared with males), screening for Barrett esophagus in females is not recommended. However, screening could be considered in individual cases as determined by the presence of multiple risk factors for Barrett esophagus or esophageal adenocarcinoma (age >50 years, Caucasian race, chronic and/or frequent GERD, central obesity: waist circumference >88 cm, waist–hip ratio >0.8, current or past history of smoking, and a confirmed family

history of Barrett esophagus or esophageal adenocarcinoma [in a first-degree relative]).

- Screening of the general population is not recommended.
- Before screening is performed, the overall life expectancy of the patient should be considered, and subsequent implications, such as the need for periodic endoscopic surveillance and therapy, if Barrett esophagus with dysplasia is diagnosed should be discussed with the patient.

In patients who have Barrett esophagus but no evidence of dysplasia, a surveillance examination should be performed in 3 to 5 years with high-definition white light endoscopy and four-quadrant biopsies for every 2 cm of Barrett esophagus. For low-grade dysplasia, once the histopathologic diagnosis is confirmed by review of the findings by a second expert pathologist, patients should undergo repeat endoscopy in 6 and 12 months for four-quadrant biopsy of each 1 cm of Barrett. If the low-grade dysplasia is stable, yearly surveillance endoscopies can be done. In patients with Barrett and high-grade dysplasia, the histopathologic diagnosis should also be confirmed by review of the findings by a second expert pathologist and a repeat endoscopy with multiple biopsies. Currently, new biomarkers are under investigation to attempt to improve the yield of surveillance in Barrett esophagus and to reduce the sampling error associated with random biopsies.

In patients with either low-grade or high-grade dysplasia, the preferred and least invasive treatment is an endoscopic therapy called *radiofrequency ablation*. In this endoscopic treatment method, the lining of the esophagus is cauterized until mucosal sloughing occurs with subsequent regrowth of normal squamous esophageal mucosa. This treatment modality can eradicate low-grade dysplasia in over 90% of patients and high-grade dysplasia in about 80% of patients. Endoscopies are then performed every 3 months, and surgery is done only if cancer is found.

The goals for treatment of patients with Barrett esophagus are to eliminate the symptoms of GERD and prevent GERD complications. Because patients with Barrett esophagus tend to have more severe degrees of GERD, they may require high doses of medication or surgery to control their symptoms. Many patients are managed on PPIs to reduce the development of dysplasia, although the long-term benefits of this strategy have not been established in the literature. Antireflux surgery does not reduce the risk of adenocarcinoma in patients who have Barrett esophagus and continued surveillance of Barrett esophagus after surgery is required, even if the surgery is successful and the patient is asymptomatic.

## Esophageal Structural Abnormalities

### Rings and Webs

The normal esophagus is about 20 mm in diameter, and patients rarely have difficulty swallowing when the luminal diameter is above 15 mm. Rings and webs are common structural abnormalities of the esophagus and can be found

in up to 5% of the asymptomatic general population. These are commonly considered to be congenital or developmental in origin, although they may develop because of inflammatory conditions. Rings are circumferential narrowings of mucosa or muscle that are most common in the distal esophagus. Webs are partial narrowings that are always mucosal in origin and most common in the proximal esophagus. Rings and webs typically cause intermittent dysphagia to solids.

A common type of ring is Schatzki ring, which occurs at the junction of the esophagus and the stomach, is thin (less than 4 mm in thickness), and is associated with a hiatal hernia. Patients with ring diameters less than 13 mm are usually symptomatic, and those with a diameter between 13 mm and 20 mm may variably have symptoms. The cause of these rings is thought to be either congenital or associated with GERD. Patients who have symptoms should be treated with mechanical dilation at the time of upper endoscopy. Although dilation is effective, it is not uncommon for patients to have recurrent symptoms requiring additional dilations. Treatment with acid-suppressing medications after dilation may reduce the recurrence rate.

### Esophageal Diverticula

The protrusion of a sac from the esophageal wall is an esophageal diverticulum. Esophageal diverticula can be of the upper esophagus, midesophagus, lower esophagus, and diffusely throughout the esophagus (intramural pseudodiverticulosis). Most esophageal diverticula are asymptomatic.

A Zenker diverticulum is located just proximal to the upper esophageal sphincter, and, although technically a hypopharyngeal diverticulum, it is often considered an esophageal diverticulum. These diverticula likely form in an area of weakness between the inferior constrictor and the cricopharyngeal muscles as a result of incomplete upper esophageal sphincter relaxation. Zenker diverticula occur most commonly in elderly males. Patients with a Zenker diverticulum may complain of dysphagia, halitosis, regurgitation of undigested food, throat discomfort, cough, and aspiration pneumonia. The diverticulum can fill with food that may be regurgitated when the patient lies down or bends over. The best test to detect a Zenker diverticulum is a video barium swallow. Although small diverticula are often asymptomatic, symptomatic large diverticula should be treated. The standard procedure is an endoscopic or surgical cricopharyngeal myotomy with incision of the septum between the esophagus and the diverticulum.

## Inflammatory and Infectious Disorders

### Eosinophilic Esophagitis

Eosinophilic esophagitis is a chronic disorder that commonly presents in young adults between the ages of 20 and 40 years. Patients typically present with dysphagia and often food impaction. This entity has been well described in children but only recently has been recognized to occur

• **Fig. 69.3** Endoscopic appearance of eosinophilic esophagitis showing multiple rings (*black arrows*) and linear furrowing (*white arrow*).

in adults. It is also known as ringed, feline, allergic, or corrugated esophagus. Although the etiology is unknown, allergic conditions as well as GERD have been associated with eosinophilic esophagitis. Eosinophilic esophagitis is predominantly identified in males (80%).

The diagnosis is made by upper endoscopy and biopsy with endoscopic findings of mucosal fragility, multiple rings, white mucosal exudates, linear furrowing of the esophagus, and strictures (Fig. 69.3). The diagnosis is confirmed by biopsies of the esophagus, which show eosinophils (>15 to 20 eosinophils per high-power field) in the esophageal mucosa more proximally than would be found in patients with GERD. It is important to exclude GERD by demonstrating a lack of clinical response to high-dose PPIs and by biopsy of both the gastroesophageal junction and more proximally in the esophagus.

The natural history of eosinophilic esophagitis is not entirely known in adults. Treatments have been primarily extrapolated from the pediatric experience with this disorder. Dietary and environmental triggers should be sought and eliminated if possible. The benefit of allergy testing and food elimination diet is moderate, but referral to an allergist and dietician should be considered. Medical therapy is usually with topical corticosteroids such as fluticasone dipropionate (220 µg used without a spacer, swallowed twice daily), leukotriene receptor antagonists, and oral corticosteroids have also been shown to be helpful. Endoscopic dilation of the strictures may be needed but must be done cautiously because the mucosa can tear easily, leading to perforation. The optimal duration of treatment is not known because symptomatic relapses commonly occur after discontinuation of therapy and long-term therapy may be required.

### Pill Esophagitis

There are many medications that can injure the esophagus. The most common medications that cause pill-induced esophagitis are listed in Box 69.2 and include alendronate, antibiotics, aspirin, iron salts, nonsteroidals, potassium

### • BOX 69.2 Medications That Can Cause Esophagitis

Alendronate  
 Antibiotics  
   Clindamycin  
   Doxycycline  
   Erythromycin  
   Penicillin  
   Tetracycline  
 Ascorbic acid  
 Aspirin  
 Iron salts  
 NSAIDs  
 Potassium chloride  
 Quinidine  
 Theophylline  
 Zidovudine

NSAIDs, Nonsteroidal antiinflammatory drugs.

chloride, quinidine, and theophylline. More than 50% of pill-induced esophagitis is caused by tetracycline and related medications, especially doxycycline. There are various mechanisms by which pills induce esophageal damage, including prolonged contact time with the esophageal mucosa and pill acidity. Commonly, pills get stuck at sites of anatomic narrowing, such as the arch of the aorta and the distal esophagus. However, patients do not need to have esophageal anatomic disorders to develop pill esophagitis. Factors that increase the risk of pill esophagitis are advancing age, swallowing position, fluid intake, and pill size. Position may be the most important risk factor for esophageal injury because medications ingested while supine with insufficient fluids may remain in the esophagus for up to 90 minutes.

The symptoms of pill-induced esophagitis are chest pain and odynophagia, which can be quite severe and prolonged. Although the diagnosis is often a clinical one, upper endoscopy can confirm the diagnosis and exclude other causes. The endoscopic appearance of pill esophagitis is variable, including erosions, ulcerations, plaques, and strictures. The mainstay of treatment is to identify and avoid the offending drug. If possible, liquid forms of medication should be used. Medications should be administered with at least 15 mL of fluids, and patients should remain in the upright position for 30 minutes after swallowing pills. Symptom relief may occur with the use of topical anesthetics (e.g., viscous lidocaine) and coating the esophagus with antacids or sucralfate suspension.

### Infectious Causes of Esophagitis

Although esophageal infections are rare in normal hosts, infectious esophagitis is not uncommon in immunocompromised patients, including those who are post transplant or on corticosteroids, and those with cancer on chemotherapy, diabetes, alcoholism, and HIV infection. Patients with infectious esophagitis typically have odynophagia

but may present with dysphagia, heartburn, fever, nausea, or bleeding. The three most common causes of infectious esophagitis are *Candida albicans*, cytomegalovirus (CMV), and herpes simplex virus (HSV). Less common infectious etiologies include Epstein-Barr virus, varicella-zoster virus, diphtheria, and primary HIV infection.

The most frequent cause of infectious esophagitis is *C. albicans*. Although *C. albicans* is normal oral flora, it can cause esophagitis in immunocompromised patients. In symptomatic patients with esophageal candidiasis, up to 75% will have oral thrush. The diagnosis is most accurately made by upper endoscopy showing white or yellow plaques and brushings or biopsies showing hyphae and budding yeast. The diagnosis may also be clinically suspected and confirmed by a response to treatment. A commonly used antifungal treatment is a 14- to 21-day course of fluconazole (400 mg orally the first day followed by 200 mg per day). Alternative medications include itraconazole and voriconazole. Refractory disease may be treated by intravenous caspofungin or amphotericin.

Infection of the esophagus with CMV often occurs as part of a generalized gastrointestinal CMV infection in immunocompromised patients. Thus the symptoms are quite variable and can be nonspecific. At upper endoscopy there may be linear or deep ulcerations, and the diagnosis is confirmed from biopsies taken from the ulcer base. Biopsies should be sent for both histology and viral cultures. Treatment of CMV infectious esophagitis is with ganciclovir, valganciclovir, or foscarnet for at least 2 weeks and often also with a maintenance regimen until immune function improves.

HSV esophagitis can occur in both immunocompetent and immunocompromised hosts. In immunocompetent hosts, this usually is from reactivation of a latent infection but may be from primary HSV. Upper endoscopy may show vesicles that rupture to form ulcers with raised edges (volcano-like). The diagnosis is confirmed with biopsies from the edge of the ulcers, sent both for histology (showing multinucleated giant cells) and viral culture. Treatment is with a course of acyclovir given intravenously until the patient can tolerate oral therapy. Alternative therapies are foscarnet and famciclovir.

## Esophageal Motility Disorders

Altered esophageal motility may occur because of primary motility disorders of the esophagus or secondary to systemic diseases. Motility disorders of the esophagus secondary to systemic diseases include scleroderma, diabetes mellitus, thyroid disease, amyloidosis, and other connective tissue diseases. Connective tissue disorders may involve the esophagus, including systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, mixed connective tissue disease, and inflammatory myopathies. The esophagus may also be affected by Behçet disease and cutaneous disorders including epidermolysis bullosa, bullous pemphigoid, cicatricial pemphigoid, pemphigus vulgaris, and lichen planus. The

best test of esophageal motility is an esophageal manometry examination.

Esophageal manometry measures the pressure within the lumen of the esophagus with a nasal catheter. The principal use of this test is to diagnose primary esophageal motility disorders such as achalasia, diffuse esophageal spasm, or ineffective esophageal motility. Manometry is not indicated for the diagnosis and management of most patients who have GERD. However, the test is helpful in the preoperative assessment of esophageal motility in patients planned to undergo fundoplication surgery.

## Achalasia

Achalasia is an esophageal motility disorder of unknown etiology characterized by both failure of LES relaxation and decreased or absent esophageal peristalsis. The incidence of achalasia is about 1 in 100,000, and it affects both sexes equally. It can occur at any age, but symptom onset is usually between the ages of 20 and 60 years. Achalasia occurs as a result of changes in Auerbach plexus (the myenteric plexus located between the circular and longitudinal muscle layers), including inflammation, fibrosis, and loss of ganglion cells. This results in a loss of the postganglionic inhibitory neurons, which contain both vasoactive intestinal polypeptide and nitric oxide, leading to unopposed cholinergic stimulation causing high LES pressures and failure of LES relaxation. There is associated decreased or absent peristalsis, also resulting from the loss of nitric oxide. Chagas disease in Central and South America from *Trypanosoma cruzi* causes a similar denervation of the esophageal smooth muscle. Because of the immigration of persons chronically infected with Chagas disease, the incidence of this diagnosis is increasing in the United States.

Pseudoachalasia is the term for disorders that simulate the clinical appearance of achalasia. Tumors at the gastroesophageal junction are the main cause of pseudoachalasia and need to be excluded. Pseudoachalasia arising from tumors is found in about 5% of patients diagnosed with achalasia.

The clinical manifestations of achalasia include dysphagia (both solid and liquid), regurgitation, chest pain, weight loss (often subtle), and aspiration pneumonia. As the symptoms are slowly progressive and may start with dysphagia to solids only, most patients are symptomatic for years before seeking medical attention. Nocturnal regurgitation of solids occurs in about one-third of patients and may lead to pulmonary complications. Patients (especially those age >60 years) with a rapid onset of symptoms (<6 months) and weight loss should be suspected of having pseudoachalasia. Chest pain is present in up to 50% of patients with achalasia, is more common in younger patients with earlier disease, and may last for hours. Weight loss occurs in up to 60% and progresses with disease duration.

A barium swallow is the typical initial test and characteristically shows a dilated esophagus with a smooth “bird’s beak” narrowing of the gastroesophageal junction (Fig. 69.4). There will be a loss of primary peristalsis of the distal two-thirds

• **Fig. 69.4** Barium swallow examination showing a bird's beak smooth narrowing of the lower esophageal sphincter region (*arrow*) and a dilated esophagus in a patient with pseudoachalasia caused by a gastroesophageal junction tumor.

of the esophagus with poor esophageal emptying, often with a dilated esophagus and an air-fluid level from retained food and secretions. Upper endoscopy should be done in all patients, with careful inspection of the gastroesophageal junction to exclude pseudoachalasia caused by tumors. The diagnosis of achalasia is confirmed by esophageal manometry showing decreased or absent LES relaxation, often with an elevated LES pressure and poor-to-absent esophageal peristalsis.

Although there is no cure for achalasia, several treatments are available to relieve symptoms and improve esophageal emptying. Medications, including nitrates and calcium channel blockers, can reduce LES pressure and provide temporary relief of symptoms. However, the benefit of medical therapy is typically of short duration, and it is most commonly used as a temporizing agent before a more effective treatment. Endoscopic therapy consists of injection of botulinum toxin or pneumatic balloon dilation. The injection of botulinum toxin at the LES inhibits the release of acetylcholine from nerve terminals. It is effective in up to 85% of patients initially, but symptoms recur in over 50% of patients at 6 months. Although repeated injections of botulinum toxin can be given, this therapy is best for elderly patients and those at high surgical risk. Pneumatic dilation at endoscopy uses large balloons to disrupt the circular muscle of the LES. Patients have a good response in 50% to 93% of dilations, although about 30% of patients require repeat dilations. The main risk of pneumatic dilation is perforation of the lower esophagus as a result of the dilation. Because perforation can occur in 2% to 5% of patients treated with pneumatic dilation, patients treated by this method should be surgical candidates and have a barium swallow examination performed after the procedure to exclude this complication.

A recent advance in the endoscopic treatment of achalasia involves an endoscopically performed myotomy (peroral endoscopic myotomy). This incisionless technique has demonstrated excellent 6- to 12-month efficacy with upwards of 95% relief of dysphagia (long-term data not yet available). The definitive traditional therapy for achalasia is a surgical myotomy (Heller myotomy with surgical incision of the anterior LES). After laparoscopic surgical myotomy, a good response is found in 80% to 94% of patients. The development of GERD is a common complication of surgical myotomy, and some surgeons will also perform an antireflux procedure (fundoplication) at the same time as myotomy.

### Diffuse Esophageal Spasm

Diffuse esophageal spasm is a motility disorder characterized by the presence of more than 30% simultaneous and repetitive contractions in the esophageal body, which may be elevated in contraction amplitude. In contrast to achalasia, LES relaxation is normal, and normal esophageal peristalsis remains. Clinically, patients may complain of chest pain or dysphagia or both. On barium swallow, the classic appearance is a “corkscrew” esophagus. Medical treatment is usually not completely effective but is directed at relaxing the esophagus with calcium channel blockers or nitrates.

### Ineffective Esophageal Motility

Ineffective esophageal motility is an esophageal motility disorder defined by low-amplitude esophageal contractions with a normal LES. This may result in increased esophageal exposure to acid and prolonged esophageal clearance times when recumbent. This is an increasingly recognized abnormality, especially in GERD patients with pulmonary symptoms.

### Hypertensive Peristalsis (Nutcracker Esophagus)

Nutcracker esophagus is characterized by high-amplitude peristaltic contractions. It is often diagnosed in patients with noncardiac chest pain. It has recently been recognized to be a marker for increased visceral pain perception and not a primary esophageal motility disorder. One variant of this condition has been termed *jackhammer esophagus* and is defined as intact esophageal peristaltic contractions with extremely elevated amplitudes.

### Scleroderma

Scleroderma is a syndrome caused by proliferation of connective tissue with fibrosis of multiple organs and a small-vessel vasculopathy. Gastrointestinal involvement occurs in more than 90% of patients, and esophageal involvement occurs in 70% to 80%. The effects of scleroderma on the esophagus include loss of esophageal peristalsis with eventual aperistalsis of the distal two-thirds of the esophagus and a very low or absent LES pressure. Esophageal symptoms of scleroderma

include heartburn, regurgitation, and/or dysphagia, which may lead to esophagitis, strictures, and Barrett esophagus. The combination of a patulous gastroesophageal junction along with esophageal aperistalsis with the inability to clear esophageal contents leads to severe and complicated reflux. Management of the esophageal manifestations requires

aggressive medical therapy, stricture dilation (if needed), and surveillance for Barrett esophagus. Surgical management of severe GERD with fundoplication must be carefully considered because patients often have significant dysphagia postoperatively due to impaired peristalsis and the surgical tightening of the gastroesophageal junction.

## Chapter Review

### Questions

1. A 34-year-old white male presents with intermittent dysphagia of solid foods for 3 years. He says that solid foods such as chicken get stuck in the base of his throat, and he needs to vomit for relief of obstruction. He denies pain on swallowing with no difficulty swallowing liquids. He also denies heartburn (although has been on a PPI for 4 weeks), gastrointestinal bleeding, and weight loss. Physical examination is normal. Endoscopy shows a ringed-like appearance of the esophagus with areas of linear furrows that are biopsied; pathology reveals an eosinophilic esophagitis.  
The next step in management should be:
  - A. Esophageal manometry
  - B. Initiate swallowed fluticasone spray therapy
  - C. Referral to a surgeon
  - D. Initiate a nocturnal H<sub>2</sub>-blocker
  - E. Botulinum toxin (Botox) injection of the LES
2. A 67-year-old woman complains of dysphagia initially to solids, which has progressed over 3 months to both solids and liquids. She has no history of prior gastroesophageal reflux, and her only other medical problem is hypertension. Her only current medication is lisinopril. Her physical examination and routine blood tests are unremarkable. She undergoes a barium swallow, which shows a dilated esophagus with a bird's beak appearance of the gastroesophageal junction.  
The patient should next:
  - A. Be referred to a surgeon
  - B. Undergo an upper endoscopy examination
  - C. Be started on a calcium channel blocker
  - D. Have an esophageal manometry examination
  - E. Have a CT of the chest and abdomen

3. A 48-year-old man with a long history of GERD undergoes an upper endoscopy that reveals several 2- to 3-cm salmon-colored mucosa extending proximally from the gastroesophageal junction. Biopsies reveal Barrett esophagus. No dysplasia is noted.  
What is the appropriate surveillance recommendation?
  - A. Biopsy of the Barrett segment every 3 to 6 months
  - B. Biopsy of the Barrett segment annually
  - C. Biopsy of the Barrett segment every 3 to 5 years
  - D. Biopsy of the Barrett segment every 10 years
  - E. No further surveillance is necessary
4. A 58-year-old woman presents with a 5-year history of progressive dysphagia for liquids and solids. She describes occasional nocturnal regurgitation of food. An upper gastrointestinal series reveals a dilated esophagus with beak-like narrowing at the level of the gastroesophageal junction. An upper endoscopy reveals no masses. Esophageal manometry is notable for high normal basal LES pressure, failure of the LES to relax with swallows, and esophageal body aperistalsis.  
Appropriate management of her disease would include any of the following except:
  - A. Pneumatic dilation
  - B. Surgical resection of the distal esophagus
  - C. Peroral endoscopic myotomy
  - D. Botulinum toxin injection

## Peptic Ulcer Disease

TYLER M. BERZIN AND KENNETH R. FALCHUK

Peptic ulcer disease (PUD) involves the stomach or duodenum and is a significant cause of morbidity and mortality both in the United States and worldwide, with a lifetime prevalence estimated at 5% to 15%. For a good part of the 20th century, PUD was felt to be a condition related to stress and dietary factors. More recently, our understanding of PUD has been advanced by research into the role of gastric acid secretion and the benefits of various classes of antisecretory medications and, perhaps most importantly, in 1984, by Warren and Marshall, who identified *Helicobacter pylori* as a pathogenic agent in this disease. Proton-pump inhibitor (PPI) therapy and *H. pylori* eradication regimens have altered the natural history of what once was a chronic disease, and they have also reduced peptic ulcer complications, limiting the need for surgery.

### Pathophysiology

The formation of gastric and duodenal ulcers must be understood considering the regulation of acid production and the normal gastrointestinal (GI) mucosal environment that protects against ulcer formation. The parietal cells of the gastric fundus and body are responsible for the majority of hydrochloric acid (HCl) secreted by the stomach. There are three major stimuli for parietal cell acid production: (1) acetylcholine secreted by the vagus nerve in the parasympathetic nervous system; (2) endocrine stimulation by gastrin from G cells in the gastric antrum; and (3) paracrine stimulation by local cells producing histamine. There are multiple overlapping negative feedback pathways through which decreased intraluminal pH in the stomach inhibits parietal cell HCl secretion.

Despite the acidity of the gastric lumen, where the pH drops below 2 during digestion, the epithelial linings of both the stomach and duodenum are protected by several factors. Mucous cells in the stomach secrete bicarbonate and a mucous gel rich in glycoprotein, creating a physical barrier and pH gradient between the acidic luminal interface and the more neutral epithelial surface environment. Duodenal bicarbonate secretion is robust and helps normalize the pH of contents arriving from the stomach. Prostaglandin E may also play an important role in regulating the mucosal and epithelial microenvironment because it appears to increase

bicarbonate secretion, inhibit acid production, and regulate local blood flow.

### Causes of Peptic Ulcer Disease

Peptic ulcers form when mucosal protective factors are overcome by a variety of mucosal aggressive factors, both endogenous and exogenous. Acid, pepsin, and bile are all potentially injurious to the mucosal lining of the GI tract. Multiple abnormalities in the homeostatic regulation of gastric acid production have been implicated as potential contributors to PUD. These factors have included abnormal basal acid output, abnormal peak acid output (during meal ingestion), elevated serum gastrin level, and many others. Here we focus on two of the most important exogenous factors implicated in PUD—namely, *H. pylori* infection and nonsteroidal anti-inflammatory drug (NSAID) medications, which exert direct toxic effects on the mucosa and disrupt mucosal protective factors. Zollinger-Ellison syndrome and other less-common conditions implicated in PUD are also reviewed.

### *Helicobacter pylori*

Historical estimates have held that *H. pylori* was responsible for up to 90% of duodenal ulcers and up to 70% of gastric ulcers; however, the prevalence of *H. pylori* is decreasing in many parts of the developed world because of a number of factors including the emergence of effective *H. pylori* eradication regimens and improved sanitation. According to several recent studies in the United States, the prevalence of *H. pylori* among patients with PUD ranges from 30% to 60%, depending on the population studied, with higher prevalence typically noted for Hispanic and African-American individuals. The prevalence of the infection tends to be highest in developing countries, with rates approaching 70% to 90% in the general population.

*H. pylori* is a helical gram-negative rod primarily residing within the mucous layer of the stomach and occasionally attaching directly to gastric epithelial cells (either within the stomach or in other areas of the GI tract with gastric metaplasia). The mode of transmission of *H. pylori* is not well understood, but it may involve oral-oral or fecal-oral spread. The pathogenic steps in *H. pylori* infection may include

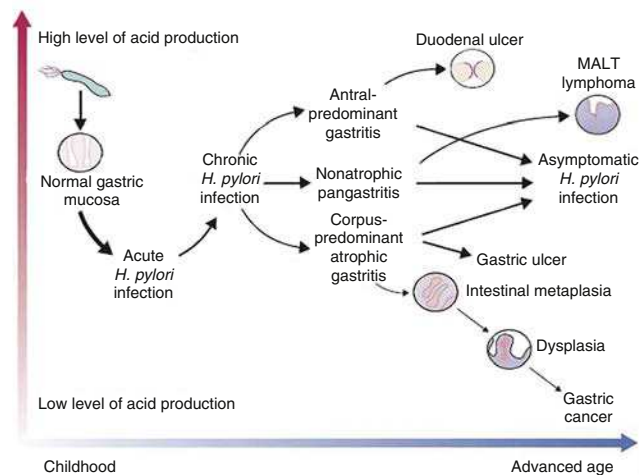

disruption of the mucous barrier, bacterial production of ammonia (by the urease enzyme), elaboration of cytotoxins, and stimulation of local inflammatory responses. Multiple virulence factors have been identified in the *H. pylori* genome, including the genes *vacA* and *cagA*, which may induce numerous local effects including modulation of local inflammatory activity and direct epithelial cell damage. These virulence factors and others may play an important role in determining the clinical phenotype of *H. pylori* infection, which can vary widely.

In virtually all patients, *H. pylori* infection causes a chronic active gastritis, leading to a reduction in the acid-regulatory hormone somatostatin and a resulting increase in gastrin secretion and parietal cell acid production. Only a minority of infected patients develop PUD. In particular, *H. pylori* infection can lead to various patterns of gastritis, including antral-predominant gastritis (generally a high-acid-output state) and corpus-predominant atrophic gastritis (generally a low-acid-output state), as well as PUD, and gastric malignancies including gastric adenocarcinoma and mucosal-associated lymphoid tissue (MALT) lymphoma (Fig. 70.1).

The reason *H. pylori* promotes ulcer formation in some individuals but not in others is not well understood. The mechanism by which *H. pylori* infection in the stomach can lead to ulcer formation in the duodenum is also the subject of intense investigation. It appears that the presence of gastric metaplasia in the duodenum allows local *H. pylori* colonization, triggering direct toxic effects and local inflammatory responses. Furthermore, *H. pylori* infection may lead to increased duodenal acidity caused by modulation of gastrin and somatostatin secretion in the stomach.

## Nonsteroidal Antiinflammatory Drugs

After *H. pylori*, NSAIDs are the second most important etiologic factor in PUD. Common estimates are that up to

• **Fig. 70.1** Natural history of *H. pylori* infection. MALT, Mucosa-associated lymphoid tissue. (From Suerbaum S, Michetti P. Medical progress: *Helicobacter pylori* infection. *N Engl J Med*. 2002;347(15):1175-1186.)

one-quarter of patients using NSAIDs chronically (including aspirin) will develop duodenal or gastric ulcers. NSAID use is felt to correlate with a higher risk of bleeding complications and death in PUD. The injurious effects of NSAIDs are in part caused by direct cytotoxic effects on epithelial cells, as well as inhibition of cyclooxygenase 1 (COX-1), with resulting reductions in prostaglandin production and bicarbonate and mucus secretion, and alterations in mucosal blood flow.

The risks of NSAID-induced ulcer formation and bleeding are greatest in patients with prior PUD and in patients using anticoagulant medications such as warfarin. In patients with NSAID-related PUD, cessation of NSAIDs is the optimal strategy to reduce the chance of ulcer recurrence. Among patients who require continuing NSAID therapy (including aspirin), misoprostol and PPIs have both been shown to decrease the risk of GI complications, although PPI therapy is strongly preferred because of tolerability and ease of use. Recommendations vary regarding which NSAID users benefit most from concomitant PPI therapy. In general, PPI cotherapy should be considered among NSAID users age >65 years and should be strongly considered for patients on anticoagulation. For patients with prior PUD, *H. pylori* eradication and continuing PPI cotherapy are mandatory if NSAIDs must be continued. COX-2-selective NSAIDs carry a smaller risk of GI ulceration, but the associated cardiac risk profile of COX-2 agents limits their practical usefulness. For patients requiring antiplatelet agents for cardiac disease, aspirin with PPI therapy has been shown to be associated with a lower risk of GI events than clopidogrel alone. For patients requiring ongoing clopidogrel therapy, PPI therapy can also be considered when clinically indicated. There were initial concerns regarding reduced efficacy of clopidogrel with PPI cotherapy, but these concerns have diminished after more robust trial data have become available supporting the safety of coadministering these medications.

## Zollinger-Ellison Syndrome (Gastrinoma)

The finding of severe PUD, particularly in the absence of obvious risk factors such as NSAID use or *H. pylori* infection, should trigger an evaluation for Zollinger-Ellison syndrome (gastrinoma). Zollinger-Ellison syndrome is rare, probably accounting for <1% of PUD. Multiple ulcers, severe gastroesophageal reflux disease, and malabsorption (leading to diarrhea and weight loss) are all classic findings of this syndrome, although many patients have PUD alone. Gastrinomas can occasionally be a feature of multiple endocrine neoplasia syndrome and may therefore occur along with parathyroid and pituitary tumors.

If Zollinger-Ellison is suspected, a fasting serum gastrin level should be measured, preferably after a patient has discontinued acid-suppressive therapy for 7 days. Although a fasting gastrin level >1000 pg/mL is virtually diagnostic of Zollinger-Ellison, a moderately elevated gastrin level (>100 pg/mL at our institution) should be followed by a secretin-stimulation test, the provocative test of choice because of its

high sensitivity. In Zollinger-Ellison syndrome, secretin causes an abnormal increase (of >200 pg/mL) in the serum gastrin level within minutes. Confirmatory testing then includes an octreotide scan (or somatostatin receptor scintigraphy), and an abdominal CT scan or endoscopic ultrasound to localize the tumor, which is typically within the pancreas or duodenum in an anatomic region termed the *gastrinoma triangle*. Although PPI therapy may control acid hypersecretion, the risk of malignancy (i.e., local metastatic spread) is such that gastrinomas must be resected when possible.

### Other Causes of Gastroduodenal Ulcers

Although NSAID ingestion and *H. pylori* infection are the two most common causes of PUD, numerous other conditions can contribute to ulcer formation (Box 70.1). The term *peptic ulcer disease* specifically refers to ulceration occurring because of acid/pepsin exposure in the GI tract; however, we have also included other conditions that can cause gastroduodenal ulceration that may be mistaken for PUD (i.e., Crohn disease and malignancy).

It is well known, although perhaps overstated, that gastric or duodenal ulcers can arise during critical illness. Stress ulcers are generally superficial and not a significant cause of major GI bleeding. The pathophysiology of stress ulcer formation is probably distinct from that of typical PUD and is thought to involve mucosal ischemia, hypoperfusion, and reperfusion. Historical terms have included Cushing ulcers, occurring in the setting of intracranial pathology, and Curling ulcers, occurring in burn patients. Known risk factors for stress ulcer formation include head trauma/neurosurgery, >30% burns, as well as mechanical ventilation and coagulopathy. Acid-suppression therapy with PPIs is indicated for stress ulcer prophylaxis in these specific settings. For the majority of patients hospitalized on general medical or surgical wards, however, stress ulcer prophylaxis is generally not necessary.

Corticosteroids are also frequently implicated in peptic ulcer formation; however, it is not clear that corticosteroid use alone increases the risk of PUD. Concomitant use of NSAIDs and corticosteroids, however, does seem to confer

an increased risk of ulcer formation when compared with NSAID use alone. Other medications, including sirolimus and bisphosphonates, appear to be associated with PUD in some cases.

Chronic mesenteric ischemia can cause mucosal ulceration anywhere in the GI tract and should be a consideration in the evaluation of patients with nonhealing *H. pylori*-negative gastroduodenal ulcers. Advanced age, known atherosclerotic disease, and smoking are all risk factors for chronic mesenteric ischemia. Atherosclerotic disease of the GI tract may be clinically silent until two of the three major splanchnic vessels are involved because of the extensive collateral network within the GI vasculature.

Rare causes of gastric or duodenal ulcer formation include cocaine use (possibly caused by vasoconstriction and/or thrombosis), herpes simplex virus and cytomegalovirus infections (largely in immunosuppressed patients), and Crohn disease. Finally, gastric adenocarcinoma is always included in the differential diagnosis of gastric ulcers, and multiple endoscopic biopsies are mandatory to rule out malignancy in the setting of a nonhealing gastric ulcer.

### Clinical Presentation

Abdominal pain is a classic feature of PUD, but it is a highly nonspecific symptom. The abdominal pain of PUD is typically epigastric, nonradiating, and may occur in the postprandial period. Some patients will report improvement with antacid medications. Dyspepsia, a broader term that refers to a constellation of (usually epigastric) abdominal symptoms including pain, bloating, and nausea, can be caused by a variety of disorders including PUD, nonnuclear dyspepsia (symptoms in the absence of mucosal ulceration), pancreaticobiliary diseases, gastroesophageal reflux, and malignancy.

The three primary complications of PUD are hemorrhage, perforation, and obstruction. All three are occurring less frequently in the era of antisecretory therapy and *H. pylori* eradication; however, PUD remains the most common cause of significant upper GI tract hemorrhage. Bleeding typically occurs when an ulcer in the stomach or duodenum erodes into a small or medium-sized blood vessel within the submucosa. Massive bleeding may be particularly likely in the rare circumstances when a posterior duodenal bulb ulcer penetrates the gastroduodenal artery or a gastric ulcer penetrates the left gastric artery. Melena (black tarry stool) is usually indicative of bleeding from the upper GI tract (above the ligament of Treitz), and hematemesis may also occur. Massive upper GI bleeding (typically >500 mL of blood loss) may also cause hematochezia (red blood in the stool). A number of clinical scoring systems exist that may predict outcome, mortality, and the need for endoscopic intervention in PUD bleeding. Of these, the Rockall score and Blatchford score are most commonly used. Most scoring systems identify advanced age, medical comorbidities, unstable hemodynamic status, and/or endoscopic findings of recent/active bleeding as the key features predictive of poor outcome. Appropriate triage to an intensive care unit,

#### • BOX 70.1 Causes of Gastric and Duodenal Ulcers

 Cytomegalovirus  
 Malignancy  
 Crohn disease

rapid resuscitation with fluid and blood products, PPIs, and early endoscopic therapy are mainstays in the treatment of PUD with bleeding, a scenario in which mortality can approach 10%.

A peptic ulcer that erodes fully through the gastric or duodenal wall and into the peritoneum is termed a *perforating ulcer*. This is in distinction to the term *penetrating*, which implies erosion into adjacent organs (the pancreas, liver, etc.). The anterior wall of the duodenum and the lesser curvature of the stomach are the most common sites for perforation. Spillage of luminal contents into the peritoneum typically leads to severe abdominal pain caused by peritonitis, which is accompanied by exquisite tenderness and abdominal rigidity on physical examination. Perforation can be confirmed by identifying subdiaphragmatic air on upright chest radiography or by identifying extraluminal air on abdominal CT scan. Urgent surgical intervention is mandatory.

Gastric outlet obstruction can occur either acutely or chronically in relation to PUD. Acute ulceration leading to edema within or near the pylorus or duodenal bulb can cause obstruction. Chronic ulceration with scarring can have similar effects. The typical symptoms of obstruction include nausea, vomiting, early satiety, and, in the chronic setting, weight loss. Physical examination may reveal distension and/or a succussion splash. Treatment of gastric outlet obstruction is initially supportive, including intravenous hydration, nasogastric tube decompression, and PPI therapy. Conservative therapy may be enough to relieve obstruction related to acute ulceration and edema in some cases, whereas obstruction caused by chronic ulceration or scarring is more likely to require endoscopic dilation or surgery. The presence of gastric outlet obstruction mandates a thorough evaluation for malignancy with endoscopic biopsies.

## Diagnostic Evaluation of Peptic Ulcer Disease

In the absence of significant complications such as bleeding, perforation, or obstruction, the symptoms of PUD can be difficult to differentiate from other causes of abdominal pain or dyspepsia. If the history is highly suggestive of acid peptic disease (i.e., postprandial epigastric discomfort, alleviation with antacids, etc.), empirical acid-suppressive therapy with a PPI or H<sub>2</sub>-receptor antagonist may be reasonable in patients who are age <55 years in the absence of alarm features (Box 70.2). *H. pylori* serology testing is also reasonable in this group of patients. Additional studies starting with upper endoscopy should be undertaken if symptoms do not subside with empiric therapy or if alarm symptoms are present.

### Testing for *Helicobacter pylori*

The first question to consider in discussing diagnostic tests for *H. pylori* is who should be tested? Should all patients with dyspepsia be evaluated for *H. pylori*, or can specific subgroups of patients be identified for whom testing will yield the greatest benefit? The American College of Gastroenterology advocates

a test-and-treat approach for *H. pylori* among certain patients who present with previously uninvestigated dyspepsia. This approach is acceptable for patients age <55 years and without alarm features (see Box 70.2). Noninvasive *H. pylori* testing (i.e., stool antigen) is reasonable in this population, particularly in regions where the prevalence of *H. pylori* is high. An alternative to the *H. pylori* test-and-treat approach in this group of patients is to begin with empirical antisecretory therapy (with H<sub>2</sub>-receptor antagonist or PPI) and cessation of any NSAID use for 4 weeks, followed by *H. pylori* testing if symptoms persist. Endoscopy is indicated for persistent symptoms, for patients with alarm features, and in patients age >55 years.

The most common noninvasive diagnostic tests for *H. pylori* are the *H. pylori* serology test, *H. pylori* stool antigen, and the urea breath test (Table 70.1). The serologic test for antibodies against *H. pylori* is widely available and approximately 80% sensitive, but specificity is significantly lower and it cannot necessarily distinguish between active and prior infection. For this reason, the stool antigen and urea breath test are generally preferred when available because they identify active infection only. The urea breath test is somewhat laborious and involves ingestion of radiolabeled urea, followed by measurement of the exhaled carbon isotope, which is released only in the presence of *H. pylori* urease activity. Fecal antigen testing for *H. pylori* is a third option and offers perhaps the best balance of cost, convenience, and accuracy, with sensitivity and specificity similar to those of the urease breath test. The urease breath test and fecal antigen tests are the best options when documentation of *H. pylori* eradication is required, although the fecal antigen test may remain positive for several weeks after antibiotic eradication therapy.

Histologic examination of mucosal biopsies obtained during endoscopy is considered the gold standard for evaluation of *H. pylori* infection with a sensitivity and specificity surpassing 95%. Multiple biopsy samples are recommended for optimal sensitivity. Samples should be obtained from the stomach antrum and body. Biopsy samples can also be assessed for *H. pylori* urease activity via a commercially available rapid urease test. The rapid urease test may be an excellent option if histologic processing and evaluation are not readily available. *H. pylori* culture is another diagnostic option and can provide information regarding antibiotic sensitivity; however, culturing the organism is technically challenging, and the sensitivity is

**TABLE 70.1** Selected Treatment Regimens for *Helicobacter pylori*

Regimen	Comments
Amoxicillin 1000 mg bid + Clarithromycin 500 mg bid + PPI bid (duration 10–14 days)	Typical first-line regimen, eradication rate ~85% in United States
Metronidazole 250 mg qid + Clarithromycin 500 mg bid + PPI bid (duration 10–14 days)	Reasonable for PCN-allergic patients. eradication rate ~85% in United States
Bismuth subsalicylate 525 mg qid + Metronidazole 250 mg qid + Tetracycline 500 mg qid + PPI bid (duration 10–14 days)	Reasonable for PCN-allergic patients, eradication rate ~85% in United States. Complicated regimen. May be more effective for strains resistant to clarithromycin or metronidazole.

*bid*, Twice daily; *PCN*, penicillin; *PPI*, proton-pump inhibitor; *qid*, four times daily.

generally lower than that of histologic examination. Polymerase chain reaction (PCR) tests are also being developed, which may have the advantage of very high sensitivity and specificity and may also provide important information regarding antibiotic sensitivity.

### Endoscopic and Radiographic Evaluation

Esophagogastroduodenoscopy (EGD) is the diagnostic modality of choice for the investigation for dyspepsia in patients age >55 years, for those with alarm symptoms (see [Box 70.2](#)), and for patients with dyspepsia that has persisted despite antisecretory therapy and/or the test-and-treat approach for *H. pylori*. Endoscopic evaluation provides several advantages over barium radiography and CT scan in the investigation of possible PUD. Endoscopy provides direct visualization of the mucosa, an opportunity for biopsy sampling of any abnormal findings including *H. pylori* histology, and an opportunity for intervention in the case of active ulcer bleeding. Nonbleeding ulcers may have endoscopic stigmata that suggest recent bleeding and increased likelihood of rebleeding. A clean-based ulcer ([Fig. 70.2B](#)) is less likely to rebleed than an ulcer with active bleeding at the time of initial endoscopic evaluation (see [Fig. 70.2A](#)). Stigmata such as a nonbleeding visible vessel (see [Fig. 70.2C](#)), an adherent blood clot, or a pigmented flat spot also predict a higher likelihood of recurrent bleeding. Among endoscopic findings of PUD, active bleeding during initial endoscopy predicts the highest rebleeding risk.

Repeat endoscopy is not required in the case of a duodenal ulcer if symptoms resolve with antisecretory therapy and/or *H. pylori* eradication treatment. Gastric ulcers are managed differently because gastric malignancy can be mistaken for PUD ([Fig. 70.3](#)). The classic teaching is that gastric ulcers require at least seven biopsy specimens to effectively rule out malignancy, and many clinicians also recommend follow-up endoscopies to document complete healing of the ulcer. Although adequate biopsy sampling is mandatory, the cost effectiveness of requiring follow-up endoscopies for all gastric ulcers is controversial, particularly in patients with clear risk factors for ulcer formation (e.g., NSAID use or *H. pylori* infection).

Upper GI radiographs with barium (i.e., upper GI series) have excellent sensitivity for the identification of gastric and duodenal ulcers, but they are not frequently used in the investigation of PUD because of the advantages of endoscopic visualization and biopsy. Endoscopy has the added capability of identifying more subtle abnormalities, such as gastritis or erosions, that may cause symptoms but cannot be identified radiographically.

Upright chest radiograph is the initial test of choice if perforation is suspected, and many recommend a second plain film (either a supine abdominal film or left lateral decubitus film) for optimal detection of free air. Abdominal CT and/or abdominal ultrasound can sometimes provide additional information if the suspicion for perforation remains high despite negative chest x-ray. Suspected gastric outlet obstruction can be evaluated initially by abdominal CT or upper endoscopy, but endoscopy remains mandatory early in the evaluation to obtain biopsies to evaluate for malignancy.

### Treatment of Peptic Ulcer Disease

There are two arms in the treatment approach for PUD: (1) antisecretory therapy and *H. pylori* eradication to heal ulcers and prevent recurrence and (2) medical, endoscopic, and surgical therapies to address the complications of PUD.

#### Antisecretory Therapy

PPIs and H<sub>2</sub>-receptor antagonists are the mainstays of medical therapy for PUD. These two classes of antisecretory medications reduce parietal cell acid production and therefore increase gastric pH. Other medications, such as misoprostol (a prostaglandin), sucralfate, and antacids, are less effective at inducing ulcer healing. In addition, they may require multiple doses per day and no longer play a central role in the treatment of PUD.

#### Proton-Pump Inhibitors

PPIs are the most effective class of medications for decreasing gastric acid secretion and inducing rapid healing of gastric and duodenal ulcers. PPIs directly inhibit HCl secretion by irreversibly inactivating the hydrogen-potassium adenosine

• **Fig. 70.2** Duodenal ulcer. (A) Clean-based duodenal ulcer with oozing blood. (B) Actively bleeding ulcer. (C) Visible vessel within base of large ulcer. (D) Duodenal ulcer after bipolar cautery therapy.

• **Fig. 70.3** Gastric ulcer. Large prepyloric gastric ulcer. Biopsies revealed adenocarcinoma.

triphosphatase on the parietal cell surface. The five PPI medications include pantoprazole, omeprazole, esomeprazole, lansoprazole, and rabeprazole. Of these, omeprazole and pantoprazole have been the most extensively studied.

For NSAID-induced gastroduodenal ulcers, one of the largest available studies has shown an ulcer healing rate (in

the setting of ongoing NSAID use) of approximately 80% at 8 weeks with omeprazole 20 or 40 mg daily, compared with a 63% healing rate for ranitidine 150 mg twice daily. Without ongoing NSAID use, the healing rate at 8 weeks on PPI therapy approaches 90%. Similar data exist for other PPIs, and we tend to use the medications within this class interchangeably.

For bleeding peptic ulcers there is clear evidence to support a benefit for PPI therapy. An initial randomized placebo-controlled trial of oral omeprazole alone (i.e., without endoscopic therapy) for treatment of bleeding peptic ulcers demonstrated that the risk of continued bleeding or rebleeding was reduced from approximately 36% with placebo to 11% in the oral omeprazole group. Intravenous (IV) omeprazole given *before* endoscopy for upper GI bleeding appears to help initiate ulcer healing and reduces the need for endoscopic therapy for bleeding. However, a separate study on IV omeprazole given after endoscopic treatment of a bleeding ulcer reduced the rebleeding rate from 22% to 7%. The dosing strategy used in both major studies consisted of an 80-mg omeprazole IV bolus followed by an 8-mg/h IV infusion for 72 hours. Over the course of the last several years, additional studies have lent further support to moving back toward high-dose oral PPI as an acceptable option for hospitalized patients with high-risk bleeding ulcers.

**TABLE 70.2** Diagnostic Evaluation of *Helicobacter pylori*

	Comments
<b>Noninvasive Testing</b>	
Antibody serology	Inexpensive. Approximately 85% sensitive, 80% specific. May remain positive after eradication.
<sup>13</sup> C- or <sup>14</sup> C-urea breath test	More expensive. >90% sensitivity and specificity. Can be used to document eradication.
Fecal antigen	Sensitivity/specificity similar to urea breath test. Can be used to document eradication, although may remain positive for >4 weeks.
<b>Endoscopic Testing</b>	
Histology	Approaching >95% sensitivity and specificity. The gold standard but requires appropriate biopsy sampling, tissue processing, experienced pathologist. Recent PPI or antibiotic use decreases sensitivity.
Rapid urease test	Can be >95% sensitive and specific, but results substantially impacted by PPI therapy. Can provide rapid diagnosis with commercially available kit.
Culture	Technically challenging and not widely available. Can provide information on antibiotic sensitivity.
PCR	Emerging option. Test characteristics include excellent sensitivity/specificity and information on antibiotic sensitivity.

*PCR*, Polymerase chain reaction; *PPI*, proton-pump inhibitor.

After peptic ulcer bleeding or other complications have resolved, there is no clearly defined strategy to determine duration of oral PPI therapy. For large or bleeding ulcers, we typically recommend twice-daily PPI therapy for 4 to 6 weeks. For patients in whom ulcer recurrence appears likely (i.e., those with recurrent PUD or patients who must continue NSAID therapy), it may be reasonable to continue PPI therapy indefinitely.

### **H<sub>2</sub>-Receptor Antagonists**

The H<sub>2</sub>-receptor antagonists, which include ranitidine, famotidine, cimetidine, and nizatidine, are also effective agents for inducing ulcer healing. This class of medications antagonizes the parietal cell histamine receptor, blocking one of the stimuli for parietal cell HCl secretion. H<sub>2</sub>-receptor antagonists and PPIs are both reasonable first-line agents for mild dyspepsia and suspected ulcer disease or gastritis. H<sub>2</sub>-receptor antagonists are not the preferred therapy in the setting of endoscopically identified significant ulcer disease or bleeding ulcers, because PPIs induce more rapid ulcer healing and reduce the chance of rebleeding.

### **Helicobacter pylori Eradication Therapy**

Eradication therapy is mandatory in all patients with PUD who are diagnosed with *H. pylori*. There is strong evidence to suggest that *H. pylori* eradication substantially reduces the risk of ulcer recurrence, including an initial trial that showed an 84% 1-year relapse rate in PUD patients with persistent *H. pylori* versus a 21% relapse rate in patients in whom *H. pylori* was eradicated. The recurrence rate is substantially lower now that *H. pylori* eradication regimens have become more effective using triple or quadruple antibiotic cocktails.

Several standard *H. pylori* eradication regimens are shown in Table 70.2. The three standard regimens used in the United States have eradication rates that are approximately equivalent (~85%). We favor a twice-daily clarithromycin/amoxicillin/PPI combination for ease of use and tolerability. For penicillin-allergic patients, metronidazole is incorporated into the regimen in place of amoxicillin. The third combination in Table 70.2, quadruple therapy with bismuth, may be particularly effective in two groups of patients: those with metronidazole-resistant *H. pylori* and those who have recurrent/persistent infection despite prior macrolide-based combination therapy. The potential disadvantage to bismuth quadruple therapy is the complicated (four times a day) dosing regimen. For all regimens, a 10- to 14-day treatment course is generally advocated, although there are some data in support of shorter duration of therapy. Continuation of PPI therapy after *H. pylori* eradication therapy for PUD is controversial, but mounting evidence suggests that eradication therapy is more important than maintenance PPI therapy in the prevention of ulcer recurrence.

### **Endoscopic Treatment of Peptic Ulcer Disease**

Upper endoscopy is mandatory in nearly all patients with clinical evidence of upper GI bleeding. In the hemodynamically unstable patient with a suspected bleeding ulcer, every effort must be made to adequately resuscitate and stabilize the patient before attempting endoscopy. There are three primary therapeutic modalities in the endoscopic treatment of an actively bleeding peptic ulcer: epinephrine injection, placement of hemoclips, and cautery. Local epinephrine injection likely works in a temporizing fashion by causing tissue tamponade as well as vasoconstriction. Hemoclips and/or cautery

are then used for more definitive treatment. Currently, the optimal endoscopic treatment for a bleeding ulcer consists of local epinephrine injection around the ulcer base, followed by the use of a second hemostatic method (hemoclip or cautery). Fig. 70.2 shows a bleeding duodenal ulcer before (see Fig. 70.2B) and after (see Fig. 70.2D) endoscopic therapy with epinephrine injection and bipolar cautery.

As discussed previously, high-dose PPI therapy (oral or IV) is clearly beneficial after endoscopic treatment of a bleeding ulcer. Biopsies for *H. pylori* are generally not obtained when an endoscopy is performed for hemostatic control of a bleeding ulcer; therefore *H. pylori* stool or serologic testing should be used to assess for infection. Although the identity of duodenal ulcers does not generally require biopsy confirmation, gastric ulcers may harbor malignancy (i.e., gastric adenocarcinoma; see Fig. 70.3) and therefore must be evaluated carefully with multiple biopsy samples as described previously, either during the initial endoscopy or during a follow-up procedure.

### Surgical Treatment of Peptic Ulcer Disease

The need for surgical intervention in PUD has fallen dramatically with the advent of potent antisecretory therapy and the identification of *H. pylori*. Elective surgeries to

reduce acid secretion such as Billroth I or Billroth II antrectomy (or subtotal gastrectomy) and truncal or selective vagotomies are now exceedingly rare. These surgeries reduce acid secretion either by removing the parietal cell mass (antrectomy) or by interrupting vagal stimulation of parietal cells (vagotomy).

Now, surgical management of PUD is focused primarily on the urgent treatment of ulcer perforation (typically at the anterior duodenal bulb and the lesser curvature of the stomach). Surgical intervention typically involves simple closure, omental patch, and/or ulcer excision, all of which may be performed laparoscopically.

Surgery is also a consideration when a bleeding peptic ulcer cannot be controlled endoscopically or with embolization by selective mesenteric angiography, in which case the bleeding ulcer can be oversewn. Finally, gastric outlet obstruction, which is a rare complication of PUD in the era of PPI therapy, is most commonly managed by antrectomy with gastrojejunostomy (Billroth II), with or without vagotomy. The gastroenterologist and surgeon must undertake a careful evaluation for malignancy in the setting of gastric outlet obstruction. Pneumatic dilation by endoscopy may be a viable therapeutic option in carefully selected patients with gastric outlet obstruction caused by PUD.

## Chapter Review

### Questions

- Which of the following statements is/are true regarding *H. pylori*?
  - H. pylori* resides almost exclusively in areas of gastric epithelium.
  - Chronic *H. pylori* infection may be a risk factor for gastric adenocarcinoma and MALT lymphoma.
  - The prevalence of *H. pylori* is rising in most parts of the world.
  - A and B
  - A, B, and C
- Which is the most sensitive and specific test for *H. pylori* infection?
  - H. pylori* antibody serology
  - H. pylori* fecal antigen testing
  - Histologic assessment of gastric biopsy specimen with multiple samples obtained
  - H. pylori* culture of gastric biopsy specimen with at least three samples obtained
  - C and D
- Which of the following should be a primary recommendation for patients with GI bleeding in the setting of NSAID use?
  - Cessation of NSAIDs if possible, initiation of PPI to promote rapid ulcer healing, and consideration of *H. pylori* testing
  - Cessation of NSAIDs if possible, initiation of H<sub>2</sub>-receptor antagonist to promote rapid ulcer healing, and consideration of *H. pylori* testing
  - Administration of COX-2 inhibitors instead of nonselective NSAIDs
  - Evaluation for other risk factors for PUD including Zollinger-Ellison syndrome
  - None of the above
- The optimal treatment of an actively bleeding duodenal ulcer is:
  - Endoscopic therapy with local therapy (cautery, hemoclipping, etc.) and administration of IV H<sub>2</sub>-receptor antagonist
  - Endoscopic therapy with local therapy (cautery, hemoclipping, etc.) and administration of IV or oral PPI
  - Endoscopic therapy with local therapy (cautery, hemoclipping, etc.) without need for antisecretory medication if hemostasis is achieved
  - IV or oral PPI administration, nasogastric lavage, and empirical *H. pylori* eradication
  - IV H<sub>2</sub>-receptor antagonist administration and rapid referral to angiography or surgery
- Which of the following endoscopic findings predicts a high risk of recurrent bleeding?
  - Visible vessel at ulcer base
  - Large size of ulcer (>2 cm)
  - Clean-based ulcer
  - Ulcer location in the duodenal bulb (proximal duodenum)
  - Ulcer location in greater curvature of stomach

## Diarrhea and Malabsorption

MOLLY PERENCEVICH AND ROBERT BURAKOFF

The objective definition of diarrhea is stool weight  $>200$  g/d. The more common subjective definition is frequency of defecation that is greater than or equal to three stools per day combined with less-than-normal form and consistency. Diarrhea is also defined by duration. Acute diarrhea is defined as  $<2$  weeks in duration, persistent diarrhea between 2 and 4 weeks, and chronic diarrhea  $>4$  weeks in duration. In the United States, most cases of acute diarrhea are caused by infections and are self-limited. Noninfectious etiologies are more common in chronic diarrhea. The evaluation and general management of acute and chronic diarrhea are discussed in this chapter.

### Normal Intestinal Physiology

Ten liters of fluid enter the jejunum daily with 2 L from food and drink and 8 L from luminal secretions (salivary, gastric, biliary, and pancreatic). Of this, 1 L enters the colon, and approximately 80 to 100 mL are ultimately excreted daily. This reflects the incredible reabsorptive capacity of the intestine. Diarrhea usually represents a 100 mL (or 1%–2%) increase in fecal fluid. Many disorders that cause diarrhea do so by disrupting this physiology.

### Acute Diarrhea

#### Etiology

The most common causes of acute diarrhea are infective illnesses (90% of cases). Infective etiologies include viruses, bacteria, and protozoa (Box 71.1). Noninfective causes include medications (Box 71.2), poorly absorbed sugars (e.g., sorbitol), enteral feeding, ischemic colitis, and diverticulitis. Fecal incontinence and fecal impaction with associated leakage should also be considered in the evaluation of diarrhea.

#### Evaluation

Fig. 71.1 shows an algorithm for the evaluation of acute diarrhea. The history and physical examination can help you decide how much evaluation to pursue. Ninety percent of cases of acute diarrhea do not need diagnostic evaluation because the majority of cases are mild and self-limited.

However, there are several clinical features that require additional testing. These include the following:

- Grossly bloody diarrhea
- Profuse diarrhea leading to dehydration and hypovolemia
- Severe abdominal pain (especially if age  $>50$  years)
- Temperature  $\geq 101.3^{\circ}\text{F}$  ( $38.5^{\circ}\text{C}$ )
- Recent hospitalization or use of antibiotics
- Duration  $\geq 48$  hours
- Diarrhea in patients who are immunocompromised or elderly ( $\geq 70$  years of age)
- Diarrhea with systemic symptoms in a pregnant patient (listeriosis should be considered)
- Diarrhea in the setting of an outbreak or if public health implications (food handlers, daycare center workers, nursing home residents, health care workers)

A detailed history about possible exposures can contribute to identifying the etiology of acute diarrhea. Several epidemiologic factors should be assessed. Patients should be asked about local and international travel. Traveler's diarrhea is caused most commonly by enterotoxigenic *Escherichia coli* and is found in endemic regions of Latin America, Africa, and Asia. Enteraggregative *E. coli* is also a cause of traveler's diarrhea. Other pathogens commonly associated with travel include *Giardia*, *Cyclospora*, and *Entamoeba histolytica*. Travel on a cruise ship is a risk factor for Norwalk virus. *Giardia* is a consideration in patients who have been camping and backpacking in wilderness areas and drinking water that has not been adequately treated.

Exposures including specific foods as well as outbreaks related to food handling should be evaluated. Specific foods include the following:

- Chicken: *Salmonella*, *Campylobacter*, *Shigella*
- Undercooked hamburger, salad greens, bean sprouts: enterohemorrhagic *E. coli* (O157:H7)
- Deli meat: *Listeria*
- Unpasteurized dairy products: *Listeria*, *Salmonella*, *Campylobacter*
- Mayonnaise or creams: *Staphylococcus aureus*, *Salmonella*
- Eggs: *Salmonella*
- Fried rice: *Bacillus cereus*
- Seafood (especially raw): *Vibrio* species, *Salmonella*

A patient's immune status is important to establish. Immunocompromised patients include those with primary immunodeficiency as well as acquired immunodeficiency (such as

Microsporidia  
*Cyclospora cayetanensis*  
*Cystoisospora belli*  
*Entamoeba histolytica*

### • BOX 71.2 Medications That Can Cause Diarrhea

Antibiotics  
Chemotherapeutic agents  
Antiinflammatory agents: NSAIDs, 5-aminosalicylates, gold  
Antiarrhythmics: quinidine, digoxin  
Antihypertensives: beta-blockers  
Antacids: especially those containing magnesium  
Acid-suppressive medications: proton-pump inhibitors,  
histamine-2 receptor antagonists  
Colchicine  
Prostaglandins: misoprostol  
Theophylline  
Antidepressants: some SSRIs (citalopram, sertraline)  
Metformin  
Vitamin and mineral supplements

NSAIDs, Nonsteroidal antiinflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

AIDS, malignancy, and immunosuppressive medications). In addition to common pathogens (which can cause more severe disease), these patients are also at risk of other opportunistic infections. Opportunistic infections include mycobacterium species, viruses (cytomegalovirus, herpes simplex virus), and protozoa (*Cryptosporidium*, *Cystoisospora belli*, *Cyclospora*, microsporidia). Neutropenic patients are at risk of developing necrotizing enterocolitis (also called *typhlitis*), which is caused by invasion of enteric flora in the setting of mucosal injury. Proctocolitis can be caused by agents transmitted per rectum such as *Neisseria gonorrhoeae*, *Chlamydia*, *Treponema pallidum*, and herpes simplex virus. Patients with hemochromatosis are at risk of infections with *Vibrio* species and *Yersinia*.

Additional exposures important to evaluate for include exposure to small children and daycares, as well as hospitalization and recent antibiotics. People with children at a day-care center or who work at a daycare center are at increased

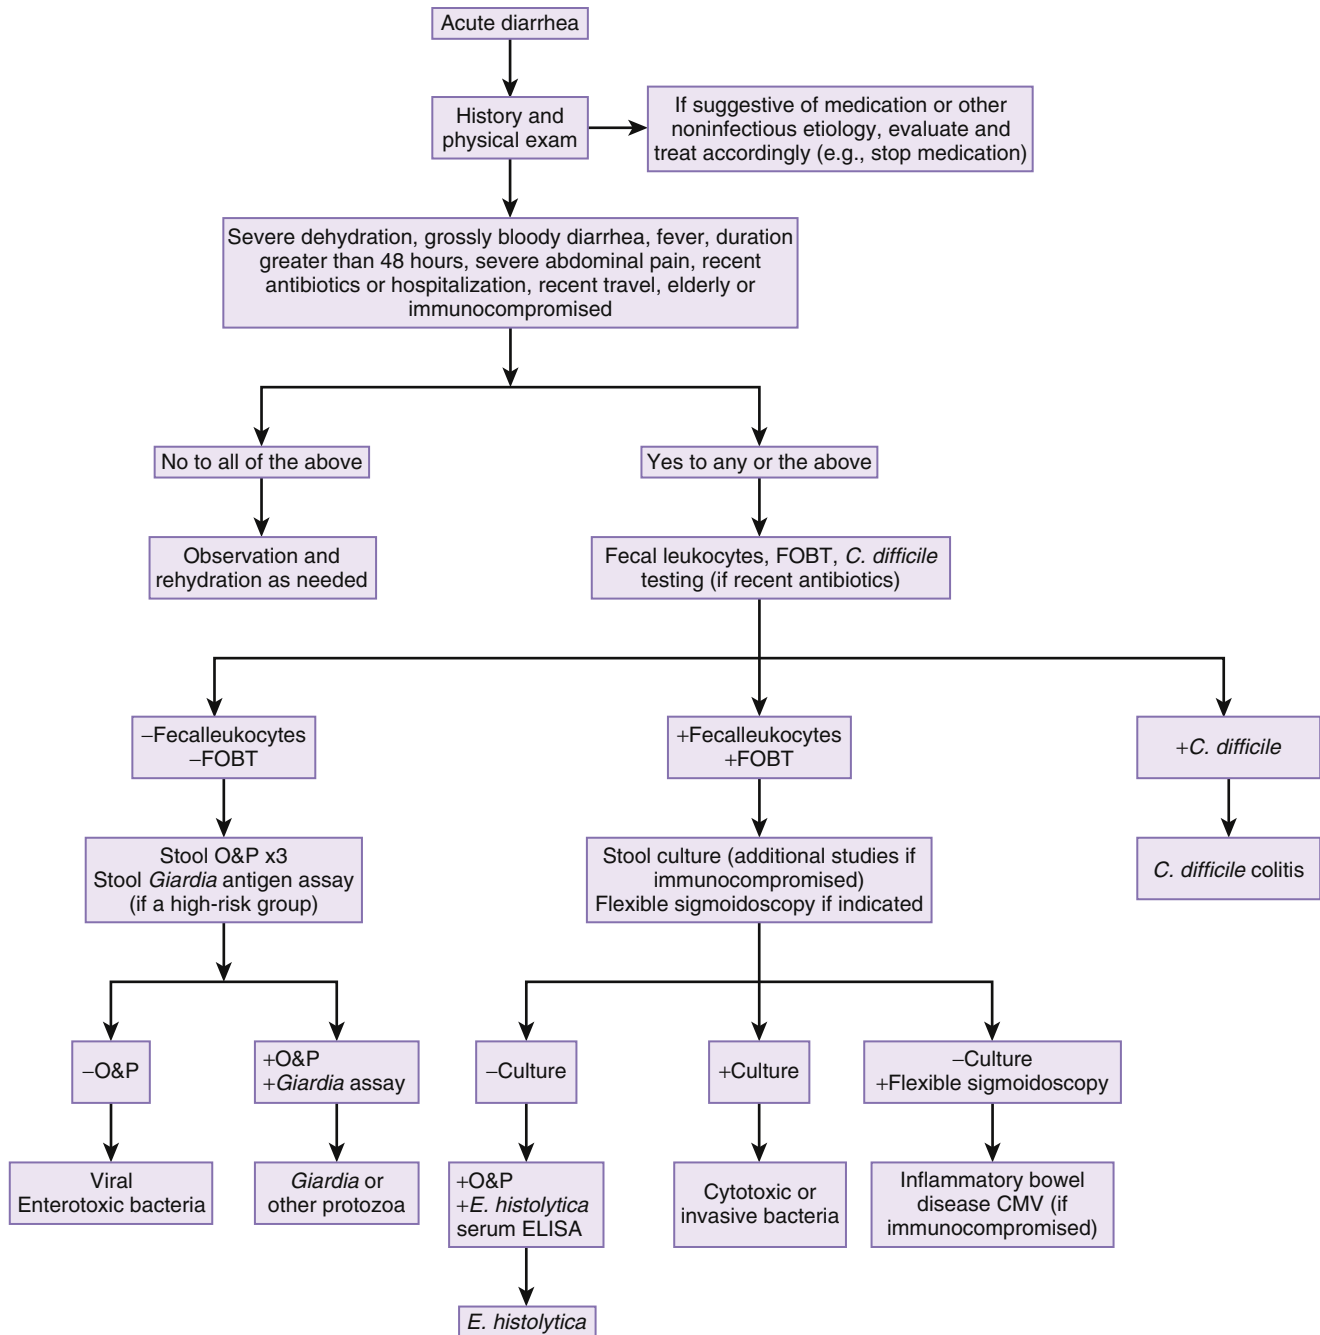

risk of infections with *Shigella*, *Giardia*, *Cryptosporidium*, and rotavirus. Risk of *Clostridium difficile* infection is higher in people with recent or current antibiotic use or exposure to health care facilities.

Incubation periods can sometimes be helpful in determining whether an exposure is a likely cause of symptom (Table 71.1). Food poisoning from preformed bacterial toxins (*S. aureus*, *B. cereus*, and *Clostridium perfringens*) usually occurs within 12 hours of exposure. The incubation period for *Salmonella* (nontyphoidal) is approximately 24 hours, whereas the majority of the other pathogens range from several days to 2 weeks.

Symptoms can also help in determining the etiology of infectious diarrhea. Key symptoms to assess for include fever, nausea and vomiting, abdominal pain, quality of diarrhea (watery, bloody, mucoid), and quantity of diarrhea (volume, frequency). The clinical picture is often related to the pathophysiology of the organism, including the location of pathogen activity (small vs. large bowel; Table 71.2) and the pathogenic mechanism (toxin production, adherent vs. invasive organisms; see Table 71.1).

Infections of the small bowel often result in larger volume and less frequent diarrhea compared with infections of the colon, which usually result in more frequent and smaller-volume diarrhea. This is caused by the greater absorptive capacity of the small intestine and reservoir capacity of the distal colon. Diarrhea caused by pathogens involving the colon more often have blood and evidence of inflammation in the stool (described further in the next section). The pathogenic mechanisms listed in Table 71.1 also correlate with symptoms. In general, pathogens whose mechanisms involve preformed toxins, enterotoxins, and adherence to enterocytes, as well as most viruses, tend to have a clinical picture with more vomiting and watery diarrhea. In comparison, pathogens that produce cytotoxins or are more invasive cause an inflammatory diarrhea with predominant abdominal pain, fever, and bloody

• **Fig. 71.1** Algorithm for the evaluation of acute diarrhea. *CMV*, Cytomegalovirus; *ELISA*, enzyme-linked immunosorbent assay; *FOBT*, fecal occult blood test; *O&P*, ova and parasites. (Modified from Sabatine MS, ed. *Pocket Medicine: The Massachusetts General Hospital Handbook of Internal Medicine*. 3rd ed. Baltimore: Lippincott Williams & Wilkins; 2004.)

diarrhea. Of note, unlike many other causes of inflammatory diarrhea, enterohemorrhagic *E. coli* (O157:H7) can present without a fever.

Several organisms have unique clinical syndromes and complications (Table 71.3). Some organisms are more likely to cause significant dehydration or vomiting as well as gastrointestinal complications such as hemorrhagic colitis and toxic megacolon. *Salmonella* has several clinical syndromes, including enteric (typhoid) fever, which is

characterized by a prolonged fever in addition to gastrointestinal and other symptoms, gastroenteritis, bacteremia, endovascular infections, localized infections (e.g., joints), and a carrier state. Enterohemorrhagic *E. coli* (O157:H7) and *Shigella* can cause hemolytic uremic syndrome. Several organisms are associated with reactive arthritis, including *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, and *C. difficile*. This is an immune-mediated aseptic synovitis that usually occurs 1 to 3 weeks after onset of the diarrhea.

**TABLE 71.1 Association Between Pathogenic Mechanism and Clinical Features**

Pathogens	Incubation Period	Fever	Nausea, Vomiting	Abdominal Pain	Diarrhea	Blood in Stool	Fecal Leukocytes
<b>Preformed Bacterial Toxins</b>							
<i>Bacillus cereus</i> , <i>Staphylococcus aureus</i>	1–8 h	–/+	+++	++	+++ (watery)	–	–
<i>Clostridium perfringens</i>	8–16 h	–/+	+++	++	+++ (watery)	–	–
<b>Enterotoxin-Producing</b>							
Enterotoxigenic <i>Escherichia coli</i> , <i>Vibrio cholerae</i>	8–72 h	–/+	++	++	+++ (watery)	–	–
<b>Enteroadherent</b>							
Enteropathogenic, enteroaggregative, and enteroadherent <i>E. coli</i> ; <i>Giardia</i> , <i>Cryptosporidium</i>	1–8 days	–/+	+	++	++ (watery)	–	–
<b>Cytotoxin-Producing</b>							
Enterohemorrhagic <i>E. coli</i> (O157:H7)	12–72 h	+	–/+	+++	++ (initially watery, quickly bloody)	+	+
<i>Clostridium difficile</i>	1–3 days	+	–/+	+++	++ (usually watery, sometimes bloody)	+	+
<b>Invasive Organisms</b>							
Minimal inflammation: rotavirus, Norwalk virus	1–3 days	+++	++	++	++ (watery)	–	–
Variable inflammation: <i>Salmonella</i> , <i>Campylobacter</i> , <i>Vibrio parahaemolyticus</i> , <i>Yersinia</i>	12 h–11 days	+++	–/+	++	++ (watery or bloody)	+	+
Severe inflammation: <i>Shigella</i> , enteroinvasive <i>E. coli</i> , <i>Entamoeba histolytica</i>	12 h–8 days	+++	–/+	+++	++ (bloody)	+	+

From Camilleri M, Murray JA. In: Fauci AS et al, eds. *Harrison's Principles of Internal Medicine*. 17th ed. New York: McGraw-Hill; 2008; Thielman NM, Guerrant RL. Acute infectious diarrhea. *N Engl J Med*. 2004;350:42.

The arthritis is usually asymmetrical, monoarthritis, or oligoarthritis of usually the large joints. There can also be enthesopathy, sacroiliitis, and dactylitis (sausage digits) of the extremities. *Campylobacter jejuni* is also associated with Guillain-Barré syndrome with onset usually within 3 months of diarrhea. Treatment with antibiotics does not prevent Guillain-Barré or reactive arthritis. *Yersinia* can have a clinical presentation that mimics acute appendicitis because of localization in the right lower quadrant, and onset can be more insidious than other causes of acute infectious diarrhea. It can also be associated with erythema nodosum as well as reactive arthritis. Listeriosis is

of particular concern in pregnancy because it can cause miscarriage, preterm delivery, and neonatal infection that can result in death. In addition to a febrile gastroenteritis, it can cause a nonspecific viral-type syndrome and a more delayed presentation of bacteremia and central nervous system infections. *C. difficile* is a particular concern in patients with inflammatory bowel disease.

### Physical Examination

The physical examination is important to assess for degree of dehydration, fever, abdominal pain, and peritoneal signs, which will help guide evaluation and treatment.

**TABLE 71.2 Association Between Location of Infection and Clinical Features**

	Small Bowel	Colon
Pathogens	<i>Vibrio cholerae</i> <i>Escherichia coli</i> : enterotoxigenic, enteropathogenic, enteroaggregative, and enteroadherent <i>Salmonella</i> <sup>ab</sup> Rotavirus Norovirus <i>Giardia lamblia</i> <i>Cryptosporidium</i>	<i>Shigella</i> <i>Escherichia coli</i> : enterohemorrhagic (O157:H7), enteroinvasive <i>Campylobacter</i> <sup>a</sup> <i>Yersinia</i> <sup>a</sup> <i>Clostridium difficile</i> Cytomegalovirus <i>Entamoeba histolytica</i>
Location of abdominal pain	Midabdomen	Lower abdomen, rectum
Volume of stool	Large	Small
Type of stool	Watery	Mucoid
Frequency of stool	Frequent	Very frequent
Visible blood in stool	Rare	Common
Fecal leukocytes	Rare	Common (except <i>E. histolytica</i> )

<sup>a</sup>These pathogens can involve the small or large bowel, although most commonly affect the location under which they are listed.  
<sup>b</sup>*Salmonella typhi* and *S. paratyphi* act predominantly at the small bowel, whereas nontyphoidal *Salmonella* acts at both the small bowel and colon.  
 From Hamer DH, Gorbach SL. Infectious diarrhea and bacterial food poisoning. In: Feldman M et al, eds. *Sleisenger & Fordtran's Gastrointestinal and Liver Diseases*, 7th ed. Philadelphia: WB Saunders; 2002:1864–1913.

**TABLE 71.3 Complications Associated With Pathogens Causing Infectious Diarrhea**

Complication	Pathogens
Dehydration	<i>Vibrio cholerae</i> , enterotoxigenic <i>Escherichia coli</i> , rotavirus
Severe vomiting	Preformed toxins ( <i>Staphylococcus aureus</i> , <i>Bacillus cereus</i> , <i>Clostridium perfringens</i> ), rotavirus, norovirus
Hemorrhagic colitis	Enterohemorrhagic <i>E. coli</i> (O157:H7), <i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i> , <i>Vibrio parahaemolyticus</i>
Toxic megacolon, intestinal perforation	<i>Shigella</i> , enterohemorrhagic <i>E. coli</i> (O157:H7), <i>Clostridium difficile</i>
Hemolytic-uremic syndrome	Enterohemorrhagic <i>E. coli</i> (O157:H7), <i>Shigella</i>
Reactive arthritis	<i>Shigella</i> , <i>Salmonella</i> , <i>Yersinia</i> , <i>Campylobacter</i> , <i>C. difficile</i>
Distant localized infections	<i>Salmonella</i>
Guillain-Barré syndrome	<i>Campylobacter</i>
Mimic of appendicitis	<i>Yersinia</i>
Erythema nodosum	<i>Yersinia</i>

From Hamer DH, Gorbach SL. Infectious diarrhea and bacterial food poisoning. In: Feldman M et al, eds. *Sleisenger & Fordtran's Gastrointestinal and Liver Diseases*. 7th ed. Philadelphia: WB Saunders; 2002:1864–1913.

### Initial Laboratory Evaluation

A serum complete blood count, electrolytes, and renal function can be used to assess for evidence of inflammation, dehydration, and electrolyte depletion. These are helpful in assessing the severity of the diarrhea. Eosinophilia can be seen in parasitic infections. Blood cultures can also be considered if a patient is sick and toxic appearing, especially if *Salmonella* is suspected, because it can often cause bacteremia and associated endovascular or localized infections.

### Stool Studies

Tests for fecal leukocytes and occult blood can be considered, although they have variable sensitivity and specificity. The standard method for assessment of fecal leukocytes is the Wright stain. However, there is variable sensitivity and specificity of the tests depending on processing and observer expertise. An alternative test is the fecal lactoferrin latex agglutination assay. Lactoferrin is a neutrophil product and therefore a marker of fecal leukocytes. This test has better

sensitivity and specificity, but it is not widely available. Tables 71.1 and 71.2 show the correlation between location and pathogenic mechanism to the presence of fecal blood and leukocytes. The presence of fecal leukocytes and occult blood often suggests a bacterial and inflammatory etiology for the diarrhea. Common bacterial etiologies include *Campylobacter*, *Salmonella*, *E. coli* O157:H7, *Shigella*, and *C. difficile*. The protozoa *E. histolytica* also causes an inflammatory diarrhea, although it often has relatively few fecal leukocytes.

If the stool is negative for fecal leukocytes and occult blood, and the patient is not severely ill, you can consider treating symptomatically for several days. The most likely etiology is either viral (>75%) or bacterial pathogens elaborating a preformed toxin or enterotoxin. Stool culture is positive in only up to 5% of these cases and is therefore not frequently informative. Diagnostic tests for viruses are not typically used. However, stool culture should be considered in several clinical settings:

- Patients with severe and bloody diarrhea: stool cultures may have higher utility with cultures positive in 40% to 60% of cases
- Immunocompromised patients
- Sick patients with significant comorbidities
- Patients with inflammatory bowel disease: higher risk of *C. difficile* infection
- Men who have sex with men: higher risk of infectious proctitis
- Food handlers or concern for outbreak

Routine culture usually includes *Campylobacter*, *Salmonella*, and *Shigella*. You may need to notify the laboratory to test for specific pathogens such as *E. coli* O157:H7 and *Yersinia*. A single specimen should be adequate for diagnosis because bacteria are shed continuously.

Additional stool testing should be done based on the clinical picture. If a patient has had a recent hospitalization or exposure to antibiotics within the past several months, stool testing for *C. difficile* should be performed. In addition, all patients with inflammatory bowel disease with new or worsening diarrhea should be evaluated for *C. difficile* infection. There are several tests that can be performed to test for *C. difficile*, including enzyme immunoassay (EIA) for glutamate dehydrogenase (GDH) antigen, EIA for toxins A and B, and polymerase chain reaction (PCR). An algorithm is often used that involves initial screening with EIA for GDH antigen and toxins A/B. If both are negative, *C. difficile* is unlikely; if both are positive, *C. difficile* infection is diagnosed; and if one is positive, then PCR is performed. If proctitis is suspected, a rectal swab can be done to assess for *Neisseria gonorrhoea*, *Chlamydia*, and herpes simplex virus.

Testing stool for parasites is not indicated for most patients with acute diarrhea, but it should be performed in high-risk groups. These include the following:

- Community waterborne outbreak: *Giardia*, *Cryptosporidium*
- Consumption of untreated water: *Giardia*

- Exposure to daycare centers: *Giardia*, *Cryptosporidium*
- Travel to endemic countries: *Giardia*, *Cryptosporidium*, *E. histolytica*
- Men who have sex with men: *Giardia*, *E. histolytica*
- Patients with AIDS: *Giardia*, *E. histolytica*, microsporidia, *Cyclospora*, *Cystoisospora belli*
- Bloody diarrhea with few or no fecal leukocytes: *E. histolytica*
- Persistent diarrhea for longer than 14 days

Because there is intermittent shedding of the pathogens (in contrast to bacteria), three specimens should be sent on consecutive days to evaluate for ova and parasites (O&P). Additional stool stains (acid-fast, trichrome) and antigen immunoassays can enhance detection of protozoa. For example, there is a stool antigen immunoassay for *Giardia* and a serum serologic test enzyme-linked immunosorbent assay for *E. histolytica*.

Stool and blood testing are generally not adequate to evaluate for enteral viral infections such as cytomegalovirus and herpes simplex virus, and endoscopic evaluation is typically needed to obtain biopsies for histology and staining.

Pathogens that should be reported to government agencies include *Salmonella*, *Shigella*, *E. coli* O157:H7, *Vibrio cholerae*, *Giardia*, and *Cryptosporidium*.

### Radiologic Evaluation

Radiologic evaluation is rarely indicated unless the patient is severely ill or has symptoms of obstruction or peritonitis. X-rays and CT scans can be used to assess for colitis, ileus, obstruction, toxic megacolon, and perforation.

### Endoscopic Evaluation

Endoscopic evaluation is rarely needed in the evaluation of acute diarrhea, but it should be considered in several patient groups. It may be considered when a diagnosis of inflammatory bowel disease is being considered and when a diagnosis of ischemic colitis is suspected but not clear. Immunocompromised or other high-risk patients should have endoscopy to evaluate for cytomegalovirus or herpes simplex virus. Endoscopy can also be used to diagnose *C. difficile* infection by identification of pseudomembranous colitis, although this is used less frequently now with better stool testing, and the absence of this finding does not exclude it (especially in inflammatory bowel disease).

Flexible sigmoidoscopy is usually performed instead of colonoscopy in the evaluation of acute diarrhea because it is usually adequate for diagnosis with decreased associated risks (such as perforation).

### Treatment

#### Supportive Therapy

Rehydration is a principal part of supportive therapy for acute diarrhea. Oral rehydration can be very effective in many patients who are not severely dehydrated. The most effective oral solutions act on the glucose-sodium cotransporter, which remains intact in many diarrheal illnesses. The

presence of glucose and salt allows the intestine to absorb water from the lumen. The World Health Organization (WHO)-recommended oral rehydration solution (ORS) is composed of 13.5 g glucose, 2.6 g sodium chloride, 1.5 g potassium chloride, and 2.9 g trisodium citrate per liter of water. Commercially available ORS with similar osmolarity can also be used. Beverages intended for sweat replacement (e.g., Gatorade) do not have enough sodium and are not equivalent to ORS. However, they are often sufficient for mild cases in otherwise healthy people. Combinations of diluted fruit juices and salted broths can be used in a similar manner. Intravenous fluids (0.9% normal saline or lactated Ringer) are often required in profoundly dehydrated patients.

Diet modification can also help with symptoms. In addition, adequate nutrition is important for regeneration of enterocytes. Boiled starches or cereals with salt, as well as the BRAT diet (bananas, rice, apple sauce, toast), are options. Because temporary postinfectious lactose malabsorption is common, a lactose-free diet is often helpful. In addition, avoiding alcohol, caffeine, and sugar substitutes may improve symptoms.

Other measures to improve symptoms include stopping any medications that are not necessary and may be contributing to the diarrhea (such as stool softeners) as well as adjustment of tube feeds (dilute to provide hydration, decrease rate, or add fiber) if relevant.

### Antidiarrheal Agents

Antidiarrheal agents can be considered in patients with mild-to-moderate nonbloody diarrhea and no significant fevers. Antimotility agents that decrease peristalsis include loperamide and diphenoxylate atropine. Loperamide (Imodium) is usually dosed at 4 mg initially and then 2 mg after each loose bowel movement with a maximum of 16 mg/d for 2 days. Diphenoxylate atropine (Lomotil) is usually dosed at one to two tablets (each tablet is 5 mg) up to four times per day for 2 days. It has central opiate and anticholinergic properties. Both agents can cause hemolytic uremic syndrome in patients infected with enterohemorrhagic *E. coli* (O157:H7). Bismuth subsalicylate (Kaopectate, Pepto-Bismol) is another antidiarrheal agent. It provides better symptom relief than placebo, but it is not as good as loperamide. The dose is 525 mg every 30 to 60 minutes up to eight doses per day for 2 days. It also helps with symptoms of nausea. Probiotics (such as lactobacillus, acidophilus, *Saccharomyces boulardii*) have potential roles in the treatment of traveler's diarrhea and *C. difficile* colitis.

### Empirical Antibiotic Therapy

Empirical antibiotic therapy has not been shown to have significant benefit in patients with mild community-acquired diarrhea in otherwise healthy patients, and it is not generally recommended in these cases. However, empirical antibiotic therapy is recommended in several patient populations:

- Severely ill immunocompetent patients with clinical features of fever, bloody diarrhea, dehydration, and more than six stools per day or symptoms for longer than 1 week
- Immunocompromised (AIDS, malignancy, transplant recipients) and elderly patients (age  $\geq 70$  years) with significant comorbidities
- Moderate-to-severe traveler's diarrhea (more than four stools per day, fever, blood or mucus in stool)
- *C. difficile* colitis

Empirical antibiotics should be avoided in patients with suspected or documented infection with enterohemorrhagic *E. coli* because there is concern for increasing toxin production and risk of causing hemolytic uremic syndrome.

Fluoroquinolones are frequently used as empirical antibiotic therapy. Ciprofloxacin 500 mg twice daily, levofloxacin 500 mg once daily, and norfloxacin 400 mg twice daily are typically used for 3 to 5 days. Alternative agents, especially if fluoroquinolone resistance is suspected, are azithromycin 500 mg daily for 3 days and erythromycin 500 mg twice daily for 5 days. Fluoroquinolone resistance is of particular concern if *Campylobacter* is suspected; the high rate of resistance is thought to be related to widespread use of fluoroquinolones in poultry feeds. For traveler's diarrhea, in addition to fluoroquinolones and azithromycin, rifaximin 200 mg three times daily for 3 days is also effective, although its utility in invasive diarrhea is not clear, and there is also *Campylobacter* resistance. Empirical treatment for *C. difficile* and *Giardia* can be initiated if clinically suspected while physicians are awaiting confirmatory studies. It is also reasonable to start empirical therapy if there is high clinical suspicion for *Listeria* in a pregnant patient or for severe *V. cholera* infection.

If an intestinal pathogen is identified, the appropriate antibiotic therapy should be initiated as outlined in [Table 71.4](#). Antibiotics are not generally recommended in enteric *Salmonella*, *Yersinia*, and *Campylobacter* infections unless the patient is severely ill, immunosuppressed, or has significant comorbidities. However, because bacteremia can occur in patients with *Salmonella* infections, patients who are at increased risk of seeding other sites (including patients age  $>50$  years and those who are immunosuppressed or have sickle cell disease, vascular grafts, artificial joints, or valvular heart disease) should receive antibiotics.

## Chronic Diarrhea

### Etiology

The etiologies of chronic diarrhea are more diverse and the evaluation often less clear. In developed countries, the major causes of chronic diarrhea are irritable bowel syndrome, inflammatory disorders (such as inflammatory bowel disease), malabsorption syndromes (such as lactose intolerance and celiac disease), and chronic infections (especially in immunocompromised patients). In developing countries chronic infections (bacterial, mycobacterial, parasitic) are the

TABLE  
71.4

## Antimicrobial Therapy for Infectious Causes of Acute Diarrhea

	First-Line Treatment	Comments and Alternative Treatment
<b>Bacteria</b>		
<i>Staphylococcus aureus</i> , <i>Bacillus cereus</i> , <i>Clostridium perfringens</i>	Not needed	
<i>Salmonella</i> Enteric (typhoid) fever Nontyphoidal Salmonellosis	FQ for 7–10 days <sup>b</sup> FQ for 3–7 days <sup>ab</sup>	Increasing FQ resistance. Alt: CTX, azithromycin. Alt: CTX, azithromycin, TMP/SMX

<i>Yersinia</i>	FQ for 5 days <sup>a</sup>	Alt: TMP/SMX
Enterotoxigenic, enteroinvasive, enteropathogenic, enteroaggregative, and enteroadherent <i>Escherichia coli</i>	FQ for 1–3 days	Alt: azithromycin, TMP/SMX
Enterohemorrhagic <i>E. coli</i> (O157:H7)	Not advised	Antibiotics should be avoided
<i>Vibrio cholerae</i> , <i>Vibrio parahaemolyticus</i>	Doxycycline (single dose)	Alt: FQ, macrolides
<i>Clostridium difficile</i>	Oral metronidazole and/or vancomycin for 10–14 days	Stop offending antibiotics if possible. Treatment depends on severity. Alt: fidaxomicin.
<b>Viruses</b>		
Norovirus, rotavirus, adenovirus	No antibiotic therapy	
Cytomegalovirus	Ganciclovir or valganciclovir for 2–3 weeks, may be followed by maintenance therapy	Usually only in immunocompromised patients. Alt: foscarnet.
<b>Protozoa</b>		
<i>Giardia lamblia</i>	Metronidazole for 7–10 days	Alt: tinidazole, nitazoxanide
<i>Entamoeba histolytica</i>	Metronidazole for 7–10 days	Alt: tinidazole, nitazoxanide. Followed by luminal amebicides (paromomycin, diloxanide furoate) for 7–10 days to prevent recurrence
<i>Cryptosporidium</i>	Nitazoxanide for 3 days if immunocompetent, <sup>a</sup> 14+ days if HIV	Immune reconstitution in patients with AIDs is critical
Microsporidia	Albendazole for 2–4 weeks	Fumagillin for <i>E. bienersi</i> . Immune reconstitution in patients with AIDs is critical.
<i>Cystoisospora belli</i> , <i>Cyclospora</i>	TMP/SMX for 7–10 days <sup>b</sup>	Alt: ciprofloxacin, nitazoxanide. Patients with AIDS may benefit from immune reconstitution and maintenance therapy.

<sup>a</sup>Antibiotics only if severe or if significant comorbidities.

<sup>b</sup>Longer duration (typically 14 days) if patient has complications or immunosuppressed.

Alt, Alternatives; CTX, ceftriaxone; FQ, fluoroquinolones (ciprofloxacin, norfloxacin, or levofloxacin); TMP/SMX, trimethoprim/sulfamethoxazole.

most common causes of chronic diarrhea. Medications can also cause chronic diarrhea (see [Box 71.2](#)). In addition, fecal incontinence and fecal impaction with associated leakage should be considered in the evaluation of chronic diarrhea.

Chronic diarrhea can be characterized by pathophysiologic mechanism as osmotic, secretory, inflammatory, steatorrheal (fatty), and dysmotility ([Box 71.3](#)). Few etiologies cause diarrhea by one mechanism alone, and most cause diarrhea by several coexisting mechanisms.

### Osmotic Diarrhea

Osmotic diarrhea is caused by the presence of poorly absorbed and osmotically active solutes that cause retention of water in the intestinal lumen. Electrolyte absorption is normal. It is characterized clinically by diarrhea that stops with fasting. There is often a large stool osmotic gap (the difference between the expected and calculated stool osmolarity) of >125 mOsm/kg (normal is <50 mOsm/kg). The stool osmotic gap is obtained by measuring stool osmolarity

### • BOX 71.3 Causes of Chronic Diarrhea Categorized by Mechanism

#### Osmotic Causes

Ingestion of poorly absorbed agents  
 Osmotic laxatives: magnesium citrate, sodium phosphate, polyethylene glycol  
 Nonabsorbed carbohydrates and fats: sorbitol, lactulose, mannitol, Splenda, Olestra  
 Lactase and other disaccharidase deficiencies: congenital and postenteritis

#### Secretory Causes

Exogenous secretagogues  
 Stimulant laxatives: senna, bisacodyl  
 Dietary: chronic ethanol ingestion, caffeine  
 Medications: prostaglandins, theophylline, colchicine  
 Endogenous secretagogues  
 Bile acid–induced diarrhea, including postcholecystectomy  
 Bile acid malabsorption: ileal resection, ileal Crohn disease, small bowel bacterial overgrowth, fistula, idiopathic  
 Hormone-producing tumors: carcinoid (serotonin), VIPoma (VIP), medullary cancer of the thyroid (calcitonin), mastocytosis (histamine), gastrinoma (gastrin), colorectal villous adenoma (prostaglandin)  
 Endocrine causes: hyperthyroidism, Addison disease  
 Congenital electrolyte absorption defects (e.g., defective Cl/HCO<sub>3</sub> transporter causing congenital chloridorrhea)  
 Loss of absorptive surface area  
 Ileocecal resection  
 Inflammatory bowel disease, microscopic colitis  
 Colon carcinoma, lymphoma  
 Vasculitis  
 Partial bowel obstruction or fecal impaction  
 Idiopathic secretory diarrhea: epidemic secretory (Brainerd) diarrhea, sporadic idiopathic secretory diarrhea  
 Dysmotility (rapid transit)

#### Steatorrheal (Fatty) Causes

Intraluminal maldigestion  
 Pancreatic exocrine insufficiency  
 Bile salt deficiency  
 Decreased synthesis: liver disease, cholestasis  
 Conjugation of bile salts: bacterial overgrowth  
 Interruption of enterohepatic circulation: ileal resection, active ileal Crohn disease  
 Mucosal malabsorption  
 Celiac sprue, tropical sprue, Whipple disease, infections (*Giardia*, *Mycobacterium avium* complex)  
 Small bowel bacterial overgrowth, short gut syndrome  
 Abetalipoproteinemia: inherited defect in chylomicron formation  
 Medications: colchicine, cholestyramine, neomycin

#### Inflammatory Causes

Inflammatory bowel disease: Crohn disease, ulcerative colitis  
 Microscopic colitis: lymphocytic colitis, collagenous colitis  
 Immune-related mucosal diseases: eosinophilic gastroenteritis, chronic graft-versus-host disease  
 Radiation enteritis/colitis  
 Ischemic colitis  
 Diverticulitis  
 Infections  
 Bacteria: *Clostridium difficile*, *Mycobacterium tuberculosis*, *Yersinia*  
 Ulcerating viral infections: cytomegalovirus, herpes simplex virus  
 Invasive parasitic infections: *Entamoeba histolytica*, strongyloides  
 Malignancy: colon cancer, lymphoma

as well as concentrations of Na<sup>+</sup> and K<sup>+</sup>. The calculated stool osmolarity = 2([Na<sup>+</sup>] + [K<sup>+</sup>]). The stool osmotic gap is then determined by the difference between the measured stool osmolarity and the calculated osmolarity. This gap reflects the nonelectrolyte substances that are causing the osmotic diarrhea. The normal stool osmolarity is approximately 290 mOsm/kg (similar to plasma). Stool osmolarity is prone to being falsely elevated because as colonic bacteria continue to metabolize carbohydrates, fecal osmolarity increases.

Exogenous causes include ingestion of poorly absorbed ions (magnesium, sulfate, and phosphate) in the form of antacids and osmotic laxatives, as well as sugar substitutes and nonabsorbable fats that are designed to be poorly absorbed. Loss of a nutrient transporter, such as congenital disaccharide deficiencies (the most common of which is lactase deficiency, which affects up to 75% of non-Caucasians), leads to carbohydrate malabsorption and results in osmotic diarrhea. The bloating and gas symptoms that are common in lactose intolerance are caused by fermentation of the nonabsorbed carbohydrate. Lactose intolerance can also be acquired for weeks to months after infectious gastroenteritis. Steatorrheal causes of diarrhea (described later) also result in an element of osmotic diarrhea caused by malabsorbed fat in the intestinal lumen.

#### Secretory Diarrhea

Secretory diarrhea is caused by alterations in fluid and electrolyte transport across the intestinal mucosa resulting in increased intestinal secretion or decreased absorption. The hallmarks are that it is large volume (>1 L/d), watery, and painless. It usually persists with fasting (although it can decrease with fasting if this decreases endogenous secretagogue production) and can occur at night. It also has a normal stool osmolar gap of <50 mOsm/kg.

Exogenous causes include stimulant laxatives, dietary secretagogues, and medications. Infection with *Vibrio* enterotoxins is also a classic cause of acute secretory diarrhea. Endogenous secretagogues include bile acids and hormones secreted by neuroendocrine tumors. Increased bile acid stimulation of colonic secretion can occur after cholecystectomy (decreased bile acid storage) and related to bile salt malabsorption (caused by Crohn ileitis, small bowel resection, bacterial overgrowth, fistula, or can be idiopathic). Hormone-producing tumors (such as carcinoid) cause secretory diarrhea by producing a variety of hormones (such as serotonin) that stimulate fluid secretion by intestinal epithelial cells. These tumors often have other associated symptoms (often systemic) related to the secreted hormones. Decreased intestinal surface area can result in

inadequate fluid and electrolyte absorption resulting in a secretory diarrhea. This can occur with ileocecal resection as well as inflammatory or infiltrative processes of the mucosa (inflammatory bowel disease, microscopic colitis, colon villosus adenoma and carcinoma, and lymphoma). Rare congenital syndromes, such as congenital chloridorrhea, cause secretory diarrhea by lacking a specific transporter (in chloridorrhea, it is the  $\text{Cl}^-/\text{HCO}_3^-$  exchanger). Other causes include vasculitis (ischemia or cytokines causing decreased absorption), partial bowel obstruction or fecal impaction (fluid hypersecretion), and rapid transit dysmotility disorders (reduced time for absorption). Last, idiopathic secretory diarrhea is a diagnosis given when no other etiology is found and the diarrhea is secretory. It can be epidemic (also called *Brainerd diarrhea*) or sporadic, and both forms tend to resolve within 2 years.

### Steatorrheal Diarrhea

Steatorrheal (or fatty) diarrhea is caused by fat malabsorption in the small intestine. The hallmarks include floating stool that is difficult to flush, greasy or foul-smelling stool, and associated weight loss and nutritional deficiencies related to malabsorption. The fat in the intestinal lumen causes a degree of osmotic diarrhea, so symptoms usually decrease with fasting. The gold standard is the quantitative 72-hour stool collection while the patient is eating >100 g of fat per day; the stool is abnormal if there is >7 g of fat per day. However, this method is rarely used because of difficulty in obtaining specimens and limited reproducibility. Alternatives to this are qualitative tests using a spot sample of stool and including the Sudan III stain and acid steatorcrit, which are not quite as accurate.

The causes of steatorrheal diarrhea are those that prevent intraluminal metabolism and absorption of fat. Intraluminal metabolism is disrupted by pancreatic exocrine insufficiency and bile salt deficiency. Pancreatic exocrine insufficiency is most commonly caused by chronic pancreatitis but can also occur with lesions obstructing the pancreatic duct. Bile salt deficiency can be caused by decreased synthesis (liver disease), deconjugation of bile salts (bacterial overgrowth), or interruption of the enterohepatic circulation (Crohn ileitis, small bowel resection).

Mucosal malabsorption can be caused by celiac disease, tropical sprue, Whipple disease, infections (*Giardia*, mycobacterium avium complex), medications, and chronic mesenteric ischemia. Patients with mucosal malabsorption usually have larger-volume diarrhea because the triglycerides are still broken down to free fatty acids in the lumen, which causes increased diarrhea. In intraluminal maldigestion, the triglycerides remain intact, and stool volumes are smaller.

### Inflammatory Diarrhea

Inflammatory diarrhea is caused by disruption of the integrity of the intestinal mucosa by an inflammatory process. The hallmarks of inflammatory diarrhea are mucoid and bloody stool combined with symptoms of abdominal pain, fever, and tenesmus. Stool examination is usually positive

for blood (gross blood or fecal occult blood test positive) and fecal leukocytes. Fecal calprotectin, a zinc and calcium binding protein that is derived mostly from neutrophils and monocytes, may be a more sensitive marker of intestinal inflammation in chronic diarrhea. Notably, some etiologies (such as microscopic colitis) may not cause enough surface damage to cause significant elevations in fecal blood or fecal leukocytes/calprotectin. The inflammatory process may also incite other mechanisms (fat or bile acid malabsorption, secretory, dysmotility) that contribute to the diarrhea.

Etiologies of inflammatory diarrhea include inflammatory bowel disease (IBD; Crohn disease, ulcerative colitis), microscopic colitis, colonic ischemia, radiation-induced enteritis/colitis, diverticulitis, eosinophilic gastroenteritis, chronic graft-versus-host disease, colorectal cancer, and chronic infections. IBD can range from mild to severe symptoms and can be associated with extraintestinal manifestations (oral ulcers, eye lesions, arthralgias, rash). Microscopic colitis includes lymphocytic and collagenous colitis. It is most common in middle age and in people taking non-steroidal antiinflammatory drugs (NSAIDs), and it presents with intermittent watery diarrhea. Macroscopic evaluation during colonoscopy is often normal, but the diagnosis is made by pathology. Eosinophilic gastroenteritis results from eosinophilic infiltration of the mucosa and is often associated with a peripheral eosinophilia. Chronic infections include *C. difficile*, invasive bacteria (*Yersinia*, *Mycobacterium tuberculosis*), ulcerating viruses (cytomegalovirus, herpes simplex virus), and invasive parasites (*E. histolytica*, *Strongyloides*).

### Dysmotility Diarrhea

Abnormal intestine motility can cause diarrhea. The hallmark is a watery diarrhea, sometimes with associated cramping. Stool features are often similar to secretory diarrhea, but mild steatorrhea can occur because of malabsorption in the setting of rapid transit.

Abnormal bowel motility can be associated with other types of diarrhea (e.g., infection) as a secondary feature, but it can also exist as a primary etiology. Systemic causes of hypermotility include hyperthyroidism, carcinoid syndrome, and diabetic autonomic neuropathy. Medications (such as prokinetic agents) and vagotomy procedures also lead to diarrhea caused by hypermotility. The hypomotility caused by scleroderma results in bacterial overgrowth, which disrupts digestion and alters electrolyte transport, resulting in diarrhea. Irritable bowel syndrome (IBS) is characterized by abnormal motor and sensory function of the intestine and can manifest with intermittent diarrhea. It is also referred to as a functional diarrhea syndrome. The stools are often loose (not usually large volume), most often occur during the day and most commonly in the morning and after meals, and rarely occur at night. They can have a mucoid component and can be associated with abdominal cramping and urgency/straining. They generally do not have significant associated weight

loss or metabolic abnormalities. Factors such as new-onset diarrhea in an older patient, weight loss, nocturnal stools, blood in the stool, and anemia or abnormal electrolytes argue against IBS. Ultimately, IBS is a clinical diagnosis for which the Rome criteria can be used. The Rome IV criteria include recurrent abdominal pain, on average, at least 1 day per week in the last 3 months, associated with two or more of the following: (1) related to defecation, (2) associated with change in stool frequency, (3) associated with change in stool form. Symptom onset should be at least 6 months before the diagnosis of IBS. Postinfectious IBS can also occur, often in patients who may have had mild IBS before the infection.

## Evaluation

### History

The history is helpful in diagnosing the type and cause of chronic diarrhea.

- Duration of symptoms, rapidity of onset (abrupt, gradual), pattern (continuous, intermittent)
- Stool characteristics: watery, bloody, mucoid, oily; volume; frequency
- Associated symptoms: abdominal pain, fever, weight loss, fecal urgency and incontinence, bloating/flatulence
- Systemic symptoms related to IBD: arthralgias, mouth ulcers, eye symptoms, rash
- Epidemiologic factors: travel, sick contacts
- Aggravation/mitigating factors: diet (dairy, alcohol, caffeine, artificial sweeteners), relationship of symptoms to eating/fasting and stress
- Past medical history: diabetes, hyperthyroidism, surgery, radiation therapy, coronary artery disease/peripheral vascular disease, immunosuppression, AIDS
- Medication history, including over-the-counter and herbals/supplements
- Sexual history (including anal intercourse), risk factors for HIV
- Family history: IBD, neoplasm, celiac disease
- Institutionalized/hospitalized: medications, tube feeding, fecal impaction, recent antibiotics, *C. difficile*

### Physical Examination

The physical examination can provide information regarding the severity and etiology of chronic diarrhea. The abdominal examination is important to evaluate for abdominal pain as well as abdominal masses and hepatosplenomegaly. Scars suggest prior abdominal surgery. The anorectal examination should include sphincter tone, occult blood, and evaluation for perianal fistula or abscesses. Clinical examination features suggesting the degree of fluid and nutritional depletion should be evaluated (dehydration, wasting, anemia). Other organ systems should be evaluated for features such as skin rashes (dermatitis herpetiformis in celiac disease, erythema nodosum in ulcerative colitis), flushing (carcinoid), mouth ulcers (IBD, celiac), thyroid palpation (and other signs of hyperthyroidism), lymphadenopathy (lymphoma, HIV), and arthritis (IBD).

## Initial Laboratory Evaluation

Initial laboratory evaluation is guided in part by the history and physical examination. Common initial serum tests include a complete metabolic panel with differential, electrolyte panel, total protein and albumin, thyroid function tests, erythrocyte sedimentation rate, and C-reactive protein. Laboratory tests to evaluate for malabsorption include iron studies, vitamin B<sub>12</sub>, folic acid, calcium, magnesium, cholesterol, albumin, carotene, and prothrombin time to determine nutritional deficiency. An elevated folic acid can be suggestive of bacterial overgrowth. Evaluation for celiac disease with anti-tissue transglutaminase IgA (and a total IgA level to ensure that the patient is not IgA deficient) should also be considered.

### Stool Studies

Initial stool studies for chronic diarrhea include fecal occult blood testing, tests for fecal white blood cells (fecal leukocytes, lactoferrin, or calprotectin), and stool culture. In addition to inflammatory or infectious disorders, stool can be occult blood positive in neoplastic disorders (such as colon cancer or small bowel lymphoma) and celiac disease.

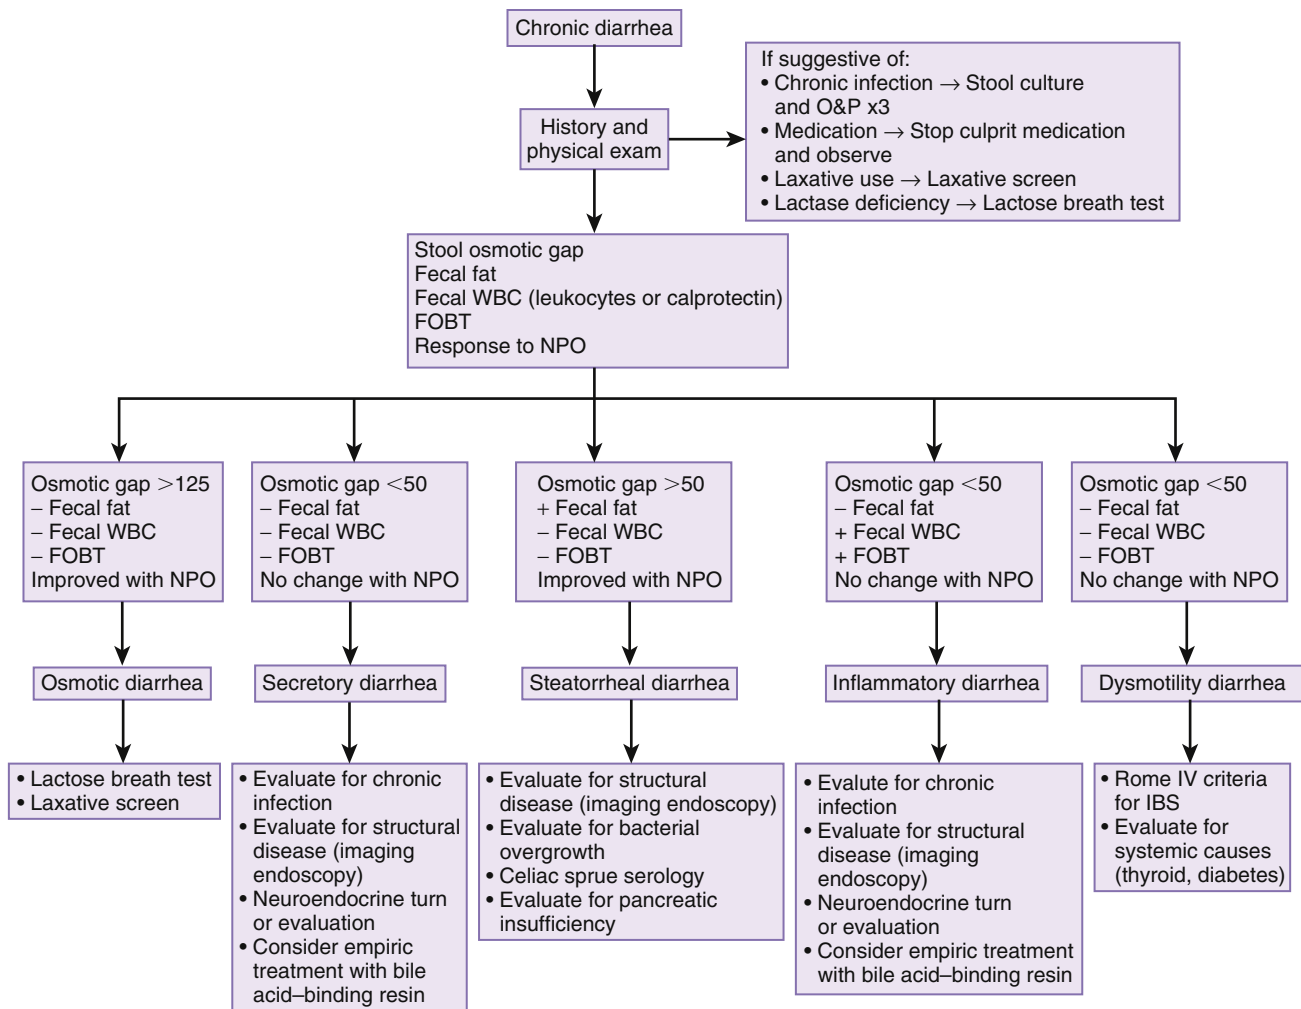

### Endoscopic Evaluation

Endoscopic evaluation is considered for many patients with chronic diarrhea. Flexible sigmoidoscopy is a reasonable initial test because it is often sufficient for diagnosis and has fewer associated risks. However, colonoscopy is indicated in patients age >50 years (and who need colorectal screening), iron deficiency anemia, and suspected IBD (terminal ileum for Crohn disease) or microscopic colitis (there is a higher yield of biopsies in the right colon). Biopsies should be taken even if the mucosa appears normal to evaluate for microscopic colitis. Upper endoscopy with biopsy may be useful for the evaluation of celiac sprue, tropical sprue, IBD, *Giardia*, and other infections. Capsule endoscopy can also be used to evaluate the small bowel, especially for evidence of Crohn disease and small bowel tumors. However, the disadvantage of a capsule endoscopy is that biopsies cannot be obtained.

## Approach to Evaluation Based on Pathophysiologic Mechanism

If the diagnosis is not clear initially, it can help to categorize the diarrhea into one of the pathophysiologic mechanisms described earlier (osmotic, secretory, steatorrheal, inflammatory, dysmotility), which can further guide evaluation and treatment. Remember to assess for common problems that can often be overlooked, such as lactose intolerance, fecal incontinence, and medications. Fig. 71.2 shows an algorithm for the evaluation of chronic diarrhea, and this is also summarized subsequently.

If the diarrhea appears to be osmotic, additional testing should include evaluation of lactose intolerance and osmotic laxative abuse. Lactose intolerance can be assessed using empirical lactose exclusion (to see if symptoms improve)

• **Fig. 71.2** Algorithm for the evaluation of chronic diarrhea. FOBT, Fecal occult blood test; IBS, irritable bowel syndrome; NPO, nothing by mouth; O&P, ova and parasites; WBC, white blood cells. (Modified from Sabatine MS, ed. *Pocket Medicine: The Massachusetts General Hospital Handbook of Internal Medicine*. 3rd ed. Baltimore: Lippincott Williams & Wilkins; 2004.)

or a lactose breath test. A stool pH of  $<5.6$  suggests carbohydrate malabsorption caused by increased fermentation in the colon. A laxative screen can be performed to identify inadvertent or surreptitious laxative use.

If the diarrhea appears to be secretory, additional testing includes evaluation for chronic infection, structural and mucosal abnormalities, stimulant laxative abuse, neuroendocrine endogenous secretagogues, and empirical treatment for bile acid-induced diarrhea. Evaluation for chronic infection is especially important if patients are immunocompromised. Assessment of a bacterial etiology often includes a routine stool culture, as well as *Aeromonas* and *Plesiomonas*. For parasitic infection, testing can include standard O&P (three samples), stool *Giardia* antigen, microsporidia, and *Cryptosporidium*. Additional testing for infectious etiologies should be determined by the patient's risk factors. Abdominal imaging and/or endoscopy with biopsy can be performed to evaluate the small bowel and colon for IBD and other mucosal diseases, intestinal lymphoma, and colorectal villous adenomas and cancer. Mesenteric angiography/CT angiography/

MR angiography will assess for small intestinal ischemia. In addition to a laxative screen, colonoscopy may also reveal melanosis coli in the setting of chronic laxative use, especially anthraquinone-containing laxatives. The evaluation for neuroendocrine endogenous secretagogues should be determined by clinical suspicion but includes thyroid-stimulating hormone, adrenocorticotropic hormone, cortisol stimulation, plasma peptides (e.g., VIPoma, gastrin, glucagon, calcitonin), and 24-hour urine collection for 5-hydroxyindoleacetic acid. Imaging and endoscopic ultrasound can also assess for pancreatic neuroendocrine tumors. Improvement in diarrhea with empirical treatment using bile acid-binding resin (cholestyramine) suggests that bile acid-induced diarrhea may play a role in a patient's diarrhea.

If the diarrhea appears to be steatorrheal, additional testing includes qualitative or quantitative examination of stool fat, as well as evaluation for small bowel bacterial overgrowth, mucosal abnormalities, pancreatic insufficiency, and some infections. Small bowel bacterial overgrowth is most commonly assessed with a breath test (lactulose,  $^{14}\text{C}$ -xylose),

but alternatives include small bowel aspirate and culture as well as empirical trial of antibiotics. Celiac sprue serology (antitissue transglutaminase IgA) and small bowel radiology and/or endoscopy with biopsy can be used to evaluate for mucosal disease of the small bowel. Pancreatic insufficiency can be assessed by imaging, endoscopy, and stool tests. MRI and/or MR cholangiopancreatography (MRCP) can show evidence of chronic pancreatitis or an obstructing pancreatic lesion. A secretin-enhanced MRCP can also be used to evaluate pancreatic exocrine function. Secretin stimulation and measurement of bicarbonate output are performed by aspiration of duodenal contents during endoscopy, but this is rarely done because it is invasive and complicated. Stool testing for fecal elastase is noninvasive, but the concentration can be diluted (falsely positive) by watery diarrhea so it is accurate only with a formed stool and is reliable only in moderate-to-severe pancreatic insufficiency. In addition, a trial of pancreatic enzymes can be diagnostic. Evaluation for chronic infections such as *Giardia* and mycobacterium avium complex should also be considered.

If the diarrhea appears to be inflammatory, additional testing includes evaluation for chronic infection (especially if immunocompromised) as well as structural or mucosal etiologies. For bacterial infections, in addition to routine stool culture, *Aeromonas* and *Plesiomonas*, testing considerations should include *C. difficile*, *Yersinia*, and *Mycobacterium tuberculosis*. For parasitic infection, in addition to standard O&P (three samples), stool *Giardia* antigen, microsporidia, and *Cryptosporidium*, testing for *E. histolytica* and *Strongyloides* should also be considered. Viral infections such as cytomegalovirus and herpes simplex virus should be considered, and testing generally requires endoscopy for biopsies.

A patient's risk factors may determine additional testing for infectious etiologies. Abdominal imaging and/or endoscopy with biopsy can be used to evaluate the small bowel and colon for IBD and other mucosal diseases, chronic ischemia, intestinal lymphoma, and colorectal cancer.

If the diarrhea appears to be caused by dysmotility, additional testing includes evaluation for a systemic etiology (such as hyperthyroidism or diabetes) as well as empirical treatment of IBS.

## Treatment

Treatment of chronic diarrhea depends on the etiology. If the underlying cause is reversible, such as stopping the culprit medication or treating an infection, the diarrhea should resolve with treatment. If the underlying cause is known but not reversible, treatment may improve the symptoms. Examples include a lactose-restricted diet in lactase deficiency, elimination of gluten from the diet in celiac disease, antiinflammatory agents in IBD, cholestyramine for bile acid malabsorption, pancreatic enzyme replacement for pancreatic insufficiency, and octreotide for carcinoid syndrome. When the specific cause is not known but infection is not likely, antimotility agents can be used to relieve symptoms. Fiber supplements may improve stool consistency. Loperamide and diphenoxylate are often used for more mild cases. Tincture of opium, oral opioids, and octreotide can be used for more severe diarrhea. Probiotics are being evaluated, but no clear recommendations can be made at this point. For all patients, attention and treatment should also be focused on maintaining adequate hydration and replacement of electrolytes and fat-soluble vitamins if necessary.

## Chapter Review

### Questions

1. A 55-year-old man is admitted to the hospital for an elective removal of a cardiac pacemaker. After removal, he develops a localized cellulitis at the incision site for which he is treated with intravenous antibiotics. On hospital day 3, the patient develops watery diarrhea with leukocytosis and a low-grade fever. What is the next best step in the management of this patient?
  - A. Send stool sample for *C. difficile* testing, and start oral metronidazole therapy.
  - B. Prescribe loperamide.
  - C. Send stool sample for *C. difficile* testing, and start intravenous vancomycin therapy.
  - D. Observe to see if the diarrhea is self-limited.
  - E. Obtain a colonoscopy to evaluate for colonic pseudomembranes.
2. A 22-year-old woman on a biking trip in southern Spain drinks water from a fresh-water pond. Approximately 2 days later she develops a profuse watery, malodorous diarrhea, severe abdominal cramps, vomiting, and fatigue. The most likely diagnosis is:
  - A. *C. difficile* infection
  - B. *V. cholerae* cholera
  - C. Crohn disease
  - D. *Campylobacter jejuni* infection
  - E. *Giardia* infection
3. A 42-year-old man who presents to the emergency department (ED) with severe abdominal cramping and bloody stools is diagnosed on stool samples with an infection from enterohemorrhagic *E. coli* O157:H7. What should be the next step in management?
  - A. Vancomycin therapy
  - B. Supportive care but no antibiotic therapy
  - C. Treatment with ciprofloxacin
  - D. Obtain a colonoscopy to evaluate for colonic pseudomembranes.
  - E. Levofloxacin therapy
4. An 88-year-old female nursing home resident with severe dementia is sent to the ED with a history of fecal impaction. The nursing home transfer note states that the patient has been complaining of abdominal distention, pain, and frequent small volume watery bowel

movements. Manual disimpaction is performed. What would you recommend to the nursing home?

- A. Start the patient on a regular dose of bisacodyl to prevent further episodes.
  - B. Increase fluid intake and add fiber to the diet.
  - C. Use of fecal incontinence diapers on a regular basis
  - D. Use of a positive-pressure rectal incontinence pad
  - E. Start the patient on an anticholinergic agent to prevent further colonic leaking.
5. A 49-year-old woman traveling from Delhi to Chicago by air develops nausea, crampy abdominal pain, and watery diarrhea. She is a little dizzy on standing and has an increase in her heart rate with standing, but her blood pressure is 130/82 mm Hg. You are asked to evaluate the patient midflight. Limited examination is unremarkable except for some mild but diffuse abdominal tenderness. The best next step is to:

- A. Ask the flight attendant if anyone on the plane has diphenoxylate and atropine (Lomotil), and start the patient on therapy immediately.
- B. Initiate oral hydration, and observe the patient carefully.
- C. Administer acetaminophen for abdominal pain, and observe the patient.
- D. Advise the patient to avoid eating, especially milk-containing foods.
- E. Recommend to the airline staff that the plane land immediately.

### Answers

- 1. A
- 2. E
- 3. B
- 4. B
- 5. B

# Inflammatory Bowel Disease

SONIA FRIEDMAN

**I**nflammatory bowel disease (IBD) is a chronic inflammatory disease of the gastrointestinal (GI) tract that can affect any site from the mouth to the anus. The two major types of IBD are Crohn disease (CD) and ulcerative colitis (UC).

## Epidemiology

The highest incidence rates of CD and UC have been reported in northern Europe, the United Kingdom, and North America. In North America, incidence rates range from 2.2 to 14.3 cases per 100,000 person-years for UC and from 3.1 to 14.6 cases per 100,000 person-years for CD. Prevalence ranges from 37 to 246 cases and from 26 to 199 cases per 100,000 person-years for UC and CD, respectively. Countries in the Pacific, including New Zealand and Australia, which share many possible environmental risk factors and similar genetic background as northwest Europe and North America, have high incidence rates of IBD. Asia is witnessing a rise in incidence in parallel with rapid socioeconomic development. The highest incidence is mainly reported in East Asia (Japan, Korea, China, Hong Kong) and South Asia (India). The highest mortality is during the first years of disease and in long-duration disease, caused by the risk of colon cancer.

The peak age of onset of IBD is between 15 and 30 years. A second peak occurs between the ages of 60 and 80 years. The male-to-female ratio for UC is 1:1 and for CD is 1.1 to 1.8:1. UC and CD have a 2-fold to 4-fold increased frequency in the Jewish populations in the United States, Europe, and South Africa and occur more frequently in Ashkenazi than Sephardic Jews. The prevalence decreases progressively in non-Jewish, Caucasian, African-American, Hispanic, and Asian populations.

The effects of cigarette smoking are different in patients with UC and CD. The risk of UC in smokers is 40% that of nonsmokers, and former smokers have a 1.7-fold higher risk for UC than those who have never smoked. In contrast, smoking is associated with an increased (1.5-fold to 2-fold) risk of developing CD. Appendectomy, especially before the age of 20, is protective against UC but probably increases the risk of CD. Oral contraceptive use is associated with an increased risk of CD with a hazard ratio of 2.82 for

current use and 1.39 for past use after adjusting for multiple risk factors including smoking. The most likely factors that explain the geographic variability of IBD rates, especially the rising incidence in developing countries and urban areas, are changes in diet (effects on the intestinal microbiota), exposure to sunlight or temperature differences, and socioeconomic status and hygiene.

IBD runs in families. If a patient has IBD, the lifetime risk that a first-degree relative will be affected is about 10%. If both parents have IBD, the risk of a child developing it is about 36%. In twin studies, concordance of monozygotic twins for CD is 58%, and that for dizygotic twins is 4%. For UC, there is a concordance among monozygotic twins of 6% and no concordance in dizygotic twins. Anatomic site and clinical subtype of CD are also concordant within families. Very early onset IBD occurs in children age <6 years. Within these patients is a subset with infantile IBD, which is defined as IBD that develops in children age <2 years. This type of IBD is often refractory to standard treatment and is caused by rare single genetic mutations in interleukin 10 (IL-10) or the IL-10 receptor as well as mutations in NCF2, XIAP, LRBA, or TTC7 among others.

## Pathology

### Ulcerative Colitis

UC is a mucosal disease that almost always involves the rectum and extends proximally to involve part or all of the colon. Between 40% and 50% of patients have disease limited to the rectum (proctitis) and rectosigmoid colon (proctosigmoiditis). Between 30% and 40% of patients have disease extending beyond the sigmoid but not involving the whole colon (extensive colitis), and 20% have a total or "pan" colitis. When the whole colon is involved, inflammation may extend 1 to 2 cm into the terminal ileum. This is called *backwash ileitis* and is probably of no clinical significance.

When the colon is mildly inflamed, the mucosa has a granular appearance. With more severe inflammation, the mucosa is edematous, erythematous, and hemorrhagic. Frank ulcerations are associated with fulminant colitis and are a warning sign that the patient requires urgent intervention

to avoid perforation. In long-standing disease, inflammatory polyps (pseudopolyps) may be present as a result of epithelial regeneration. In remission, the mucosa may appear normal, but in patients with many years of poorly treated inflammation, it appears atrophic and featureless, and the whole colon becomes narrowed and shortened.

## Crohn Disease

CD can affect any part of the GI tract from the mouth to the anus. Between 30% and 40% of patients have small bowel disease alone, 40% to 55% have disease involving both the large and small intestines, and 15% to 25% have colitis alone. In the 75% of patients with small intestinal disease, the terminal ileum is involved in 90%. Unlike UC, which almost always involves the rectum, the rectum is often spared in CD. CD is segmental with skip areas in the middle of diseased intestine. Perirectal fistulas, fissures, abscesses, and anal stenosis are present in one-third of patients with CD, particularly those with colonic involvement. Rarely, CD may also involve the liver or the pancreas.

Unlike UC, CD is a transmural process. Endoscopically, aphthous or small superficial ulcerations characterize mild disease; in moderate disease, stellate ulcerations fuse longitudinally or transversely to demarcate islands of mucosa that are frequently histologically normal. This cobblestone appearance is characteristic of CD. As in UC, pseudopolyps can form in CD. Active CD is characterized by focal inflammation and formation of fistula tracts and eventual fibrosis and stricturing of the bowel. Chronic and recurrent bowel obstructions are caused by a narrowing and thickening of the bowel. Projections of thickened mesentery, “creeping fat,” encase the bowel, and serosal and mesenteric inflammation promote fistula formation.

## Clinical Presentation

### Ulcerative Colitis

The clinical presentation of UC depends on the location of the disease. The major symptoms of UC are diarrhea, bleeding, tenesmus, passage of mucus, and crampy abdominal pain (Table 72.1). Patients with proctitis alone tend to have bleeding and constipation because the stool is backed up behind an inflamed rectum. Patients with more extensive colitis have blood mixed with the stool or grossly bloody diarrhea. When the disease is severe, patients pass a liquid stool containing blood, pus, and fecal matter. Diarrhea is often nocturnal or postprandial and is almost always urgent. Although severe pain is not a predominant symptom, patients typically experience low-grade, crampy abdominal pain relieved by defecation. Other symptoms in moderate to severe disease include anorexia, nausea, vomiting, fever, and weight loss.

The physical examination in patients with proctitis is significant for a tender anal canal and blood on rectal examination. With more extensive disease, patients have tenderness to palpation directly over the inflamed parts of the colon.

**TABLE 72.1**

**Ulcerative Colitis: Disease Presentation**

	Mild	Moderate	Severe
Bowel movements	<4 per day	4–6 per day	>6 per day
Blood in stool	Small	Moderate	Severe
Fever	None	<37.5°C mean	>37.5°C mean
Tachycardia	None	<90 mean pulse	>90 mean pulse
Anemia	Mild	>75% of normal	≤75% of normal
Sedimentation rate	<30 mm		>30 mm

Patients with a toxic colitis have severe pain and bleeding, and those with megacolon have hepatic tympany. Both may have signs of peritonitis if a perforation has occurred.

### Complications

Only 15% of patients with UC present initially with severe disease. Massive hemorrhage occurs in 1% of patients, and treatment for the inflammation usually stops the bleeding. A colectomy is indicated if a patient requires more than 6 to 8 units of blood within 1 to 2 days. Toxic megacolon occurs when the transverse colon dilates to more than 5 to 6 cm and can occur in about 5% to 6% of attacks. It can be precipitated by electrolyte imbalances, prolonged bed rest, and narcotics. About 50% of acute colonic dilations will resolve with medical therapy alone, but the rest will require surgical intervention. Perforation is the most dangerous of complications, and the symptoms of peritonitis may be masked by high doses of glucocorticoids. The mortality rate for a perforated toxic megacolon is 15%. A small number of patients may develop a toxic colitis with severe ulcerations that may perforate without first dilating. Colon strictures that form in patients with UC have a high probability of being malignant, and surgical resection should be performed if a colonoscope cannot be passed through the stricture.

### Laboratory Findings

Active disease is associated with a rise in acute-phase reactants (C-reactive protein [CRP]), erythrocyte sedimentation rate (ESR), platelet count, and a decrease in hemoglobin. In severely ill patients, the serum albumin will fall quickly. Leukocytosis may be present but is not an indicator of disease severity. Stool cultures for bacterial pathogens, *Clostridium difficile* toxin, and ova and parasite (O&P) should be performed. Diagnosis is based on negative stool examination and a sigmoidoscopy and biopsy, which reveal chronic active inflammation. Fecal calprotectin is a measure of intestinal inflammation that correlates well with endoscopic inflammation and can be used to help diagnose an IBD flare. Levels >150 µg/g can help distinguish infection from inflammation.

### • BOX 72.1 Vienna Classification of Crohn Disease

#### Age at Diagnosis

A1 <40 years  
A2 ≥40 years

#### Location

L1 Terminal ileum  
L2 Colon  
L3 Ileocolon  
L4 Upper gastrointestinal

#### Behavior

B1 Nonstricturing, nonpenetrating  
B2 Stricturing  
B3 Penetrating

From Gasche C, Scholmerich J, Brynskov J, et al. A simple classification of Crohn's disease: report of the Working Party for the World Congresses of Gastroenterology, Vienna 1998. *Inflamm Bowel Dis*. 2000;6(1):8–15.

### Endoscopic and Radiographic Findings

Sigmoidoscopy is used to assess disease activity. If the patient is not acutely flaring, a full colonoscopy is very helpful in assessing extent of disease. Pathology is also very helpful in grading disease activity. Colonoscopy is more useful than barium enema and CT scanning in assessing extent and activity of UC.

### Crohn Disease

CD usually presents as acute or chronic bowel inflammation and evolves to one of two disease phenotypes: a fibrostenotic-obstructing pattern or a penetrating fistulous pattern (Box 72.1). Disease location and disease phenotype dictate treatment and prognosis.

#### Ileocolitis

The most common site of inflammation is the terminal ileum, and the most common presentation is a history of diarrhea, night sweats, gradual weight loss, and right lower quadrant pain. Pain is usually crampy and precedes and is relieved by defecation. It is uncommon to have frankly bloody diarrhea. Sometimes, the presentation will mimic acute appendicitis with significant right lower quadrant pain, a palpable mass, fever, and leukocytosis. Usually the fever is low grade; a high-grade fever suggests that an intraabdominal abscess might be present. Because CD has a more insidious onset than UC, symptoms may be ignored until they are severe, and 10% to 20% of body weight is often lost.

An inflammatory mass may be palpated in the right lower quadrant of the abdomen. This mass is composed of inflamed bowel, adherent and thickened mesentery, and enlarged abdominal lymph nodes. Extension of the mass can cause right ureter or bladder inflammation or obstruction of the right Fallopian tube in women. With inadequate or no treatment, bowel obstruction can occur. Inflammation can

cause edema of the bowel wall and intermittent pain and obstructive symptoms. The inflamed bowel wall will eventually scar down and form a stricture. In this scenario, obstruction is caused by impacted food or medication and can be resolved by intravenous (IV) fluids, nasogastric decompression, and bowel rest.

Severe inflammation of the ileocecal area may lead to localized wall thinning with microperforation and fistula formation to the adjacent bowel, skin, bladder, or to an abscess cavity in the mesentery. Enterovesical fistulas usually present as dysuria or recurrent bladder infections or, less commonly, with pneumaturia or fecaluria. Enterocutaneous fistulas typically drain through abdominal surgical scars. Enterovaginal fistulas are rare and only occur in women who have had a hysterectomy. Patients present with dyspareunia or with a foul-smelling, often painful vaginal discharge.

### Colitis and Perianal Disease

Patients present with low-grade fevers, abdominal pain, weight loss, crampy abdominal pain, and nonbloody diarrhea. Pain is caused by passage of stool through a narrowed and inflamed colon, and diarrhea can be partially caused by rectal inflammation with decreased compliance. Toxic megacolon is rare in Crohn colitis, as is gross bleeding. Stricturing in the colon occurs in 4% to 16% of patients and can cause symptoms of bowel obstruction. If a colonoscope cannot pass through the stricture, surgery is recommended because of the risk of a hidden colon cancer. Colonic disease may fistulize into the stomach or duodenum, causing feculent vomiting, or to the small bowel, causing diarrhea by short-circuiting of intestinal contents. Ten percent of women with Crohn colitis will develop a rectovaginal fistula.

One-third of patients with Crohn colitis develop perianal disease manifested by incontinence, large hemorrhoidal skin tags, anorectal fistulas, anal strictures, and perirectal abscesses. Not all patients with perianal disease will have evidence of colonic inflammation.

#### Jejunioileitis

Extensive CD of the small intestine is associated with a loss of digestive and absorptive surface, resulting in malabsorption and weight loss. Patients will often have nutritional deficiencies including vitamin D, calcium, niacin, and vitamin B<sub>12</sub> deficiency and should be checked for these as well as for osteoporosis. Malabsorption can also cause hypoalbuminemia, hypomagnesemia, coagulopathy, and hyperoxaluria with nephrolithiasis in patients with an intact colon. Diarrhea is characteristic of active disease and is caused by a combination of active inflammation, bacterial overgrowth from Crohn strictures, and bile acid and occasionally fatty acid malabsorption caused by extensive ileal disease.

### Gastroduodenal Disease

Symptoms and signs of upper-GI-tract disease include nausea, vomiting, epigastric pain, and a *Helicobacter pylori*-negative gastritis. Patients can present with a gastric outlet

obstruction caused by a stricture at the pylorus or in the duodenum. The second portion of the duodenum is more commonly involved than the duodenal bulb. Fistulas involving the stomach or duodenum can arise from the small or large bowel and do not necessarily signify the presence of upper GI tract involvement.

### Complications

Because CD is a transmural process, serosal adhesions develop providing direct pathways for fistula formation. Free perforation is rare and occurs in 1% to 2% of patients, usually in the ileum or, less commonly, in the jejunum or as a complication of toxic megacolon. The peritonitis of free perforation may be fatal. Intraabdominal and pelvic abscesses occur in 10% to 60% of patients and almost always require IV antibiotics and CT-guided drainage. Most patients will need eventual surgery to remove the offending bowel segment. Systemic glucocorticoids increase the risk of intraabdominal and pelvic abscesses in Crohn patients who have never had an operation. Other complications include bowel obstruction in 40%, severe perianal disease, malabsorption, and, rarely, massive hemorrhage.

### Laboratory Findings

Laboratory abnormalities include an elevated ESR and CRP. Findings in more severe disease include hypoalbuminemia, anemia, and leukocytosis. Stool O&P, *Giardia* antigen, *C. difficile* toxin, and bacterial cultures should be negative. Fecal calprotectin may also be useful for detecting small bowel and large bowel CD activity, and several abstracts have shown it to be as sensitive and specific as ileocolonoscopy and capsule endoscopy.

### Endoscopic and Radiographic Findings

Endoscopic features of CD include rectal sparing, aphthous ulcerations, fistulas, and macroscopic and microscopic skip lesions. Colonoscopy allows examination and biopsy of the colon and terminal ileum. Wireless capsule endoscopy allows direct visualization of the entire small bowel mucosa but cannot be used in the setting of a small bowel stricture. Capsule retention occurs in 4% to 6% of patients with established CD but in only <1% of patients with suspected CD. Early radiographic findings in the small bowel include thickened folds, aphthous ulcerations, and longitudinal ulcerations and transverse ulcerations. In more advanced disease, strictures, fistulas, inflammatory masses, and abscesses can be detected. The radiographic string sign represents long areas of circumferential inflammation and fibrosis, resulting in long segments of luminal narrowing. A rare cause of luminal narrowing is intestinal cancer. The segmental nature of CD results in long gaps of normal or dilated bowel between involved segments.

Both CT and MRI of the small bowel are performed by CT enterography (CTE) or MR enterography (MRE) using oral and IV contrast. Although CTE, MRE, and small bowel follow-through (SBFT) have been shown to be equally accurate in the identification of active small bowel inflammation,

CTE and MRE have been shown to be superior to SBFT in the detection of extraluminal complications including fistulas, sinus tracts, and abscesses. Currently the use of CT scans is more common than MRI because of institutional availability and expertise. However, MRI is thought to offer superior soft tissue contrast and has the added advantage of avoiding radiation exposure. The lack of ionizing radiation is particularly appealing in younger patients and when monitoring response to therapy where serial images will be obtained. MRI is superior for visualizing pelvic lesions such as perirectal fistulas and ischiorectal abscesses.

### Complications

Because CD is a transmural process, serosal adhesions develop providing pathways for fistula formation and reducing the influence of free perforation. Free perforation occurs in 1% to 2% of patients, usually in the ileum but occasionally in the jejunum or as a rare complication of toxic megacolon. The peritonitis of free perforation, especially colonic, may be fatal. Generalized peritonitis may also result from the rupture of an intraabdominal abscess. Other complications include intestinal obstruction in 40% of patients, massive hemorrhage, which is rare, malabsorption, and severe perianal disease.

### Serologic Markers

Several serologic markers may be used to differentiate between CD and UC and help to predict the course of disease. Increased titers of anti-*Saccharomyces cerevisiae* antibody (ASCA) have been associated with CD, whereas increased levels of perinuclear antineutrophil cytoplasmic antibody (pANCA) are more commonly seen in patients with UC. However, when evaluated in a meta-analysis of 60 studies, the sensitivity and specificity of an ASCA+/pANCA–pattern for identification of CD was 55% and 93%, respectively. In addition to ASCA, multiple other antibodies to bacterial proteins (Omp-C and I2), flagellin (CBir1), and bacterial carbohydrates have been studied and associated with CD, including laminaribioside (ALCA), chitobioside (ACCA), and mannoside (SMCA). These serologic markers tend to have low sensitivity and specificity and may be elevated due to other autoimmune diseases, infections, and inflammation outside of the GI tract.

### Differential Diagnosis of Ulcerative Colitis and Crohn Disease

UC and CD have similar features to many other diseases. Because there is no key diagnostic test, a combination of clinical, laboratory, histopathologic, radiographic, and therapeutic observations are required. Once a diagnosis of IBD is made, distinguishing between UC and CD is difficult to impossible in 10% to 15% of cases. These are termed *indeterminate colitis*. The diseases commonly mistaken for IBD are detailed in [Box 72.2](#).

## • BOX 72.2 Diseases Mistaken for Crohn Disease

### Infectious

#### Bacterial

*Salmonella*, *Shigella*, toxigenic *Escherichia coli*,  
*Campylobacter*, *Yersinia*, *Clostridium difficile*, gonorrhea,  
*Chlamydia trachomatis*

#### Mycobacterial

Tuberculosis, *Mycobacterium avium*

#### Parasitic

Amebiasis, *Isospora*, *Trichuris trichiura*, hookworm,  
*Strongyloides*

#### Viral

Cytomegalovirus, herpes simplex, HIV

### Inflammatory

Appendicitis, diverticulitis, diversion colitis, collagenous/  
lymphocytic colitis, Behçet syndrome, solitary rectal ulcer,  
eosinophilic gastroenteritis, neutropenic colitis, ischemic  
colitis, radiation colitis/enteritis, graft-versus-host disease

### Neoplastic Drugs and Chemicals

Nonsteroidal antiinflammatories, phosphosoda, chemotherapy,  
lymphoma, lymphosarcoma, carcinoma of the ileum,  
familial polyposis, metastatic carcinoma

## Indeterminate Colitis

There are some cases of IBD that cannot be recognized as either UC or CD and are called *indeterminate colitis*. Long-term follow-up over a period of years reduces the number of patients labeled indeterminate to about 10%. The serologic markers of ASCA, pANCA, and anti-OmpC were of limited utility of predicting a patient's subsequent disease phenotype in one study. The disease course of indeterminate colitis is unclear, and surgical recommendations are difficult because about 20% of pouches in these patients will fail and eventually require an ileostomy. A multistage ileal pouch anal anastomosis (the initial stage consisting of a subtotal colectomy with Hartmann pouch) with careful histologic evaluation of the resected specimen to exclude CD is advised. Medical therapy is similar to UC and CD.

## Atypical Colitides

Two atypical colitides, collagenous colitis and lymphocytic colitis, have completely normal endoscopic appearances. Collagenous colitis has two main histologic components: increased subepithelial collagen deposition and colitis with increased intraepithelial lymphocytes. Male-to-female ratio is 9:1, and most patients present in the sixth or seventh decade of life. The main symptom is chronic watery diarrhea and sometimes weight loss. Treatments are variable and range from sulfasalazine or Imodium and Lomotil to bismuth to budesonide or glucocorticoids for refractory disease.

Lymphocytic colitis has features similar to collagenous colitis including age of onset and clinical presentation,

but it has almost equal incidence in men and women and no subepithelial collagen deposition on pathologic section. However, intraepithelial lymphocytes are increased. Celiac disease should be excluded in all patients with lymphocytic colitis because the frequency ranges from 9% to 27%. The treatment is the same as in collagenous colitis except for a gluten-free diet in patients with celiac disease.

Diversion colitis is an inflammatory process that arises in segments of the large intestine that are excluded from the fecal stream. Diversion colitis usually occurs in patients with ileostomies or colostomies when a mucous fistula or a Hartmann pouch has been created. Diversion colitis is reversible by surgical reanastomosis. Clinically, patients have mucous or bloody discharge from the rectum, and erythema, granularity, friability, and, in more severe cases, ulceration can be seen on endoscopy. There are areas of active inflammation with foci of cryptitis and crypt abscesses on histopathology. Crypt architecture is normal, and this differentiates it from UC. It may be impossible to distinguish it from CD. Short-chain fatty acid enemas will help in diversion colitis, but this treatment is difficult to tolerate, and the definitive therapy is surgical reanastomosis.

## Extraintestinal Manifestations

IBD is associated with a variety of extraintestinal manifestations. Up to one-third of patients have at least one. Patients with perianal CD are at higher risk for developing extraintestinal manifestations than other IBD patients. The extraintestinal manifestations are detailed in [Table 72.2](#).

## Treatment

### 5-Aminosalicylic Acid Agents

One of the main therapies for mild-to-moderate UC is sulfasalazine and the other, 5-aminosalicylic acid (5-ASA) agents ([Table 72.3](#)). Sulfasalazine consists of 5-ASA joined to a sulfapyridine moiety. It is effective in treating mild-to-moderate UC but its high rate of side effects limits its use. At the more effective, higher doses of 6 to 8 g/d, up to 30% of patients experience allergic reactions or intolerable side effects such as headache, anorexia, nausea, and vomiting that are attributable to the sulfa moiety. Many patients experience hypersensitivity reactions such as rash, fever, hepatitis, agranulocytosis, hypersensitivity, pneumonitis, pancreatitis, worsening of colitis, and reversible sperm abnormalities. Sulfasalazine can also impair folate absorption, and patients should be supplemented with folic acid.

Sulfa-free aminosalicylate formulations include alternative azo-bonded carriers, 5-ASA dimmers, pH-dependent tablets, and continuous release preparations. Each has the same efficacy as sulfasalazine when equal concentrations are used. Balsalazide contains an azo-bonded mesalamine, the carrier molecule 4-aminobenzoyl-beta-alanine; it is effective in the colon.

**TABLE 72.2** Extraintestinal Manifestations

Category	Clinical Course	Treatment
<b>Rheumatologic Disorders (5%–20%)</b>		
Peripheral arthritis	Asymmetric, migratory Parallels bowel activity	Reduce bowel inflammation
Sacroiliitis	Symmetric: spine and hip joints Independent of bowel activity	Steroids, injections, methotrexate, anti-TNF
Ankylosing spondylitis	Gradual fusion of spine Independent of bowel activity	Steroids, injections, methotrexate, anti-TNF
<b>Dermatologic Disorders (10%–20%)</b>		
Erythema nodosum	Hot, red, tender, nodules/extremities Parallels bowel activity	Reduce bowel inflammation
Pyoderma gangrenosum	Ulcerating, necrotic lesions/extremities, trunk, face, stoma Independent of bowel activity	Antibiotics, steroids, cyclosporine, infliximab, dapsone, azathioprine, intralesional steroids, thalidomide, not debridement or colectomy
Pyoderma vegetans	Intertriginous areas Parallels bowel activity	Evanescient; resolves without progression
Pyostomatitis vegetans	Mucous membranes Parallels bowel activity	Evanescient; resolves without progression
Metastatic Crohn disease	Crohn disease of the skin Parallels bowel activity	Reduce bowel inflammation
Sweet syndrome	Neutrophilic dermatosis Parallels bowel activity	Reduce bowel inflammation
Aphthous stomatitis	Oral ulcerations Parallels bowel activity	Reduce bowel inflammation/topical RX
<b>Ocular Disorders (1%–11%)</b>		
Uveitis	Ocular pain, photophobia, blurred vision, headache Independent of bowel activity	Topical or systemic steroids
Episcleritis	Mild ocular burning Parallels bowel activity	Topical corticosteroids
<b>Hepatobiliary Disorders (10%–35%)</b>		
Fatty liver	Secondary to chronic illness, malnutrition, steroid RX	Improve nutrition, reduce steroids
Cholelithiasis	Patients with ileitis or ileal resection Malabsorption of bile acids, depletion of bile salt pool, secretion of lithogenic bile	Reduce bowel inflammation
Primary sclerosing cholangitis	Intrahepatic and extrahepatic Inflammation and fibrosis leading to biliary cirrhosis and hepatic failure; 7%–10% cholangiocarcinoma	ERCP/high-dose ursodiol lowers risk of colonic neoplasia

ERCP, Endoscopic retrograde cholangiopancreatography; RX, prescription; TNF, tumor necrotic factor.

Delzicol and Asacol HD are an enteric-coated form of mesalamine, but they have a slightly different release pattern with the 5-ASA liberated at pH >7. They disintegrate with complete breakup of the tablet in many different areas of the gut ranging from the small intestine to the splenic flexure. Some 50% to 75% of patients with mild-to-moderate UC improve when treated with 2 g/d of 5-ASA. MMX mesalamine (Lialda) is a newer formulation of mesalamine that comes in capsules of 1.2 g. It can be given once or twice daily. Apriso is a newer form of mesalamine that is effective at a pH >6. The treatment effect is the same as that of Delzicol and Asacol HD at similar dosages.

Pentasa is another mesalamine formulation that uses an ethyl cellulose coating to allow water absorption into small beads containing the mesalamine. Water dissolves the 5-ASA, which then diffuses out of the bead into the lumen. The capsule disintegrates in the stomach, and the microspheres then disperse throughout the entire GI tract from the small intestine to the distal colon in both fasted and fed conditions. Topical mesalamine enemas are effective in mild-to-moderate UC. Clinical response occurs in up to 80% of UC patients with colitis distal to the splenic flexure. Mesalamine suppositories at doses of 1000 mg once or twice a day are effective in treating proctitis.

**TABLE 72.3** 5-Aminosalicylic Preparations

Preparation	Formulation	Delivery	Dosing (Per Day)
<b>Oral 5-ASA Preparations</b>			
Azo-bond sulfasalazine (500 mg) (Azulfidine)	Sulfapyridine-5-ASA	Colon	3–6 g (acute), 2–4 g (maintenance)
Olsalazine (250 mg) (Dipentum)	5-ASA-5-ASA	Colon	1–3 g
Balsalazide (750 mg) (Colazal)	Aminobenzoyl-alanine-5-ASA	Colon	6.75–9 g
Delayed-release mesalamine (400, 800 mg) (Delzicol, Asacol HD)	Eudragit S (pH 7)	Distal ileum-colon	2.4–4.8 g (acute), 1.6–4.8 g (maintenance)
Mesalamine (1.2 g) (Lialda)	MMX mesalamine (SPD476)	Ileum-colon	2.4–4.8 g (acute)
Delayed- and extended-release mesalamine (0.375 g) (Apriso)	Intellicor extended-release mechanism	Ileum-colon	1.5 g (maintenance)
Sustained-release mesalamine (250, 500 mg) (Pentasa)	Ethylcellulose microgranules	Stomach-colon	2–4 g (acute), 1.5–4 g (maintenance)
<b>Rectal 5-ASA Preparations</b>			
Mesalamine suppository (1000 mg) (Canasa)		Rectum	1–1.5 g (acute), 500 mg–1 g (maintenance)
Mesalamine enema (1, 4 g) (Rowasa)	60 mL, 100 mL suspension	Rectum-splenic flexure	1–4 g (acute), 1 g/d to 3 times/wk (maintenance)

5-ASA, 5-Aminosalicylic.

## Glucocorticoids

The majority of patients with moderate-to-severe UC benefit from oral or parenteral glucocorticoids. Prednisone is usually started at doses of 40 to 60 mg/d for active UC that is unresponsive to 5-ASA therapy. IV glucocorticoids may be administered as IV hydrocortisone 300 mg/d or methylprednisolone 40 to 60 mg/d in divided doses. A new glucocorticoid for UC, Uceris (budesonide), is released entirely in the colon and has minimal-to-no steroid side effects. The dose is 9 mg/d for 8 weeks, and no taper is required.

Topically applied glucocorticoids are also beneficial for distal colitis and may serve as an adjunct in those who have rectal involvement plus more proximal disease. Hydrocortisone enemas or foam may control active disease, although they have no proven role as maintenance therapy. These glucocorticoids are significantly absorbed from the rectum and can lead to adrenal suppression with prolonged administration.

Glucocorticoids are also effective for treatment of moderate-to-severe CD and induce a 60% to 70% remission rate compared with a 30% placebo response. Glucocorticoids play no role in maintenance therapy in either UC or CD. Once clinical remission has been induced, they should be tapered according to the clinical activity, normally at a rate of no more than 5 mg/wk. They can usually be tapered to 20 mg/d within 4 to 5 weeks but often take several months to be discontinued altogether. The side effects are numerous including fluid retention, abdominal striae, fat redistribution, hyperglycemia, subcapsular cataracts, osteonecrosis, myopathy, emotional disturbances, and withdrawal

symptoms. Most of these side effects, except for osteonecrosis, are related to the dose and duration of therapy.

Controlled ileal-release budesonide has been nearly equal to prednisone for ileocolonic CD with fewer glucocorticoid side effects. Budesonide is used for 2 to 3 months at a dose of 9 mg/d, then tapered. Budesonide 6 mg/d is effective in reducing relapse rates at 3 to 6 months but not at 12 months in CD patients with a medically induced remission.

## Antibiotics

Despite numerous trials, antibiotics have no role in the treatment of active or quiescent UC. However, in pouchitis, which occurs in about 30% to 50% of UC patients after colectomy, an ileal pouch–anal anastomosis usually responds if treated with metronidazole and/or ciprofloxacin.

Metronidazole is effective in active inflammatory, fistulizing, and perianal CD. The most effective dose is 15 to 25 mg/kg/d used in three divided doses. It is usually continued for several months. However, side effects impair its use. They include nausea, metallic taste, and disulfiram-like reactions. Peripheral neuropathy can occur with prolonged administration over several months' time and, on rare occasions, is permanent despite discontinuation. Cipro, 500 mg twice a day, is also beneficial for inflammatory, perianal, and fistulizing CD. The side effects of ciprofloxacin include arthralgias and Achilles tendon rupture, and thus Cipro should be used long-term only with caution. The drugs are typically used for mild disease in patients who do not wish to start immunosuppressive therapy or in patients with perianal abscess before drainage.

## Azathioprine and 6-Mercaptopurine

Azathioprine (AZA) and 6-mercaptopurine (6-MP) are purine analogues commonly used in the management of glucocorticoid-dependent IBD. AZA is rapidly absorbed and converted to 6-MP, which is then metabolized to the active end product, thiopurine nucleosides, an inhibitor of purine ribonucleotide synthesis and cell proliferation. These agents also inhibit the immune response. Efficacy is seen at 6 to 12 weeks. Adherence can be monitored by monitoring the levels of 6-thioguanine nucleotides and 6-methylmercaptopurine, end products of 6-MP metabolism. AZA, 2 to 2.5 mg/kg/d, or 6-MP, 1 to 1.5 mg/kg/d, has been used successfully as a glucocorticoid-sparing agent in up to two-thirds of CD and UC patients previously unable to be weaned from glucocorticoids. They are also effective as concomitant therapy in patients using anti-tumor necrotic factor (TNF) or anti-integrin drugs.

Although these medications are usually well tolerated, pancreatitis can occur in up to 3% to 4% of patients; it usually occurs within the first month of therapy and is completely reversible after the drug is stopped. Other side effects of these drugs include nausea, fever, rash, and hepatitis. Bone marrow suppression, particularly leukopenia, is dose related and often delayed, necessitating regular monitoring of the complete blood count. In addition, 1 in 300 individuals lacks thiopurine methyltransferase, the enzyme responsible for drug metabolism. An additional 11% of the population are heterozygotes with intermediate enzyme activity. Both are at increased risk of toxicity because of increased accumulation of thiopurine metabolites. Thiopurine methyltransferase phenotype can be checked to rule out a severe deficiency. In patients with intermediate activity, AZA/6-MP can be started at one-third or one-half of the usual dose. One metaanalysis demonstrated a 4-fold risk of lymphoma in IBD patients on AZA/6-MP. No increased risk of solid organ tumors has been documented in IBD patients taking these medications long term.

## Methotrexate

Methotrexate inhibits dihydrofolate reductase, resulting in impaired DNA synthesis. Intramuscular or subcutaneous methotrexate at 25 mg/wk is effective in inducing remission and reducing glucocorticoid dosage, and 15 mg/wk is effective in maintaining remission of CD. This medication is often used concomitantly with biologics in patients intolerant or refractory to AZA/6-MP. Potential toxicities include leukopenia and hepatic fibrosis, necessitating periodic evaluation of complete blood counts and liver enzymes. The role of liver biopsy in patients on long-term methotrexate is uncertain. Hypersensitivity pneumonitis is a rare but serious complication of therapy.

## Cyclosporine

Cyclosporine (CSA) alters the immune response by acting as a potent inhibitor of T-cell-mediated responses. Although

CSA acts primarily via inhibition of IL-2 production from T-helper cells, it also decreases recruitment of cytotoxic T cells and blocks other cytokines including IL-3, IL-4, interferon- $\alpha$ , and TNF. It has a more rapid onset of action than 6-MP and AZA.

CSA is most effective given at 2 to 4 mg/kg/d in continuous infusion in severe UC refractory to IV steroids. In this scenario, about 80% of patients respond. CSA can be an alternative to colectomy, but the long-term success of oral CSA is not as dramatic. If patients are started on 6-MP or AZA at the time of discharge from the hospital, remission can be obtained. IV CSA is effective in 80% of patients with refractory fistulas, but 6-MP and AZA must be used to maintain remission. Serum levels should be monitored and kept within a range of 200 to 400 ng/mL as measured by a high-performance liquid chromatography assay. The levels should be anywhere between 300 and 500  $\mu$ g/mL as measured by monoclonal radioimmunoassay.

CSA has the potential for significant toxicity, and renal function should be frequently monitored. Hypertension, gingival hyperplasia, hypertrichosis, paresthesias, tremors, headaches, and electrolyte abnormalities are common side effects. Creatinine elevation calls for dose reduction or discontinuation. Seizures may complicate therapy especially if the patient is hypomagnesemic or if serum cholesterol levels are <120 mg/dL. Opportunistic infections, most notably *Pneumocystis carinii* pneumonia, have occurred with combination immunosuppressive treatment. Prophylaxis should then be given.

To compare IV CSA versus infliximab, a large trial was conducted in Europe by the GETAID (Group d'Etudes Thérapeutiques des Affections Inflammatoires Digestives) group. The results indicated identical 7-day response rates between CSA 2 mg/kg (with doses adjusted for levels of 150–250 ng/mL) and infliximab 5 mg/kg, with both groups achieving response rates of 85%. Serious infections occurred in 5 of 55 CSA patients and 4 of 56 infliximab patients. Response rates were similar in the two groups at day 98 among patients treated with oral CSA versus infliximab at the usual induction dose and maintenance dose regimen (40% and 46%, respectively).

## Anti-Tumor Necrotic Factor Therapy

Infliximab, a chimeric monoclonal antibody directed against the proinflammatory cytokine TNF- $\alpha$ , is approved by the US Food and Drug Administration (FDA) for use in moderate-to-severe CD. Of active CD patients refractory to glucocorticoids, 6-MP, or 5-ASA, 65% will respond to IV infliximab (5 mg/kg); one-third will enter complete remission. Of the patients who experience an initial response, 40% will maintain remission for at least 1 year with repeated infusions of infliximab every 8 weeks. Infliximab is also effective in CD patients with refractory perianal and enterocutaneous fistulas, with a 68% response rate (50% reduction in fistula drainage) and a 50% complete remission rate. Reinfusion, typically every 8 weeks, is necessary to continue therapeutic benefits in many patients.

The SONIC (Study of Biologic and Immunomodulator-Naïve Patients with CD) trial compared infliximab plus AZA, infliximab alone, and AZA alone in immunomodulator and biologic naïve patients with moderate-to-severe CD. At 1 year, of 508 randomized patients the infliximab plus AZA group exhibited a steroid-free remission rate of 46% compared with 35% (infliximab alone) and 24% (AZA alone). There was also increased complete mucosal healing at week 26 with the combined approach relative to either infliximab or AZA alone (44% vs. 30% vs. 17%). The adverse events were equal among groups.

The development of antibodies to infliximab (ATI) is associated with an increased risk of infusion reactions and a decreased response to treatment. Patients who receive on-demand or episodic infusions rather than periodic (every 8 weeks) infusions are more likely to develop ATI. If infliximab is used episodically for flares, patients must use concomitant immunosuppression with AZA, 6-MP, or methotrexate in therapeutic doses to decrease the clinical consequences of immunogenicity of the chimeric antibodies. Moreover, prophylaxis with hydrocortisone before each infusion of infliximab will also decrease the formation of ATI. When the quality of response or the response duration to infliximab infusion decreases, this will be caused by high titers of ATI with formation of complexes and early elimination. Increase of the dosage administered to 10 mg/kg may restore the efficacy of the drug. Infliximab trough levels and antibodies to infliximab can be measured to determine whether a patient needs a dose increase because of low levels or whether a patient has antibodies to infliximab and thus needs a different anti-TNF medication. A recent metaanalysis attempted to quantify the risk of non-Hodgkin lymphoma associated with anti-TNF use in IBD. In 26 studies including nearly 9000 patients and more than 20,000 patient-years of follow-up, the lymphoma rate was approximately 6 per 10,000 patient-years. This equated to a standardized incidence ratio of 3.23 (95% confidence interval, 1.5–6.9). The majority of the patients had also been exposed to immunomodulators such that it was not possible to identify whether anti-TNF monotherapy is associated with an increased risk of lymphoma. However, in this analysis the risk of lymphoma was higher in patients exposed to anti-TNF (mostly combination therapy) than thiopurines alone, suggesting that there is probably an additive risk of anti-TNF therapy on top of thiopurines.

Other morbidities of infliximab include acute infusion reactions, severe serum sickness, and increased risk of infections, particularly histoplasmosis and reactivation of latent tuberculosis. Rarely, infliximab has been associated with optic neuritis, seizures, new onset or exacerbation of clinical symptoms, and/or radiographic evidence of central nervous system demyelinating disorders including multiple sclerosis. It may exacerbate symptoms in patients with New York Heart Association functional class III/IV heart failure.

New-onset psoriasiform skin lesions develop in nearly 5% of IBD patients treated with anti-TNF therapy. Most often, these can be treated topically, and rarely, anti-TNF

therapy must be decreased, switched, or stopped. The risk of melanoma is increased almost 2-fold with anti-TNF and not thiopurine use. The risk of nonmelanoma skin cancer is increased with thiopurines and biologics, especially with  $\geq 1$  year of follow-up. Patients on these medications should have a skin check at least once a year.

Infliximab is also standard therapy for moderate-to-severe UC. In two large randomized placebo-controlled trials, 37% to 49% of patients responded to infliximab, and 22% and 20% of patients were able to maintain remission after 30 and 54 weeks, respectively. Patients received infliximab at 0, 2, and 6 weeks and then every 8 weeks until the end of the study.

The fully human monoclonal antibody adalimumab (Humira) and the PEGylated humanized monoclonal antibody certolizumab pegol (Cimzia) are also approved for the treatment of CD. Adalimumab is a recombinant human monoclonal IgG1 antibody containing only human peptide sequences and is injected subcutaneously. Adalimumab binds TNF- $\alpha$  and neutralizes its function by blocking the interaction between TNF and its cell surface receptor. Therefore it seems to have a similar mechanism of action to infliximab but with less immunogenicity. Certolizumab is made up of the Fab' fragment of a humanized monoclonal antibody to TNF- $\alpha$  linked with two molecules of polyethylene glycol. Because it lacks the Fc portion of the antibody, certolizumab pegol only exerts its activity through binding to soluble TNF- $\alpha$  and cannot bind to cell surface receptors. Infliximab, adalimumab, and certolizumab all have about equal efficacy in CD.

Adalimumab and most recently golimumab (another fully human IgG1 antibody against TNF- $\alpha$ ) are also approved for the treatment of moderately to severely active UC.

### Inhibitors of Leukocyte Adhesion

Integrins are expressed on the surface of leukocytes and serve as mediators of leukocyte adhesion to vascular endothelium. Alpha-4-integrin along with its  $\beta 1$  or  $\beta 7$  subunit interacts with endothelial ligands termed *adhesion molecules*. Interaction between  $\alpha 4\beta 7$  and mucosal addressin cellular adhesion molecule (MAdCAM-1) is important in lymphocyte trafficking to gut mucosa. Natalizumab is a recombinant humanized IgG4 antibody against  $\alpha 4$ -integrin that has been shown to be effective in induction and maintenance of patients with CD. Natalizumab is approved in CD for the treatment of patients with moderate-to-severe disease who have failed to respond or who have lost response to immunosuppressive therapy and anti-TNF antibodies. The rate of response and remission at 3 months are about 60% and 40%, respectively, with a sustained remission rate of about 40% at 36 weeks. Because of the risk of progressive multifocal leukoencephalopathy (PML), we will rarely consider natalizumab in patients who have not previously failed two TNF inhibitors, at least one in combination with an immunosuppressive (AZA, 6-MP,

methotrexate). Natalizumab is administered intravenously, 300 mg every 4 weeks. Labeling requirements mandate that it not be used in combination with any immunosuppressive medications.

The FDA approved a commercial enzyme-linked immunosorbent assay (ELISA) kit to assay anti-John Cunningham virus (JCV) antibodies (Stratify JCV Antibody ELISA, Focus Diagnostics, Cypress, CA) in early 2012. Patients are tested for JCV carriage before initiating natalizumab and then rechecked in the first 6 months to exclude a false-negative result as well as a new seroconversion. Patients are monitored with JCV serologies annually, because 1% to 2% of patients will seroconvert yearly. The chances of a patient developing PML in the absence of exposure to JCV are negligible to nonexistent. In contrast, a CD patient who has been treated with natalizumab for more than 2 years and has been exposed to the JCV is at an inordinately high risk of developing PML (1/100).

## Nutritional Therapies

Dietary antigens may act as stimuli of the mucosal immune response. Patients with active CD respond to bowel rest along with total enteral or total parenteral nutrition (TPN). Bowel rest and TPN are as effective as glucocorticoids for inducing remission of active CD but are not as effective as maintenance therapy. Enteral nutrition in the form of elemental or peptide-based preparations is also as effective as glucocorticoids or TPN, but these diets are not palatable. In contrast to CD, active UC is not effectively treated by either elemental diets or TPN. Medical therapies for IBD are shown in [Box 72.3](#).

## Surgical Therapy

### Ulcerative Colitis

Nearly half of patients with extensive, chronic UC undergo surgery within the first 10 years of their illness. The indications for surgery are listed in [Box 72.4](#). Morbidity is about 20% in elective, 30% for urgent, and 40% for emergency proctocolectomy. The risks are mainly hemorrhage, sepsis, and neural injury.

The ileal-pouch anal anastomosis (IPAA) is the most frequent continence-preserving operation performed. Because UC involves only the mucosa, the mucosa of the rectum can be dissected out and removed down to the dentate line of the anus or about 2 cm proximal to it. The ileum is then fashioned into a pouch that serves as a neorectum. This pouch is then sutured circumferentially to the anus in an end-to-end fashion. If performed carefully, this operation preserves the anal sphincter and maintains continence. The overall operative morbidity is 10%, the major complication being bowel obstruction. Pouch failure necessitating conversion to permanent ileostomy occurs in 5% to 10% of patients. Some inflamed rectal mucosa is usually left behind, and endoscopic surveillance is necessary. Primary dysplasia of the ileal mucosa of the pouch has rarely occurred.

## • BOX 72.3 Medical Management of Inflammatory Bowel Disease

### Distal Ulcerative Colitis

5-ASA (rectal and/or oral)  
 Glucocorticoid (rectal)  
 Glucocorticoid (oral)  
 Glucocorticoid (intravenous)  
 6-MP or azathioprine  
 Infliximab, adalimumab, golimumab  
 Vedolizumab  
 Cyclosporine

### Extensive Ulcerative Colitis

5-ASA (oral and rectal)  
 Glucocorticoid (oral and rectal)  
 Glucocorticoid (intravenous)  
 6-MP or azathioprine  
 Infliximab/adalimumab/golimumab  
 Vedolizumab  
 Cyclosporine

### Inflammatory Crohn Disease

Budesonide (ileal and right-sided colonic disease)  
 Prednisone  
 Intravenous glucocorticoid  
 6-MP/azathioprine  
 Methotrexate  
 Infliximab/adalimumab/certolizumab pegol  
 Vedolizumab  
 Natalizumab if JCV AB negative  
 Intravenous cyclosporine or tacrolimus

### Fistulizing Crohn Disease

Antibiotics  
 6-MP/azathioprine  
 Methotrexate  
 Infliximab/adalimumab/certolizumab pegol  
 Vedolizumab  
 Natalizumab if JCV AB negative  
 Intravenous cyclosporine or tacrolimus  
 Total parenteral nutrition

AB, Antibody; JCV, John Cunningham virus; 6-MP, 6-mercaptopurine.

Patients with IPAA usually have about six to eight bowel movements a day and one at night. The most frequent late complication of IPAA is pouchitis. In about 30% to 50% of patients with UC, this syndrome consists of increased stool frequency, watery stools, cramping, urgency, nocturnal leakage of stool, arthralgias, malaise, and fever. Although it usually responds to antibiotics 3% to 5% of the time, it is refractory to even immunomodulators or infliximab and requires pouch takedown.

### Crohn Disease

Most patients with CD require at least one operation in their lifetime. The need for surgery is related to duration of disease and site of involvement. Patients with small bowel disease alone have an 80% chance of requiring surgery; those with colitis alone have a 50% chance. The indications for surgery are shown in [Box 72.4](#).

### • BOX 72.4 Indications for Surgery

#### Ulcerative Colitis

Intractable disease  
Fulminant disease  
Toxic megacolon  
Colonic perforation  
Massive colonic hemorrhage  
Extracolonic disease  
Colonic stricture  
Colon dysplasia or cancer

#### Crohn Disease of Small Intestine

Stricture and obstruction unresponsive to medical therapy  
Massive hemorrhage  
Refractory fistula  
Abscess  
Malignancy

#### Crohn Disease of Colon and Rectum

Intractable disease  
Fulminant disease  
Perianal disease unresponsive to medical therapy  
Refractory fistula  
Colonic stricture  
Colon dysplasia or cancer

### Small Intestinal Disease

CD is chronic and recurrent with no clear surgical cure, so as little intestine as possible is resected. For treating obstructive CD, the current surgical alternatives are resection or stricturoplasty. Resection of the diseased segment is the more frequently performed operation, and in most cases, primary anastomosis can be performed. If much of the small bowel has been resected and the stricture is short, a stricturoplasty can be performed. In this procedure, a strictured area of intestine is incised longitudinally, and the incision is sutured transversely, thus widening the narrowed area. Complications include ileus, hemorrhage, fistula, abscess, leak, and restriction.

### Colorectal Disease

There are several alternatives available ranging from the use of a temporary ileostomy to resection of segments of

diseased colon or even a total proctocolectomy. In 20% to 25% of patients with extensive colitis, the rectum is spared sufficiently to consider rectal preservation (J-pouch construction). Most surgeons believe that an IPAA is contraindicated in Crohn with a high rate of pouch failure. Even though a diverting colostomy can help heal severe perianal disease or rectal vaginal fistulas, the disease recurs with reanastomosis. Often these patients require a total proctocolectomy and ileostomy.

### Cancer in Inflammatory Bowel Disease

The risk of neoplasia in chronic UC increases with duration and extent of disease. For patients with pancolitis, the risk of cancer rises 0.25% to 0.5% per year after 8 to 10 years of disease. This observed increase in cancer rates has led to the endorsement of surveillance colonoscopy with biopsies for patients with chronic UC as the standard of care. Annual or biennial colonoscopy with multiple biopsies has been advocated for patients with >8 to 10 years of pancolitis or 12 to 15 years of left-sided colitis and has been widely used to screen and survey for subsequent dysplasia and carcinoma.

Risk factors for developing colorectal cancer in CD are a history of colonic (or ileocolonic) involvement and long-disease duration. The cancer risks in CD and UC are probably equivalent for similar extent and duration of disease. The same endoscopic surveillance strategy used for UC is recommended for patients with chronic Crohn colitis. A pediatric colonoscope can be used to pass narrow strictures in CD patients, but surgery should be considered in symptomatic patients with impassable strictures.

IBD patients are also at greater risk for other malignancies. Patients with CD may have an increased risk of developing non-Hodgkin lymphoma and squamous cell carcinoma of the skin. There is an increased risk of melanoma with anti-TNF therapy and nonmelanoma skin cancer with thiopurines. Although CD patients have a 12-fold increased risk of developing small bowel cancer, this type of carcinoma is extremely rare.

## Chapter Review

### Questions

1. A 25-year-old female is referred to the gastroenterology clinic with a 6-month history of daily right lower quadrant pain, at least 8 to 10 loose bowel movements a day, and a weight loss of 15 lb over the past 6 months. She reports low-grade fever at home and increasing night sweats. She has difficulty tolerating many foods, including fresh fruits and vegetables, red meat, and milk products. She has just started a job teaching high school science and has missed too many days of work caused by pain, fatigue, and urgent bowel movements. Her physical examination is significant for a fever of 99.5°F, her blood pressure is 124/82 mm Hg, and

her heart rate is 96 beats per minute. Her lungs are clear, and her cardiac examination is normal. Her abdominal examination is significant for right lower quadrant pain to palpation. Her rectal examination is guaiac negative, and she has no perianal skin tags, fissures, or fistulas. Her hemoglobin is 10 g/dL, her CRP is 7 g/dL, and her white blood cell count is 9600/ $\mu$ L. Stool studies for O&P are negative, stool *Giardia* antigen is negative, and stool for *C. difficile* and bacterial cultures is negative. Serologies are negative for celiac disease or thyroid abnormalities. Lactose breath test is negative for lactose intolerance.

The history, examination, and laboratory data are suspicious for CD.

What further studies should be done?

- A. Small bowel series
  - B. Colonoscopy and biopsy
  - C. MRE
  - D. IBD serology 7 blood testing for ASCA IgA and IgG, anti-OmpC IgA, anti-CBir1, and pANCA
2. For the patient in Question 1, MRE is performed and reveals chronic thickening of the last 20 cm of the terminal ileum and the right colon. Colonoscopy and biopsy are then performed. The cecum and ascending colon are severely inflamed with deep ulcerations, and the rest of the colon is macroscopically and microscopically normal. The terminal ileum is severely inflamed with deep ulcerations. Ileal biopsies reveal severe chronic active ileitis, and right-sided colon biopsies reveal severe chronic active colitis.

What medical therapy should be started first?

- A. AZA/6-MP
  - B. Infliximab/adalimumab/certolizumab pegol
  - C. Pentasa
  - D. Budesonide
  - E. Prednisone
  - F. Infliximab/adalimumab/certolizumab pegol + AZA/6-MP
3. The patient in Question 1 is given oral budesonide, 9 mg each morning. Symptoms worsen, and she now has severe right lower quadrant pain and fever to 39.4°C. CT of the abdomen reveals a terminal ileal abscess.

What should be done now?

- A. IV hydrocortisone
  - B. Surgical resection of the abscess and the terminal ileum
  - C. CT-guided abscess drainage and IV antibiotics
  - D. Stop budesonide and oral antibiotics at home.
4. An 18-year-old man presents to the gastroenterology clinic with a 5-week history of bloody diarrhea. His symptoms started after eating a bad turkey sandwich, and he has had diarrhea mixed with blood each time he eats or drinks. He has lost 10 lb and is having crampy abdominal pain. Most recently, he has been waking up in the middle of the night to use the bathroom. He has been previously healthy with no history of non-steroidal antiinflammatory drug use and no history of

smoking. He has no family history of IBD or colon cancer.

On physical examination, he is tachycardic at 102 beats per minute, and his blood pressure is 105/82 mm Hg. His abdominal examination is significant for left-sided tenderness with no rebound. His rectal examination is negative for any fissures, skin, tags, or fistulas. His hemoglobin is 9.5 g/dL, his sedimentation rate is 40 mm/h, and his platelet count is 556,000/ $\mu$ L. His temperature is 38°C. Stool bacterial cultures, O&P, and *C. difficile* are negative. Flexible sigmoidoscopy shows active inflammation, marked erythema, and contact bleeding to 30 cm and beyond the reach of the scope. Biopsies reveal moderate chronic active colitis.

What is the first-line treatment for this patient?

- A. Prednisone
  - B. A 5-ASA agent
  - C. IV hydrocortisone
  - D. AZA
5. Mesalamine at 2.4 g a day is given, and symptoms worsen. The dose is increased to 4.8 g a day and symptoms worsen still. What is the next step?
- A. Prednisone
  - B. IV hydrocortisone
  - C. Infliximab
  - D. Hydrocortisone enema twice a day
6. The patient starts prednisone at 40 mg a day. Within 24 hours, he is markedly better. He decreases the prednisone by 5 mg a week. When he reduces to 15 mg, some symptoms of diarrhea, blood, and abdominal cramps return. What is the next step?
- A. IV hydrocortisone
  - B. AZA
  - C. Increase prednisone to 40 mg a day
  - D. Infliximab
  - E. Colectomy

## Pancreatic Disease

DAVID X. JIN AND JULIA MCNABB-BALTAR

### Acute Pancreatitis

Acute pancreatitis is an acute inflammatory disorder of the pancreas characterized by severe abdominal pain and often the development of loco-regional and systemic complications. Its annual incidence ranges from 13 to 45 cases per 100,000 individuals worldwide. Within the United States alone, acute pancreatitis accounts for 270,000 hospital admissions annually with hospital costs exceeding \$2.5 billion. With an overall mortality of 2% to 5%, and exceeding 10% to 30% in severe cases, an understanding of key principles is necessary to provide optimal patient care.

### Pathogenesis

The pathogenesis of acute pancreatitis is being elucidated but generally considered in three phases. In the first phase, premature activation of trypsin within the pancreatic acinar cells leads to the activation of a variety of injurious digestive enzymes. Changes in the acinar cell, such as disruption of calcium signaling, decreased activity of the intracellular pancreatic trypsin inhibitor, and premature cleavage of trypsinogen to trypsin are proposed mechanisms.

In the second phase, autodigestion and cellular injury lead to an amplification of the inflammatory cascade within the pancreatic acinar cell. This is mediated through cytokine-driven activation of inflammatory cells, chemoattraction of activated inflammatory cells to the microcirculation, and subsequent migration into areas of inflammation via adhesion molecules.

In the third phase, extrapancreatic inflammation occurs in up to 20% of patients, typically resulting in the systemic inflammatory response syndrome (SIRS). In some instances, SIRS predisposes to pancreatic necrosis and/or systemic multiorgan failure including hypotension, acute kidney injury, and acute respiratory distress syndrome. It is not clearly understood why certain patients develop systemic toxicity and greater disease severity. In 80% of cases, acute pancreatitis is mild and self-limited.

### Etiology

The most common causes of acute pancreatitis are listed in [Box 73.1](#). Within the United States, gallstones and alcohol account for approximately 70% of cases. Many drugs have been observed to cause acute pancreatitis although fewer than half of all cases are recognized, and most result in mild disease. Postendoscopic retrograde cholangiopancreatography (ERCP) pancreatitis is the most common iatrogenic cause with an incidence rate of 4% to 6%. High serum triglyceride levels can result in acute pancreatitis typically when levels exceed 1000 mg/dL with severity that is level dependent. Other etiologies include hypercalcemia, various infections, exposures to certain toxins, and trauma.

Variations in pancreatic anatomy have been implicated as potential causes of acute pancreatitis. Pancreas divisum is a common congenital abnormality found in 7% of the US population caused by the incomplete or absence of fusion between the dorsal and ventral pancreatic ducts during embryogenesis. Pancreatitis is thought to develop when there is obstruction of dorsal ductal drainage across a stenotic minor ampulla, although the majority of individuals with pancreas divisum never develop the disease. Anomalous pancreaticobiliary junction, papillary stenosis, periampullary diverticuli, and sphincter of Oddi dysfunction may rarely lead to pancreatitis because of disruptions in pancreatic ductal drainage.

In approximately 15% to 20% of cases, no cause is found. Although classified as idiopathic, a significant proportion are caused by biliary sludge (microlithiasis) not evident on initial abdominal ultrasonography. Endoscopic ultrasound (EUS) examination after symptoms resolve evaluates the gallbladder or biliary tree for sludge, as well as the pancreatic parenchyma for underlying neoplasia. Magnetic resonance cholangiopancreatography (MRCP) may detect underlying variations in pancreatic anatomy. Triglyceride levels may normalize when patients are fasting, and serum calcium levels may be normal in severe acute pancreatitis. These should be rechecked if a cause is not identified. In young patients with recurrent idiopathic pancreatitis or in patients with a family history of pancreatitis, genetic testing is appropriate.

### • BOX 73.1 Causes of Acute Pancreatitis

- Biliary (gallstones, sludge)
- Alcohol
- Medications (commonly implicated)
  - 6-Mercaptopurine
  - Alpha-methyl dopa
  - Azathioprine
  - Codeine
  - Enalapril
  - Dexamethasone
  - Furosemide

  - Periampullary diverticulum
  - Papillary stenosis
  - Sphincter of Oddi dysfunction
- Genetic
  - Cationic trypsinogen/serine protease 1 gene (*PRSS1*) mutation
  - Cystic fibrosis transmembrane conductance regulator gene (*CFTR*) mutation
  - Serine protease inhibitor Kazal type 1 gene (*SPINK1*) mutation
  - Chymotrypsin C gene (*CTRC*) mutation
- Trauma
  - Postendoscopic retrograde cholangiopancreatography, iatrogenic, blunt, or penetrating trauma
- Toxins
  - Scorpion venom
  - Organophosphate exposure
- Other
  - Autoimmune pancreatitis (IgG4-related disease)
  - Vasculitis: polyarteritis nodosa, lupus
  - Ischemia
- Idiopathic

### Clinical Presentation

Acute pancreatitis presents with pain localized to the mid-epigastrium that radiates to the back in approximately one-half of cases. The onset of pain may be swift, particularly in

• **Fig. 73.1** Acute interstitial pancreatitis. There is peripancreatic fat stranding; the pancreas is edematous but enhances completely; a gallstone is present (*arrow*).

biliary pancreatitis, reaching maximum intensity within 30 minutes. Pain is often accompanied by nausea, vomiting, and anorexia and characteristically persists for at least 24 hours. Physical examination usually reveals severe abdominal tenderness at times associated with guarding or rebound tenderness. Other findings may include fever, tachycardia, tachypnea, or hypotension.

Grey-Turner's sign is bluish discoloration of the flanks resulting from pancreatitis-induced intraabdominal hemorrhage. Cullen's sign is a similar discoloration around the periumbilical area. Both signs occur in <3% of cases but are associated with mortality as high as 35% when either is present.

### Diagnosis

The diagnosis of acute pancreatitis requires at least two of the following: (1) characteristic abdominal pain; (2) serum amylase and/or lipase level greater than three times the upper limit of normal; and (3) characteristic findings of acute pancreatitis (**Fig. 73.1**) on contrast-enhanced computed tomography (CT) or MR imaging. In the large majority of patients, the diagnosis can be made using nonradiographic criteria. Situations when early CT or MRI may be helpful include diagnostic uncertainty (e.g., patient sedated, amylase/lipase <3× upper limit of normal) or a need to rule out other life-threatening disorders (e.g., duodenal perforation) in the face of clinical deterioration. Otherwise, cross-sectional imaging should be deferred at least 72 to 96 hours after symptom onset and when there is clinical evidence of increased severity and suspicion for the interval development of pancreatic necrosis (**Fig. 73.2**) or other complications.

Once the diagnosis has been made, the etiology of acute pancreatitis should be elucidated using a detailed history

• **Fig. 73.2** Acute necrotizing pancreatitis. Area of poor contrast enhancement involving the pancreatic head and body represents parenchymal necrosis (yellow arrow); the pancreatic tail is relatively spared (white arrow).

(previous episodes, known gallstones, alcohol intake, medication use, recent procedures), family history of pancreatic disease, physical examination, laboratory testing (liver enzymes, calcium, triglycerides), and imaging (right upper quadrant ultrasound).

### Disease Classification

Disease severity is stratified according to the Revised Atlanta Classification into mild, moderately severe, and severe acute pancreatitis.

The majority of patients (80%) will develop mild disease, defined as the absence of organ failure or local or systemic complications. These patients usually do not need pancreatic imaging, have a mortality <1%, and will have short-term resolution with hospitalizations lasting 3 to 7 days.

Moderately severe acute pancreatitis is characterized by transient organ failure (lasting <48 h) or the presence of local or systemic complications. Organ failure is determined by degree of respiratory, renal, or cardiovascular compromise defined as an arterial oxygen partial pressure/fractional inspired oxygen <300, creatinine >1.9 mg/dL, or systolic blood pressure <90 mm Hg not responsive to intravenous (IV) fluids, respectively. Local complications include those that develop in the acute setting (peripancreatic fluid collections and acute necrotic collections), as well as those that develop after 4 weeks (pancreatic pseudocysts and walled-off necrosis). Systemic complications are defined as exacerbations of pre-existing comorbidities, including congestive heart failure or chronic lung disease.

Patients with severe acute pancreatitis have persistent organ failure for >48 hours. Most of these patients develop

pancreatic necrosis, are hospitalized for weeks to months, and have mortality rates reaching 30%. Early mortality in these patients is typically caused by systemic toxicity and organ failure. Mortality beyond 2 weeks is related to infected necrosis.

### Predictors of Severity

In 1974 Ranson et al. published 11 clinical signs that help predict severity in acute pancreatitis. Five are measured at admission and six during the initial 48 hours, with increasing number of signs correlating with increased morbidity and mortality. Although these signs continue in use, accurate predictors of severity are needed much earlier than 48 hours and ideally at time of admission. The need to rapidly determine which patients are at risk for developing severe acute pancreatitis has led to the development of several other predictive scoring systems as well as clinical, laboratory, and radiographic markers of disease severity.

Risk factors for a severe course include older age (>55 years), obesity (body-mass index >30), organ failure at admission, and pleural effusions. Patients with these characteristics may require close observation in an intensive care unit (ICU). Gender, etiology, and degree of amylase or lipase elevation offer no prognostic significance.

The acute physiologic and chronic health evaluation (APACHE-II) score evaluates 12 physiologic parameters in addition to patient age and history of chronic organ insufficiency or immunocompromised state. APACHE-II scores can be calculated at any time during hospitalization and are an accurate predictor of severe disease particularly when the score is >8.

The bedside index for severity in acute pancreatitis (BISAP) scoring system takes into consideration five signs: blood urea nitrogen (BUN) >25 mg/dL, impaired mental status, presence of SIRS, age >60 years, and the presence of a pleural effusion. The accuracy of BISAP has been validated in many studies, with predicted mortality increasing with scores of 3, 4, and 5 (5.3%, 12.7%, and 22.5%, respectively).

The harmless acute pancreatitis (HAPS) scoring system focuses on three criteria at admission (normal hematocrit, normal creatinine, and the absence of guarding or rebound tenderness) to identify patients who will have a mild, self-limited course with high specificity (96%) and high positive predictive value (98%).

The use of SIRS has been advocated to predict severe acute pancreatitis at admission, owing to its widespread familiarity, simplicity, and comparable accuracy to the scoring systems mentioned previously. Patients who do not fulfill SIRS criteria (<2 of the following) during the first 24 hours of hospitalization, (1) temperature <36°C or >38°C; (2) heart rate >90 beats per minute; (3) respiratory rate >20 breaths per minute; (4) white blood cells <4 × 10<sup>6</sup>/mL, >12 × 10<sup>6</sup>/mL, or >10% immature bands, have an extremely low likelihood of developing pancreatic necrosis or persistent

organ failure, needing ICU level care, or death. The likelihood of severe disease increases as more SIRS criteria are met and especially in those with persistent SIRS (>48 h).

Several single laboratory tests have been used as markers of severity. A serum hematocrit >44% on admission is a marker for necrosis and organ failure, and patients with further increases in hematocrit after 24 hours invariably developed pancreatic necrosis. Elevated BUN at admission and further increases in BUN during the first 24 hours correlate with increased mortality. Elevated levels of the acute phase reactant, C-reactive protein, correlate with necrosis when greater than 150 mg/L within 72 hours of hospitalization. However, because peak levels are not typically reached until after 36 to 72 hours, its use to assess acute pancreatitis severity at time of admission is limited.

CT classification systems, such as the modified CT severity index, help predict severity by assessing the degree of necrosis, pancreatic inflammation, and extrapancreatic complications. CT scoring systems are not superior to clinical scoring systems in predicting disease severity or prognosis, and because the extent of necrosis may only become apparent 72 to 96 hours after symptom onset, CT imaging should only be used thereafter in most cases.

## Treatment

The principles of treatment include an early estimation of severity, symptomatic support, aggressive fluid resuscitation, appropriate triage, and treatment of the underlying etiology.

Proper supportive care is essential. Vital signs (including oxygen saturation) should initially be obtained at frequent (every 4 h) intervals. Daily fluid balance should be carefully measured. Supplemental oxygen should be administered in the first 24 to 48 hours, particularly if opiates are used for analgesia.

Aggressive early IV fluid resuscitation is crucial. Lactated Ringer solution is preferred because it decreases the incidence of SIRS when compared with normal saline, although it should not be given to the rare patient with hypercalcemia. In practice, infusions start with a fluid bolus of 20 mL/kg ideal bodyweight, followed by 3 mL/kg/h until resuscitation goals are reached: heart rate <120 per minute, mean arterial pressure 65 to 85 mm Hg, urine output >0.5–1 mL/kg/h, and downtrending hematocrit and BUN within the first 24 hours.

Analgesic support should be provided with IV opiate medications such as morphine or hydromorphone in the early stage. There is no advantage of any particular type of opiate. Analgesic requirements should be carefully monitored by experienced physicians or dedicated pain services.

Transfer to an ICU should take place for sustained organ failure including hypoxemia or labored breathing, hypotension refractory to IV fluids, or sustained renal failure. Patients who need very aggressive fluid resuscitation to overcome hemoconcentration, especially the elderly and those with underlying congestive heart failure or chronic

renal insufficiency, warrant ICU monitoring. Referral to a specialist center is necessary for patients with severe acute pancreatitis and for patients who may need endoscopic, surgical, or interventional radiologic procedures.

Specific therapy for underlying causes of acute pancreatitis should be instituted early. For mild cases of suspected biliary pancreatitis, a cholecystectomy performed before discharge reduces the risk of biliary complications posthospitalization. Patients who develop moderately severe or severe biliary pancreatitis should have surgery postponed until symptoms have resolved and oral intake resumes. Offending medications should be discontinued for drug-induced pancreatitis. Treatment of hypertriglyceridemia includes infusions of insulin and/or plasmapheresis until serum triglyceride levels remain <500 mg/dL.

## Nutritional Support

Oral feeding in mild pancreatitis can be restarted once abdominal pain is decreasing, nausea and vomiting have ceased, and when the patient is hungry (usually within 3–7 days). There is no need to wait for normalization of lipase levels. Feeding generally begins with a low-fat, solid diet.

In patients with severe acute pancreatitis, nutritional support should be initiated when it becomes clear that the patient will be unable to consume nourishment by mouth for over 1 week. When nutritional support is needed, enteral is preferred over parenteral feeding because of decreased rates of systemic infections, multiorgan failure, and mortality. Ideally, nutrition is delivered into the jejunum because it theoretically decreases stimulation of the pancreas. However, small studies have shown nasogastric feeding to be a safe alternative. In patients with severe acute pancreatitis who are able to tolerate nourishment by mouth, restarting oral feeding 72 hours after admission is a safe alternative to enteral nutrition.

## Antibiotic Prophylaxis

Intravenous antibiotic prophylaxis does not reduce rates of infected necrosis, systemic complications, or mortality. It is therefore not recommended in acute pancreatitis, including in those who are predicted to develop severe and/or necrotizing pancreatitis.

In cases of pancreatic necrosis, patients may appear septic during the first 7 to 10 days with fever, leukocytosis, and/or organ failure. It is reasonable to start empiric antibiotics during this interval, while an evaluation for sources of infection (cultures of blood, urine, and CT-guided percutaneous aspiration of intraabdominal fluid collections) is undertaken. If no source of infection is identified, antibiotics should be discontinued.

## Treatment of Pancreatic Necrosis

The majority of patients with sterile necrotizing pancreatitis can be managed without intervention. Common indications for radiologic, endoscopic, or surgical intervention include a high suspicion for or documented infected necrosis

• **Fig. 73.3** Infected pancreatic necrosis. There is a heterogeneous, acute necrotic collection in the pancreatic and peripancreatic area with gas; an air-fluid level is present within this infected collection (*arrow*).

(Fig. 73.3), ongoing organ failure, severe abdominal pain from bowel ischemia or abdominal compartment syndrome, and/or ongoing gastric-outlet, intestinal, or biliary obstruction caused by mass effect. When debridement is indicated, it should ideally be deferred for at least 4 weeks until necrotic collections have consolidated with development of walled-off necrosis. A step-up approach beginning with direct endoscopic necrosectomy and, if necessary, minimally invasive surgical necrosectomy results in better outcomes compared with an open surgical approach.

### Role of Endoscopic Retrograde Cholangiopancreatography

ERCP is indicated in biliary pancreatitis with associated common bile duct obstruction or cholangitis. It is reasonable to await spontaneous resolution of biliary obstruction for 24 to 48 hours; however, ERCP should be performed urgently (<24 h) for acute cholangitis. In the absence of these indications, there is no benefit to routine ERCP, regardless of predicted severity.

### Prognosis and Aftercare

For individuals with mild acute pancreatitis, prognosis is excellent with little or no long-term sequelae. Mortality in severe disease remains elevated (10%–30%), especially in the setting of infected necrosis. In patients with severe necrotizing pancreatitis, both exocrine and endocrine insufficiency can occur during healing. In these cases, short-term pancreatic enzyme supplementation may be necessary, and a hemoglobin A<sub>1c</sub> should be measured after 3 months to monitor for the incident development of diabetes mellitus. Approximately 10% of patients with an initial episode of acute pancreatitis and 36% of patients with recurrent acute pancreatitis will develop chronic pancreatitis. The risk is highest among smokers, alcoholics, and men.

## Chronic Pancreatitis

Chronic pancreatitis is defined as structural damage to the pancreas caused by progressive fibroinflammatory changes. Pain, pancreatic exocrine, and endocrine insufficiency are hallmarks of the disease. In the United States, the prevalence of chronic pancreatitis has been estimated to vary from 0.04% to 0.5%, with an annual incidence of approximately 27.4 per 100,000 people.

### Pathogenesis

The underlying mechanisms leading to chronic pancreatitis are incompletely understood. Proposed hypotheses focus on the role of oxidative stress (bile reflux rich in reactive oxidation by-products), toxic-metabolic factors (alcohol, tobacco, hypercalcemia), ductal obstruction (formation of proteinaceous plugs resulting from protein hypersecretion), or necrosis leading to fibrosis (injury and remodeling from recurrent acute pancreatitis). A unifying model explaining the two consistent findings in all cases of chronic pancreatitis, impaired bicarbonate secretion and patchy inflammatory changes, remains to be elucidated.

### Etiology

Although several risk factors for the development of chronic pancreatitis have been identified, the cause remains equivocal in many instances. Chronic alcohol ingestion is associated with a majority (60%–70%) of cases, with affected individuals having consumed >150 g of ethanol daily for at least 6 years. Cigarette smoking has been found to be an independent, dose-dependent risk factor. Other causes include tropical pancreatitis, genetic mutations of cystic fibrosis transmembrane conductance regulator (*CFTR*), serine protease 1 (*PRSS1*), serine protease inhibitor Kazal type 1 (*SPINK-1*), and chymotrypsin C (*CTRC*), autoimmune disease, hypercalcemia, and hypertriglyceridemia. These etiologic agents typically lead to chronic calcific pancreatitis, characterized by recurrent episodes of acute pancreatitis during the early course of disease, with development of pancreatic ductal stones later.

Pancreatic ductal obstruction may lead to chronic pancreatitis. Distal obstruction caused by neoplasia (ductal adenocarcinoma, cystic neoplasms) or postinflammatory strictures (following acute pancreatitis or trauma) leads to inflammation upstream and eventual atrophy. Whether ductal obstruction from pancreas divisum or sphincter of Oddi dysfunction leads to chronic pancreatitis remains controversial.

Autoimmune pancreatitis (AIP) is a distinct form of chronic pancreatitis that presents clinically with obstructive jaundice and responds dramatically to steroid therapy. Histology reveals a lymphoplasmacytic infiltrate with storiform fibrosis. Imaging may display a pancreatic mass or sausage-shaped pancreas with surrounding edema. Type 1 AIP is associated with elevated serum IgG4 levels as well

as other organ involvement in the majority of cases. Type 2 AIP, or idiopathic duct-centric pancreatitis, is associated with inflammatory bowel disease in up to 30% of cases.

### Clinical Features

The clinical findings associated with chronic pancreatitis are pain and pancreatic insufficiency. Depending on the etiology and age of onset, these features can differ remarkably between patients.

Abdominal pain is similar to that in acute pancreatitis and described as epigastric, frequently with radiation to the back, associated with nausea and vomiting. Early in the disease course, pain is intermittent but may later evolve to become constant, severe, and debilitating. Although pain is a dominant feature, it is not a prerequisite for diagnosis and may be absent in up to 45% of patients.

Signs of exocrine (steatorrhea) or endocrine insufficiency (diabetes mellitus) may occur 12 to 15 years after disease onset. Steatorrhea occurs only after >90% of the gland has been destroyed. Insulin-dependent diabetes is a result of decreased islet cell mass and is typically a late complication.

### Diagnosis

The diagnosis of chronic pancreatitis is relatively clear cut in the later stages of disease when pain, steatorrhea, and calcifications are present. In early stages, the diagnosis can be equivocal and often based on the combination of structural abnormalities seen on imaging, impairment in pancreatic functional testing, and the aforementioned clinical features.

### Imaging Studies

A variety of imaging modalities are used to evaluate for structural changes consistent with chronic pancreatitis. Plain abdominal radiographs may reveal pancreatic calcifications that are diagnostic but only seen in 30% of cases. Abdominal CT has a sensitivity that ranges from 75% to 90% for moderate-to-severe disease. Findings include calcifications (Fig. 73.4), parenchymal atrophy, and pancreatic ductal dilation. MRCP in combination with conventional abdominal MRI is as sensitive as CT and provides the added benefit of detailed pancreatic ductal system evaluation. Given its noninvasiveness and avoidance of ionizing radiation, MRCP has become the diagnostic procedure of choice in most patients. Similar to CT, small duct changes and calcifications may be missed.

ERCP assesses for characteristic beading of the main pancreatic duct and ectatic side branches diagnostic of chronic pancreatitis. The degree of ductal abnormalities may be graded according to the Cambridge classification. Because of a risk of complications such as acute pancreatitis (4%–6%), ERCP is typically reserved for cases when other methods are nondiagnostic or when therapeutic interventions such as pancreatic duct stenting or stone removal are considered.

• **Fig. 73.4** Chronic pancreatitis. Multiple brightly enhancing calcified stones are present within the body and tail of an atrophic pancreas (arrow).

EUS provides a high-resolution image of not only the pancreatic duct but also the pancreatic parenchyma. It may be particularly useful in early chronic pancreatitis when changes are not yet evident on other imaging modalities. The Rosemont classification describes 11 ductal and parenchymal features on EUS and stratifies patients into consistent-with, suggestive-of, or indeterminate-for chronic pancreatitis depending on the combination of features seen. Disadvantages of EUS include the need for invasive testing and significant interobserver disagreement on the interpretation of EUS features, especially in elderly or alcoholic patients.

### Functional Testing

Fecal pancreatic elastase-1 (FPE-1) is a marker of exocrine pancreatic function. Its widespread availability has reduced the need for 24-hour fecal fat quantification as a means for evaluating steatorrhea. A level >200  $\mu\text{g/g}$  of stool is considered normal, and levels <100  $\mu\text{g/g}$  of stool correlate with severe exocrine pancreatic insufficiency. Pancreatic enzyme supplementation does not interfere with interpretation of FPE-1 results, but testing should be performed on formed stool to avoid false positives.

The gold standard for evaluating pancreatic exocrine insufficiency is the secretin-stimulated pancreatic function test. After placement of a dual-lumen tube into the proximal duodenum, pancreatic secretions are aspirated every 15 minutes for a total of 60 minutes following the administration of secretin. A peak bicarbonate level <80 mEq/L is consistent with chronic pancreatitis. Pancreatic function testing is most useful early in the disease course when chronic pancreatitis is suspected, but imaging is equivocal.

### Treatment

Treatment for chronic pancreatitis begins with lifestyle modifications. Patients should be advised to quit smoking, avoid alcohol, and consume smaller, low-fat meals.

### Exocrine Insufficiency

Depending on the severity of malabsorption, fat restriction to 20 g/d by itself may reduce steatorrhea. Patients with severe exocrine insufficiency require pancreatic enzyme supplementation. Enzymes are given with the initial ingestion of food in sufficient amounts to prevent clinical signs of steatorrhea. Nonenteric coated preparations should be given with acid suppression (e.g., proton-pump inhibitor) to avoid inactivation by gastric acid. There is some evidence that pancreatic enzyme supplementation may decrease pain in chronic pancreatitis, possibly mediated through reduced duodenal cholecystokinin release and decreased pancreatic stimulation.

### Pain Management

Chronic pain can be difficult to manage. A comprehensive approach through a dedicated pain center and multidisciplinary management team is recommended.

Analgesics are considered if lifestyle modifications and pancreatic enzyme replacement fail to control pain. Tricyclic antidepressants such as amitriptyline and nortriptyline have been shown to reduce neuropathic pain. Chronic opioids may be required in patients with significant, persistent pain. Short-term hospitalizations are needed for severe flares. Percutaneous or endoscopic celiac plexus blocks have been performed with limited success. In responders, symptoms often recur within 2 to 6 months. Surgical management may be considered in carefully selected patients. Options include lateral pancreaticojejunostomy (Puestow procedure), distal pancreatectomy, pancreaticoduodenectomy (Whipple procedure), and total pancreatectomy with autologous islet-cell transplantation.

### Complications and Prognosis

Complications include pseudocyst formation, duodenal or biliary obstruction from mass effect, splenic vein thrombosis, and pseudoaneurysm formation, particularly of the splenic artery. Pseudocysts develop in approximately 10% of patients as a result of ductal disruptions. Most are asymptomatic, although complications include pain, bowel obstruction, infection, bleeding, and pancreatic ascites arising from fistulization into the peritoneal cavity.

Four percent of all patients with chronic pancreatitis will develop pancreatic ductal adenocarcinoma. The risk is increased 3-fold in smokers. Hereditary pancreatitis is associated with up to a 40% chance of developing adenocarcinoma by 70 years of age. Significant changes in symptoms, especially in older individuals, should prompt cross-sectional imaging to assess for malignancy.

The natural history of chronic pancreatitis remains poorly defined because of its highly variable nature. The 20-year survival rate is 40% to 50%. Early identification of modifiable risk factors such as alcohol and smoking may result in improved outcomes.

## Pancreatic Neoplasms

Pancreatic cancer is the second most common gastrointestinal malignancy and the fourth leading cause of cancer-related deaths in the United States. In 2015 there were 48,960 new cases, and almost all are expected to die from the disease. The overall 5-year survival remains low at 4% to 6%. The disease is more common in men than women (1.3:1) and in certain racial groups (blacks, Polynesians). It is rare before age 45 years, but incidence rises sharply thereafter.

The majority of pancreatic cancers are exocrine tumors. Examples include pancreatic ductal adenocarcinoma (90% of tumors), carcinomas arising from cystic pancreatic neoplasms (5%), and acinar cell carcinoma (<1%). Tumors that arise from endocrine cells (pancreatic neuroendocrine tumors or PNET) are much less common.

### Pancreatic Ductal Adenocarcinoma

Pancreatic ductal adenocarcinoma (PDAC) accounts for the large majority of pancreatic cancer and is highly lethal with a 1-year survival of <10%. This partly reflects the absence of characteristic symptoms early in the disease and the low resectability rate at diagnosis. Patients may present with vague abdominal discomfort associated with weight loss, anorexia, and weakness. In patients with tumors of the head of the pancreas, >50% develop painless jaundice. A minority will present with new adult-onset diabetes or unexplained pancreatitis. Risk factors for PDAC include cigarette smoking, chronic pancreatitis (particularly hereditary pancreatitis), first-degree relatives with pancreatic cancer, and several genetic syndromes (e.g., Peutz-Jeghers, hereditary nonpolyposis colorectal cancer, familial atypical multiple mole melanoma, and *BRCA-2* mutations).

### Pathogenesis

The pathogenesis of PDAC is thought to arise from a neoplasia-carcinoma sequence. According to this model, dysplastic areas in the ductal epithelium known as pancreatic intraepithelial neoplasia (PanIN) progress from low grade to high grade (PanIN-1 to 3) coincident with the activation of oncogenes (e.g., *K-ras*), inactivation of tumor suppressor genes (e.g., *CDKN2A*, *P53*), and mutation of DNA mismatch repair genes (e.g., *MLH-1* and *MSH-2*).

### Diagnosis and Staging

In patients with clinical suspicion for PDAC, an initial multidetector pancreas protocol CT scan helps establish a diagnosis and stage the tumor (Fig. 73.5). EUS is considered a complementary test because it is more accurate for diagnosing smaller lesions, for staging local extent including vascular invasion (T staging) and nodal status (N staging), and offers the capacity for fine-needle aspiration (EUS-FNA) of the primary tumor or lymph nodes. The primary role of staging studies is to determine whether the tumor is resectable, locally advanced and unresectable, or metastatic.

Tumor markers such as CA 19-9 may increase in pancreatic cancer, but they lack sufficient sensitivity or specificity for screening or diagnostic purposes. For example, biliary obstruction of any etiology (e.g., cholangitis) can elevate CA 19-9. When levels are elevated, tumor markers can be useful for monitoring treatment response.

### Treatment of Resectable Disease

Approximately 10% to 15% of patients are candidates for operative resection, which is the only chance for cure. Even so, the 5-year survival rate is 20% and even lower in those with large tumors, positive surgical margins, or presence of lymph node metastases. The most common surgery is the Whipple procedure for tumors located to the head of the pancreas. If the tumor involves the body or tail, a distal pancreatectomy with splenectomy is performed. Most patients receive postoperative adjuvant gemcitabine-based chemotherapy with or without radiation therapy.

• **Fig. 73.5** Pancreatic ductal adenocarcinoma. A mass is shown in the head of the pancreas (yellow arrow) causing pancreatic ductal dilatation (white arrow).

### Management of Unresectable Disease

For the 40% of patients who present with locally advanced, unresectable, nonmetastatic disease, optimal treatment remains controversial but generally consists of a combination of chemotherapy and radiation. For metastatic disease, the multidrug regimen FOLFIRINOX has become standard of care. Symptom palliation is essential and includes stenting for biliary, gastric outlet, or duodenal obstruction, pain management, and nutritional support.

### Cystic Neoplasms

Pancreatic cysts are being diagnosed with increasing frequency because of the widespread usage of cross-sectional imaging. Incidental cystic lesions are found in 2% to 3% of asymptomatic adults, with prevalence increasing with age. Symptoms of abdominal pain, pancreatitis, weight loss, or jaundice warrant referral for operative resection. With growing experience and a better understanding of their natural history, it has become clear that these cystic lesions encompass a broad spectrum of benign, borderline, and malignant tumors. As such, differentiating among them and accurately predicting those at highest risk of malignancy have a profound impact on management.

Pancreatic cystic neoplasms may be classified into four principal types: serous cystadenomas (SCAs), solid pseudopapillary neoplasms (SPNs), mucinous cystic neoplasms (MCNs), and intraductal papillary mucinous neoplasms (IPMNs). Although the majority of cystic neoplasms are benign, all have the potential to develop into malignancy with varying degrees of risk. Table 73.1 compares the clinical and epidemiologic characteristics of these lesions.

### Diagnostic Techniques

The diagnostic standard is by histopathologic assessment of surgically resected cysts. Preoperative characterization and risk-stratification remains challenging. CT and MRI are excellent tests for the initial detection and evaluation of cystic lesions; however, differentiation between the variety of cyst types and distinguishing benign from malignant cysts

**TABLE 73.1**

**Epidemiologic and Clinical Characteristics of Pancreatic Cystic Neoplasms**

Type	Sex Predilection	Peak Decade	% Cystic Neoplasms	CEA	Cytology
IPMN	F = M	6–7 <sup>th</sup>	21–33	High	Mucinous epithelial cells with variable atypia
MCN	F > M	5 <sup>th</sup>	10–45	High	Mucinous epithelial cells with variable atypia
SCA	F > M	7 <sup>th</sup>	32–39	Low	Cuboidal cells with glycogen-rich cytoplasm
SPN	F > M	4 <sup>th</sup>	<10	Low	Papillary structures, bland cells with round nuclei

CEA, Carcinoembryonic antigen; IPMN, intraductal papillary mucinous neoplasm; MCN, mucinous cystic neoplasm; SCA, serous cystadenoma; SPN, solid pseudopapillary neoplasm.

are difficult. EUS-FNA has become the technique of choice for evaluating cyst structure and obtaining cyst fluid for cytologic, chemical, and tumor marker analysis.

Cytologic analysis of cyst fluid has a high specificity for detecting malignancy, but its sensitivity is low. Furthermore, the yield of cytology from EUS-FNA is frequently insufficient. Cyst fluid carcinoembryonic antigen (CEA) levels are typically elevated in mucinous cysts (MCN and IPMN). A cyst CEA cutoff of 192 ng/mL was found to be most accurate for differentiating mucinous from nonmucinous cysts, although recent studies have shown lower cutoffs increase sensitivity without sacrificing specificity. Notably, cyst fluid CEA does not help differentiate malignant from nonmalignant cysts. DNA analysis revealing *KRAS* and *GNAS* mutations, high DNA content, or loss of heterozygosity suggests malignant transformation.

### Mucinous Cystic Neoplasms

MCNs are mucinous tumors that occur nearly exclusively in women, peak in the fifth decade of life, and are mostly localized to the pancreatic body and tail. The presence of malignancy is estimated to be 11% to 39%. On imaging, MCNs are generally large, located peripherally, and do not communicate with the pancreatic ductal system. The presence of calcifications or mural nodules is suggestive of malignancy. Analysis of cyst fluid reveals high viscosity and elevated CEA levels. On histopathology, MCNs display requisite ovarian-type stroma. Because of malignant potential, surgical resection is advised. Five-year survival rates are >95% for benign and borderline tumors and 50% to 75% for malignant tumors with negative margins.

### Intraductal Papillary Mucinous Neoplasms

IPMNs are the most common cystic neoplasm and are mucinous tumors that originate in the main pancreatic

duct (main duct IPMN) or its side branches (branch duct IPMN). They occur equally in men and women. The median age of presentation is 65 years. The type of IPMN predicts its malignant potential, which ranges from 36% to 100% in main duct varieties to 6% to 47% in branch duct varieties. Imaging reveals communication with the pancreatic ductal system. Mural nodules, main pancreatic duct dilation >15 mm, and cyst size >3 cm are associated with malignant disease. Cyst fluid CEA levels are characteristically elevated. A patulous ampulla of Vater with extruding mucus (fish mouth papilla) seen on ERCP is pathognomonic.

Surgical resection is recommended for all main duct IPMNs. Five-year survival rates are 35% to 75% although recurrence occurs in over one-half of patients. In asymptomatic patients with branch duct IPMNs <3 cm without high-risk imaging features, surveillance is recommended.

### Serous Cystadenomas

SCAs are the second most common cystic neoplasm. These tumors generally affect women, peak in the seventh decade, and occur in the pancreatic body and tail. On imaging, SCAs have a honeycomb or sunburst appearance, caused by the formation of multiple fibrous septa around a central calcified scar. SCAs have almost no malignant potential (<1%). Cyst fluid analysis reveals low viscosity with low CEA levels. In asymptomatic patients, observation with serial imaging is appropriate.

### Solid Pseudopapillary Neoplasms

SPNs are rare cystic neoplasms found almost exclusively in young women. Imaging may reveal solid components with cellular aspirates containing papillary structures. SPNs are often indolent and rarely metastasize. Surgical resection is typically curative.

## Chapter Review

### Questions

1. A 42-year-old male, who is otherwise healthy, presents with a 6-hour history of severe, steady upper abdominal pain radiating to the back, which started 2 hours after eating dinner. He is afebrile with normal vital signs. His initial laboratory tests are notable for aspartate transaminase 180 U/L, alanine transaminase 200 U/L, total bilirubin 0.9 mg/dL, alkaline phosphatase 180 U/L, and serum lipase of 1500 U/L. An abdominal ultrasound reveals multiple gallstones and a normal caliber common bile duct without evidence of choledocholithiasis. He is admitted for IV fluids and pain control. By day 3 of hospitalization, he has minimal abdominal pain, and his liver function tests are normal. What do you recommend at this time regarding his management?
  - A. ERCP to evaluate for ductal abnormalities
  - B. MRCP to evaluate for ductal abnormalities
  - C. Surgical referral for laparoscopic cholecystectomy before discharge
  - D. Discharge home on clear liquid diet
  - E. CT scan to assess for pancreatic necrosis
2. A 35-year-old woman who has been hospitalized for 5 weeks for severe acute pancreatitis is about to be discharged. She is currently tolerating a low-fat diet without abdominal pain. A CT scan obtained 3 days ago showed a 10-cm pseudocyst in the body of the pancreas, which was not present on a CT scan obtained the day of admission. The medical team is worried about sending her home with this finding. What do you recommend?
  - A. Contact the surgical team to arrange for surgical drainage of the cyst.
  - B. Discharge the patient, and arrange for follow-up at a later date.
  - C. Schedule an EUS-FNA of the cyst.
  - D. Check a CA 19–9, and reimaging the abdomen in 6 weeks.
  - E. Discharge the patient with a 2-week course of ciprofloxacin.

3. A 50-year-old female is referred to you for evaluation of a newly diagnosed pancreatic cyst that was incidentally discovered during an evaluation for possible kidney stones. On review of her MRI, you note that the cyst is 5.5 cm in size with a few internal septations. It is localized to the midbody of the pancreas and associated with dilation of the main pancreatic duct proximally. She reports 15 lbs of unintentional weight loss over the past 4 months but is otherwise in good health. She denies a history of pancreatitis. What do you recommend?
- Check serum CA 19-9 level.
  - EUS-FNA of the cyst for CEA and cytology
  - Surgical referral for operative resection
  - Repeat abdominal MRI in 6 months with close observation.
  - None of the above
4. A 38-year-old male with a 2-year history of chronic abdominal pain and alcohol use is referred to you for evaluation. He reports dull epigastric pain punctuated

by periods of severity leading to three emergency department visits in the past year. Each time he is evaluated, he has normal serum lipase values. Which of the following would be consistent with a diagnosis of chronic pancreatitis?

- Abdominal x-ray revealing pancreatic calcifications
- CT revealing calcifications within a dilated main pancreatic duct and parenchymal atrophy
- Endoscopic pancreatic function test revealing peak bicarbonate level of 70 mEq/L
- EUS satisfying the Rosemont criteria
- All of the above

## Liver Disease

PATRICIA PRINGLE, BRIAN HYETT, RAYMOND T. CHUNG, AND SANJIV CHOPRA

The proper evaluation of liver disease can present a challenge to the practicing clinician. Physicians are often faced with a confusing array of what are commonly referred to as “liver function tests.” In fact, with the commonplace use of automated serum testing batteries, abnormal results are increasingly detected in asymptomatic persons. There are numerous examples of algorithms and flow diagrams designed to aid clinicians in completion of an adequate diagnostic valuation when faced with a particular set of abnormalities on liver function tests. However, a clearer understanding of these tests might be of greater value than such a systematic and regimented approach to the evaluation of liver disease.

An ideal liver function test would be one that could detect minimal liver disease, point to a particular liver function disorder, and be capable of reflecting the severity of the underlying problem. Because no such laboratory test exists, the term *liver function tests* generally refers to a group of serologic tests that evaluate different aspects of liver function; it is a term that is best used keeping in mind the clinical context and in conjunction with serial determinations to ascertain the evolution of the hepatic disorder. In addition, cholangiography, ultrasound, CT, MRI, and histologic assessment (via liver biopsy) are often used to delineate the nature of the liver disease and as such may also be viewed in the broad context as tests of liver function.

### Serum Transaminases

Aspartate aminotransferase (AST), previously called *serum glutamic oxaloacetic transaminase*, and alanine aminotransferase (ALT), previously called *serum glutamic pyruvic transaminase*, are markers of hepatocyte injury. These enzymes transfer amino groups from aspartate and alanine to ketoglutaric acid. When liver cells are injured, their cell membranes become permeable, and enzymes leak into the systemic circulation. Therefore elevations in aminotransferases suggest that liver cells are being damaged. ALT is primarily localized to the liver but can originate from muscle. AST is in the liver as well, but it is also found on skeletal and cardiac muscle, the kidneys, and the brain. Thus an isolated elevation of AST could be indicative of injury to one of these other organs.

Both AST and ALT are commonly used to assess liver function. Elevations to the thousands of serum AST, a mitochondrial enzyme, and ALT, a cytosolic enzyme, are encountered in acute viral hepatitis, acute drug-induced or toxin-induced liver damage, autoimmune hepatitis, Wilson disease, HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, acute fatty liver of pregnancy, and ischemic hepatitis. The height of the elevation does not, however, correlate with extent of liver cell necrosis evident on liver biopsy and therefore has no predictive prognostic value. Rapidly decreasing transaminase levels together with a rising bilirubin level and prolongation of the prothrombin time (PT) predict a very poor prognosis.

In most of these conditions, the transaminase levels usually return to normal over several weeks to months with resolution of the primary hepatic disorder. An exception is ischemic hepatitis, where the transaminase levels often return to normal within days as the hypotension or left ventricular failure is corrected or alleviated. The transaminase elevations are mild to modest in alcoholic hepatitis.

A common cause of transaminitis is medication-induced hepatic injury. Several drugs may cause raised liver enzymes. Common ones implicated frequently include nonsteroidal antiinflammatory drugs, antibiotics, statins, antiepileptics, and antituberculosis drugs (Box 74.1). Several other medications and substances have also been implicated as injurious agents in liver disease (Table 74.1). Other causes of transaminitis include viral hepatitis, hemochromatosis, and alpha-1-antitrypsin deficiency.

Characteristically, the ALT level is much higher than the AST, but this is variable in disease states, and patterns of their relationship are indicative of various conditions. For instance, in acute alcoholic hepatitis with cirrhosis (which has an

**• BOX 74.2 Etiologies of Serum Aminotransferase Levels Exceeding 500 IU/L**

Acute viral hepatitis  
Drug or toxic liver injury  
Ischemic hepatitis  
Severe chronic active hepatitis  
Common bile duct stone  
Acute Budd-Chiari and venoocclusive disease  
Acute fatty liver of pregnancy and HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome  
Wilson disease

inordinately high mortality), the AST and ALT are almost always <300 IU/L with an AST-to-ALT ratio <2:1. Elevations >500 IU in either transaminase level are unusual and signify a narrow differential diagnosis (Box 74.2). In patients with extrahepatic obstruction, both transaminase levels are almost invariably <1000 IU/L. One study of 140 patients with non-alcoholic steatohepatitis (NASH) confirmed by liver biopsy or alcoholic liver disease found a mean AST/ALT ratio of 0.9 in patients with NASH and 2.6 in patients with alcoholic liver disease. Within the population studied, 87% of patients with an AST/ALT ratio of  $\leq 1.3$  had NASH (87% sensitivity, 84% specificity). The severity of NASH as measured by the degree of fibrosis increased, as did the AST/ALT ratio. A mean ratio of 1.4 was found in patients with cirrhosis related to NASH. Wilson disease, a rare condition, can cause the AST/ALT ratio to exceed 4. Lastly, hepatic involvement with metastatic tumors, tuberculosis, sarcoidosis, and amyloidosis may cause a modest (up to 3-fold) rise in aminotransferases.

Significant elevations of transaminase levels have been noted in a few normal, healthy subjects while consuming a diet of conventional foods containing 25% to 30% of total calories as sucrose. False-positive elevations in AST levels have been reported in patients receiving erythromycin estolate or para-aminosalicylic acid and during diabetic

**• BOX 74.3 Underlying Etiologies for Normal or Only Marginally Elevated Serum Aminotransferase Values Despite Significant Liver Disease**

Chronic hepatitis C infection  
Idiopathic genetic hemochromatosis  
Nonalcoholic fatty liver disease  
Patients receiving methotrexate

ketoacidosis, when the AST level has been determined by calorimetric assay. The opposite, that is, falsely lowered (sometimes absent) transaminases, has been observed in azotemic patients. AST activity increases significantly after hemodialysis, but the inhibitor does not appear to be urea. As for intrinsic changes in these enzymes, ALT has diurnal variation, may vary day to day, and may be affected by exercise. AST may be 15% higher in black men than white men at baseline. In addition, a study of Danish twins showed that genetic factors accounted for 33% to 66% of the variation in ALT in patients age 73 to 94 years.

Although elevations in transaminase levels may be the first laboratory signal of liver disease (preicteric phase) or the only signal (anicteric hepatitis) to a physician, remember that significant liver damage may be present in a patient with normal levels of transaminases despite advanced liver disease (Box 74.3). This is well represented in a study of 22 NASH patients, in which there were almost twice as many patients with fibrosis progression than with regression (32% vs. 18%), yet progression of fibrosis occurred despite normalization of aminotransferase values and could not be confidently predicted by clinical or standard biological data. On the other hand, 1% to 4% of the asymptomatic population may have elevated serum liver chemistries.

“Unexplained” (normal liver biopsy results) elevations of both transaminase levels may have their basis in a primary

• **BOX 74.4** Causes of “Unexplained” Alanine Aminotransferase Elevations and Associated Laboratory Testing<sup>a</sup>

### Disease Testing

Muscle disease/injury: creatine phosphokinase

Celiac disease: tissue transglutaminase antibody

Adrenal insufficiency: cortisol

Thyroid dysfunction: thyroid-stimulating hormone

<sup>a</sup>Remember the mnemonic “MCAT.”

muscle disorder, celiac sprue, thyroid disease, or adrenal insufficiency. Hence obtaining serum for cortisol levels, tissue transglutaminase (TTG), thyroid-stimulating hormone (TSH), and creatine phosphokinase (CPK) is crucial to the complete workup of such patients (Box 74.4). Immediately after muscle injury, the AST/ALT ratio is generally >3 but approaches 1 within a few days because of a faster decline in the serum AST. As for celiac disease, one study of 140 consecutive patients with elevated transaminases and a comprehensive negative serologic workup and no significant pathology on biopsy found 13 patients (9.3%) with positive antigliadin and antiendomysial antibody tests and duodenal biopsies consistent with celiac disease. In most cases of celiac disease–induced transaminitis, the ALT and AST levels will normalize on a gluten-free diet.

## Alkaline Phosphatase

Although alkaline phosphatase is used routinely as a marker of biliary injury, the physiologic significance of the enzyme is not known. However, *in vitro*, alkaline phosphatase catalyzes the hydrolysis of phosphate esters in an alkaline environment. The hepatic isoenzyme is located on the luminal surface of the canalicular membrane. Obstruction of any part of the biliary tree results in increased synthesis of alkaline phosphatases, subsequent reflux of the enzyme into the hepatic sinusoids, and rise in serum level. Although patients with elevated alkaline phosphatases are often suspected of having a liver disorder, the possibility that serum alkaline phosphatase elevations stem from other organs (especially bone) should be considered given that as many as one-third of individuals with elevated alkaline phosphatase levels have no evidence of liver disease.

Serum alkaline phosphatase originates from liver, bone, intestine, or placenta. Occasionally, patients with a malignant tumor may have elevations that are not caused by liver or bony metastases but instead are caused by an isoenzyme. This molecule, referred to as Regan isoenzyme, is biochemically and immunologically indistinguishable from placental alkaline phosphatase and, in addition to being present in serum, can also be present in tumor tissue or in malignant effusion fluids. Women in the third trimester of pregnancy have elevated serum alkaline phosphatase caused by an influx into blood of placental alkaline phosphatase. Individuals with blood types O and B who are ABH secretors

and Lewis antigen positive can have elevated serum alkaline phosphatase after ingesting a fatty meal caused by an influx of intestinal alkaline phosphatase. There are reports in the literature of a benign familial occurrence of elevated serum alkaline phosphatase caused by intestinal alkaline phosphatase. In one report, 2-fold to 4-fold elevations in serum alkaline phosphatase levels were reported in several members of a family. No bone or hepatic disorder was present in this family, who demonstrated the enzyme elevation in a pattern suggesting autosomal dominant inheritance. Alkaline phosphatase levels also vary with age; rapidly growing adolescents can have serum alkaline phosphatase levels that are twice those of healthy adults secondary to leakage of bone alkaline phosphatase into blood. The normal serum alkaline phosphatase gradually increases from age 40 to 65 years. For instance, the normal alkaline phosphatase for an otherwise healthy 65-year-old woman is >50% higher than that of a healthy 30-year-old woman.

Patients with cholestasis have increased levels of alkaline phosphatase. Markedly elevated levels of serum alkaline phosphatase are also found in patients with osteoblastic bone disorders or with cholestatic (both intrahepatic and extrahepatic) disease. Hence, in patients with jaundice, distinguishing intrahepatic cholestasis including primary biliary cirrhosis (PBC) or granulomas in the liver from extrahepatic obstruction including stones, strictures, “silent” malignancies, and other possibilities is not possible on the basis of the height of the serum alkaline phosphatase level. Patients with stage I or II Hodgkin disease, hypernephroma, congestive heart failure, myeloid metaplasia, peritonitis, diabetes, subacute thyroiditis, or uncomplicated gastric ulcer have been reported to have mild elevations in serum alkaline phosphatase levels that are probably stemming from the liver in the absence of overt liver involvement.

In the case of renal cell carcinoma, cholestasis may be seen as part of a paraneoplastic syndrome. This is referred to as nephrogenic hepatic dysfunction syndrome or Stauffer syndrome. The cause is unknown but may relate to secretion of interleukin-6. Other rare causes of cholestasis with associated elevations in alkaline phosphatase include hyperthyroidism, amyloidosis, and benign recurrent intrahepatic cholestasis (Summerskill-Walsh-Tygstrup) syndrome. Patients with Wilson disease often have normal or below-normal values despite transaminitis.

Although an elevation of the serum alkaline phosphatase level may be the first clue to hepatobiliary disease, the alkaline phosphatase level is normal on some occasions despite extensive metastatic hepatic deposits or complete bile duct obstruction. When alkaline phosphatase levels are markedly elevated, it may be useful to concurrently measure serum 5'-nucleotidase, gamma-glutamyl transpeptidase, or leucine aminopeptidase. In such instances, elevations of the levels of any of these three enzymes generally imply that the source of the elevated alkaline phosphatase level is hepatobiliary and not bony. The most common causes of liver-related increases in alkaline phosphatase are outlined in Box 74.5.

### • BOX 74.5 Common Causes of Elevations in Alkaline Phosphatase

Complete or partial bile duct obstruction  
 Primary biliary cirrhosis  
 Primary sclerosing cholangitis  
 Adult bile ductopenia  
 Certain drugs such as androgenic steroids and phenytoin and toxins associated with cholestasis  
 Infiltrative diseases including sarcoidosis, tuberculosis  
 Granulomatous diseases  
 Cancer metastatic to the liver and associated obstructive jaundice  
 Bile duct stricture  
 Liver allograft rejection  
 Viral hepatitis  
 Infectious hepatobiliary diseases seen in patients with AIDS (e.g., cytomegalovirus or microsporidiosis and tuberculosis with hepatic involvement)

## Gamma-Glutamyl Transpeptidase

Gamma-glutamyl transpeptidase (GGT) is found in hepatocytes and biliary epithelial cells. GGT is very sensitive for detecting hepatobiliary disease but lacks specificity. Elevated levels of serum GGT have been reported in a variety of clinical conditions, including myocardial infarction, pancreatic disease, renal failure, chronic obstructive pulmonary disease, diabetes, and alcoholism. High serum GGT values are also found in patients taking medications such as phenytoin and barbiturates and in the setting of alcohol use. In fact, a markedly elevated serum GGT level for several days often follows moderate alcohol ingestion. This has been used by many physicians to detect alcohol abuse in patients who underestimate or deny the ingestion of alcohol.

Medications such as phenytoin, carbamazepine, and barbiturates may also cause a mild rise in GGT. With other enzyme abnormalities, a raised GGT would support a hepatobiliary source. It would, for instance, confirm hepatic source for a raised alkaline phosphatase. An elevated GGT with raised transaminases and a ratio of AST to ALT of  $\geq 2:1$  would suggest alcohol-related liver disease. But other than conferring liver specificity to an elevated alkaline phosphatase and possibly being used in identifying patients with alcohol abuse, serum GGT offers no advantage over aminotransferases and alkaline phosphatase. In one prospective study that included 1040 inpatients, 13% had an elevated serum GGT activity; but only 32% had hepatobiliary disease.

In the remaining patients, elevated serum GGT may have been caused by alcohol ingestion or medications without underlying liver disease.

## 5'-Nucleotidase

5'-Nucleotidase is found in the liver, intestines, brain, heart, blood vessels, and endocrine pancreas. Similar to alkaline phosphatase, this enzyme is located subcellularly to

hepatocytes. Despite its wide distribution in various organs, serum levels of 5'-nucleotidase are thought to be secondary to hepatobiliary release by detergent action of bile salts on the plasma membranes of hepatocytes. Values are lower in children than in adults, rise gradually in adolescence, and reach a nadir as late as age 50 years. Elevations in serum 5'-nucleotidase are seen in conjunction with, and attributed largely to, the same causes of increased serum alkaline phosphatase. Studies suggest that serum alkaline phosphatase and 5'-nucleotidase are equally useful tests for demonstrating biliary obstruction or hepatic infiltrative lesions. Although values of the two enzymes are generally well correlated, the concentrations may not rise proportionately in individual patients. Thus in selected patients, one enzyme may be elevated and the other normal.

Leucine aminopeptidase and 5'-nucleotidase levels may increase in normal pregnancy, whereas gamma-glutamyl transpeptidase levels do not. Unlike GGT, the predominant usefulness of the 5'-nucleotidase assay is its specificity for hepatobiliary disease. An increased serum 5'-nucleotidase concentration in a nonpregnant person suggests that a concomitantly increased serum alkaline phosphatase is of hepatic origin. However, because of the occasional dissociation between the two enzymes, a normal serum 5'-nucleotidase does not rule out the liver as the source of an elevated serum alkaline phosphatase.

## Bilirubin

Bilirubin results from the enzymatic breakdown of heme. Unconjugated bilirubin is transported to the liver bound to albumin. It is water insoluble and cannot be excreted in urine. Conjugated bilirubin is water soluble and appears in urine. Within the liver, it is conjugated to bilirubin glucuronide and is secreted into bile and the gut. The intestinal flora breaks it down into urobilinogen, some of which is reabsorbed and either excreted via the kidney into urine or excreted by the liver into the gastrointestinal tract. The remainder is excreted in the stool as stercobilinogen. Bilirubin production increases in hemolysis, ineffective erythropoiesis, and resorption of a hematoma. In all these cases the bilirubin is mainly in an unconjugated form. Conjugated hyperbilirubinemia characteristically occurs in parenchymal liver disease and biliary obstruction. The serum conjugated bilirubin level does not become elevated until the liver has lost at least one-half of its excretory capacity.

Liver disease predominantly impairs the secretion of conjugated bilirubin into bile. As a result, conjugated bilirubin is filtered into the urine, where it can be detected by a dipstick test. The finding of bilirubin in urine is a sensitive indicator of the presence of an increased serum conjugated bilirubin level. In many healthy people, the serum unconjugated bilirubin is mildly elevated, especially after a 24-hour fast. If this is the only liver function test abnormality and the conjugated bilirubin level and complete blood count (CBC) are normal, this can be assumed because of Gilbert syndrome, with no further evaluation required. Gilbert syndrome is

• **BOX 74.6** Causes of Elevations in Serum Bilirubin With Normal ALT, AST, Alkaline Phosphatase

### Unconjugated

1. Increased bilirubin production
  - Hemolysis
  - Ineffective erythropoiesis
  - Blood transfusion
  - Resorption of hematomas
2. Decreased hepatic uptake
  - Gilbert syndrome
  - Drugs; for example, rifampicin
3. Decreased conjugation
  - Gilbert syndrome
  - Crigler-Najjar syndrome
  - Physiologic jaundice of the newborn

### Conjugated

1. Dubin-Johnson syndrome
2. Rotor syndrome

ALT, Alanine aminotransferase, AST, aspartate aminotransferase.

related to a variety of partial defects in uridine diphosphate-glucuronosyl transferase, the enzyme that conjugates bilirubin. Mild unconjugated hyperbilirubinemia (total bilirubin level  $<5$  mg/dL) is seen not only in Gilbert disease but also in uncomplicated hemolytic disorders and congestive heart failure. Mild conjugated hyperbilirubinemia is a constant finding in Dubin-Johnson and Rotor syndromes. Conjugated hyperbilirubinemia of varying intensity is seen in a variety of liver disorders including acute viral, drug-induced and toxin-induced hepatitis, shock liver, and metastatic disease to the liver (Box 74.6). Even in fulminant hepatitis, the liver is capable of conjugating bilirubin. The height of the serum bilirubin level is not useful in distinguishing intrahepatic cholestasis from extrahepatic obstruction. In fact, elevations in total serum bilirubin levels have been reported in patients with non-biliary tract sepsis. Although patients with fulminant hepatitis may be anicteric, the level of serum bilirubin is important prognostically in conditions such as alcoholic hepatitis, PBC, and halothane hepatitis. For instance, in PBC, elevations of  $>2.0$  mg/dL in the total bilirubin level usually occur late in the course of the disease and imply a poor prognosis, whereas levels  $>10$  mg/dL have been associated with 60% mortality in patients with halothane hepatitis.

When a patient has prolonged severe biliary obstruction followed by the restoration of bile flow, the serum bilirubin level can decline rapidly for several days and then slowly return to normal over a period of weeks. The slow phase of bilirubin clearance results from the presence of delta-bilirubin, a form of bilirubin chemically attached to serum albumin. Because albumin has a half-life of 3 weeks, delta-bilirubin clears more slowly than bilirubin-glucuronide. Clinical laboratories can measure delta-bilirubin concentrations, but such measurements are usually unnecessary if the physician is aware of the delta-bilirubin phenomenon.

## Albumin and Gamma-Globulins

Albumin is only one of many proteins that are synthesized by the liver. However, because it is easy to measure, it represents a reliable and inexpensive laboratory test for physicians to assess the degree of liver damage present in any particular patient. When the liver has been chronically damaged, the albumin may be low. This would indicate that the synthetic function of the liver has been markedly diminished. The serum albumin concentration is usually normal in chronic liver diseases until cirrhosis and significant liver damage are present. Albumin levels can be low in conditions other than liver diseases including malnutrition, some kidney diseases, and other rarer conditions.

Approximately 10 g of albumin is synthesized and secreted by the liver every day. With progressive liver disease, serum albumin levels fall, reflecting decreased synthesis. Albumin levels are dependent on a number of factors such as the nutritional status, catabolism, hormonal factors, and urinary and gastrointestinal losses. These should be taken into account when interpreting low albumin levels. Still, albumin concentration does correlate with the prognosis in chronic liver disease. Because two-thirds of the amount of body albumin is located in the extravascular, extracellular space, changes in distribution can alter the serum concentration. Albumin is synthesized by hepatic parenchymal cells and has a serum half-life of about 20 days. Hypoalbuminemia secondary to excessive loss of the protein is seen in patients with nephrotic syndrome or protein-losing enteropathy.

A rise in levels of globulins, primarily gamma-globulins, is frequently seen in patients with chronic hepatitis or cirrhosis. Elevations in IgA levels are common in alcoholic cirrhosis, and elevations in IgG levels are common in autoimmune chronic active hepatitis. Elevations in IgM levels are seen in PBC. Diminished levels of alpha-1-globulins caused by deficient alpha-1-antitrypsin activity can be associated with chronic active hepatitis and cirrhosis in children and adults.

## Prothrombin Time

The liver synthesizes blood clotting factors II, V, VII, IX, and X. The PT measures the rate of conversion of prothrombin to thrombin (requiring the above-mentioned factors) and reflects the synthetic function of the liver. The PT does not become abnormal until  $>80\%$  of liver synthetic capacity is lost. This makes PT an insensitive marker of liver dysfunction. Still, abnormal PT prolongation may be a sign of liver dysfunction. Besides liver disease, the PT may be prolonged in vitamin K deficiency, warfarin therapy, and disseminated intravascular coagulation. The prognostic utility of an elevated PT is exemplified by the 100% mortality reported in a study of patients with halothane hepatitis who had a PT  $>20$  seconds. Other clinically relevant aspects of coagulopathies include the necessity to correct these factor deficiencies in patients with significant bleeding and the fact

that certain procedures such as liver biopsy are contraindicated in patients with a significant coagulopathy.

Because factor VII has a short half-life (6 hours), it is sensitive to rapid changes in liver synthetic function. Thus PT is very useful for following liver function in patients with acute liver failure. Vitamin K is required for the gamma-carboxylation of the above-named factors. Hence, an elevated PT can result from a vitamin K deficiency. This deficiency usually occurs in patients with chronic cholestasis or fat malabsorption from disease of the pancreas or small bowel. A trial of vitamin K is a useful and well-established way to exclude vitamin K deficiency in such patients. The PT should improve within a few days if it is caused by fat malabsorption but will not if secondary to intrinsic liver disease.

### Antimitochondrial Antibody

Antimitochondrial antibody (AMA) is an autoantibody that is detected in the serum by a variety of methods. Mitochondrial antibodies are found in 0.8% to 1.6% of the general population, 6% of patients with cryptogenic cirrhosis, 10% of patients with chronic active hepatitis, and 85% to 90% of patients with PBC. The height of the AMA titer has no prognostic significance. The 10% to 15% of patients with PBC who are AMA negative have the same natural history of the disease as AMA-positive patients. Antimitochondrial antibodies are also found in a significant number of asymptomatic relatives of patients with PBC and chronic active hepatitis. Modern AMA assays have great diagnostic relevance with 95% sensitivity and 98% specificity for PBC. When such antibodies are not detected in the serum, a diagnosis of PBC should be made with caution and only after a careful period of clinical follow-up.

### Serum Ceruloplasmin

Ceruloplasmin, a copper-containing glycoprotein, is an acute-phase reactant. Up to 95% of patients with Wilson disease have serum ceruloplasmin concentrations <20 mg/dL. Up to 10% of heterozygotes have low ceruloplasmin levels but remain healthy. Low concentrations may also be seen in patients with fulminant hepatitis unrelated to Wilson disease, nephrotic syndrome, and protein-losing enteropathies. Still, measurement of serum ceruloplasmin alone does not reliably establish or exclude the diagnosis. Further testing, usually urinary copper excretion, assessment for Kayser-Fleischer rings (Fig. 74.1), or liver biopsy, is required.

### Serum Ferritin

Serum ferritin levels accurately reflect hepatic and total-body iron stores. Serum ferritin levels are low in iron deficiency and elevated in iron overload disorders such as genetic idiopathic hemochromatosis. Occasionally, normal levels of serum ferritin may be found in patients with precirrhotic hemochromatosis. Conversely, a very high level of serum ferritin may be present in patients who turn out not to have hemochromatosis. Serum ferritin levels may be

• **Fig. 74.1** Eye findings in Wilson disease; Kayser-Fleischer ring. (Courtesy Jonathan Kruska, MD, Chair of Radiology, Beth Israel Deaconess Medical Center.)

### • BOX 74.7 Causes of Elevations in Serum Ferritin

- Idiopathic genetic hemochromatosis
- Hepatocellular necrosis
- Hodgkin disease
- Leukemia
- Hyperthyroidism
- Uremia
- Rheumatoid arthritis

elevated in the absence of iron overload in a variety of conditions (Box 74.7). Measurement of serum iron concentration, percentage transferrin saturation, and serum ferritin level is the screening regimen currently recommended for idiopathic genetic hemochromatosis. Of note, cirrhosis is very unlikely in hemochromatosis if the patient is age <40 years, has no hepatomegaly, has normal transaminases, and has a serum ferritin <1000 ng/mL.

### Antismooth Muscle Antibodies

Smooth muscle antibodies are directed against cytoskeletal proteins such as actin, troponin, and tropomyosin. They frequently occur in high titers in association with antinuclear antibodies (ANAs). They are associated with autoimmune hepatitis and have been shown to occur in advanced liver diseases of other etiologies and in infectious diseases and rheumatic disorders. Although less prevalent than ANA, they are more specific, particularly when present in titers of  $\geq 1:100$ . Circulating antismooth muscle antibodies are also found in patients with chronic hepatitis C. The mean titer is generally higher in patients with autoimmune hepatitis.

### Antinuclear Antibody

ANAs are an often-used serologic marker of autoimmune disease and are present in several disorders (Box 74.8). These antibodies can also provide diagnostic and

### • BOX 74.8 Common Diseases Associated With Positive Antinuclear Antibody

Hashimoto thyroiditis  
Graves disease  
Autoimmune hepatitis  
Primary biliary cirrhosis  
Autoimmune cholangitis  
Pulmonary arterial hypertension

prognostic data concerning patients who have minimal symptoms or who have clinical features of more than one autoimmune disease. They are the most common circulating autoantibodies in autoimmune hepatitis. They are seen in both type 1 disease and rarely in type 2 disease. In most laboratories, a titer of  $\geq 1:100$  is considered positive. ANA may be the only autoantibody present or may occur in conjunction with antismooth muscle antibody. In one study, the specific immunofluorescence patterns of ANAs did not distinguish clinical features of liver disease, although speckled patterns were associated with a younger age and greater aminotransferase activity, and multiple autoantibodies were frequently associated with each immunofluorescent pattern.

## Lactate Dehydrogenase

Serum lactate dehydrogenase comes from myocardium, liver, skeletal muscle, brain, or kidney tissue and red blood cells. Thus an elevated serum lactate dehydrogenase value is nonspecific. Hepatic serum lactate dehydrogenase can be verified by isoenzymes. Increased lactate dehydrogenase levels are seen in patients with a variety of hepatobiliary disorders including acute viral or drug hepatitis, congestive heart failure, cirrhosis, and extrahepatic obstruction. Marked elevations in serum lactate dehydrogenase and alkaline phosphatase levels are highly suggestive of metastatic disease to the liver.

## Ultrasound

Ultrasonography with Doppler flow studies presents a non-invasive, commonly used modality that provides valuable information regarding the appearance of the liver and blood flow in the portal and hepatic veins in cirrhosis and several other liver diseases. A study using high-resolution ultrasonography in cirrhotic patients (confirmed by biopsy or laparoscopy) found a sensitivity and specificity for cirrhosis of 91.1% and 93.5%, respectively, and positive and negative predictive values of 93.2% and 91.5%, respectively. Ultrasonography is a relatively inexpensive radiology study and does not pose the radiation exposure risks of other studies. Thus it is appropriately the test of choice in the evaluation of liver and biliary tract disease in children and pregnant women. Ultrasonography also lacks the risk of nephrotoxicity from intravenous contrast seen in CT. Nodularity, irregularity, increased echogenicity, and atrophy are the

ultrasonographic hallmarks of cirrhosis. It should be noted, however, that the absence of the above-mentioned features does not rule out cirrhosis.

Marked obesity and excessive intestinal gas can be limiting factors in obtaining good resolution of the images. Ultrasound examination of the liver will often identify mass lesions  $\geq 1$  cm to 2 cm in size in the hepatic parenchyma and do this independently of hepatic function. Ultrasound can facilitate guided aspiration of cysts or biopsy specimens of lesions. Ultrasonography is a useful procedure for detecting gallstones and confirming the presence of ascites, keeping in mind that study in the fasting state is important. Ultrasound is often used as the first test in the evaluation of patients with cholestatic jaundice. Dilated bile ducts can be readily seen on ultrasound examination in patients with mechanical extrahepatic biliary tract obstruction. Dilation of the bile ducts may not be evident if the obstruction is incomplete or intermittent or if it has been present for a short duration. Serial ultrasound examinations may provide clues in these circumstances. Note that the common bile duct is frequently dilated following cholecystectomy. Hence an enlarged duct in this situation does not necessarily signify ongoing biliary tract obstruction.

## Computed Tomography and Magnetic Resonance Imaging

The predominantly used imaging tools other than ultrasonography in imaging the liver are CT and MRI. The goals of imaging patients with liver failure are to evaluate for cirrhosis and portal hypertension, to identify conditions that may complicate or preclude treatment, and to identify and stage tumors within the liver or extrahepatic malignancies. Continuous improvements in these imaging modalities over the recent years have expanded their role and improved their utility. At most centers, CT is the predominant tool in evaluating patients with advanced liver disease, whereas ultrasonography, MRI, and angiography maintain important screening and problem-solving roles (Figs. 74.2–74.4).

CT and MRI are quite accurate in depicting hepatocellular carcinoma (HCC) lesions and complications such as portal or hepatic venous invasion or biliary ductal obstruction. Venous tumor thrombi, for example, are detected as vessel expansion, enhancing tumor thrombi, and contiguity with a parenchymal mass. Evaluations of potential liver donors and recipients are an equally important use of CT and/or MRI. Common variants, including hepatic arterial anomalies, trifurcation of the portal veins, or large accessory or anomalous hepatic veins may preclude the use of a potential donor liver or may mandate alternate surgical approaches. Noninvasive imaging of the biliary tree of a potential living donor presents an ongoing challenge. MR cholangiography (MRC) has provided excellent depictions of the biliary tree, but experience with operative correlation is limited to small case series.

## Enhanced Magnetic Resonance Cholangiography

In routine MRC, T2-weighted sequences in multiple planes depict the water content of bile in the biliary ducts and in the gallbladder. This represents a noninvasive method requiring no contrast agent. However, because of limited resolution, MRC is not always conclusive. MRC is also sensitive to motion artifacts and does not provide any information on hepatobiliary function.

In recent years, several new liver-specific MR imaging contrast media have been used. Some of the agents are targeted to hepatocytes: gadobenate dimeglumine, Gd-BOPTA (MultiHance; Bracco Imaging, Milan, Italy), gadoxetic acid, Gd-EOB-DTPA (Primovist; Schering, Berlin, Germany), and mangafodipir trisodium, Mn-DPDP (Teslascan; GE Healthcare, Chalfont St. Giles, United Kingdom). All these substances are to some extent eliminated by biliary excretion and may therefore be useful for investigating hepatobiliary function. In one head-to-head study, the earlier onset and longer duration of a high contrast between common hepatic duct and liver for Gd-EOB-DTPA facilitated examination of hepatobiliary excretion, concluding that Gd-EOB-DTPA may provide adequate hepatobiliary imaging within a shorter time span than Gd-BOPTA.

## Liver Biopsy

Percutaneous needle biopsy of the liver is a commonly used, safe procedure that can be performed at the bedside. It often provides tissue diagnosis without resorting to general anesthesia and laparotomy, and most agree that it can be performed as an outpatient procedure provided facilities are available for short-term observation and hospitalization if necessary. Indications for liver biopsy are outlined in [Box 74.9](#). Of note, liver biopsy provides no information regarding the site or nature of the obstructing lesion.

Contraindications for needle biopsy of the liver include uncooperative or comatose patients, hydatid cyst disease,

### • BOX 74.9 Indications for Liver Biopsy

- Hepatocellular disease of uncertain cause
- Unexplained hepatomegaly and/or splenomegaly
- Hepatic filling defects demonstrated by radionuclide scanning ultrasound or computed tomography scans
- Chronic hepatitis
- Fever of unknown origin
- Alcoholic liver disease
- Workup for hemochromatosis
- Workup for Wilson disease
- Workup for glycogen storage diseases
- Assessment of portal hypertension
- Staging of malignant lymphoma
- Workup for type I Crigler-Najjar syndrome

hemangioma or angiosarcoma of the liver, right pleural disease or local infection at the proposed biopsy site, and significant coagulopathy. Providers usually will not perform a biopsy if a prolongation of the PT is >4 seconds over control, a partial thromboplastin time is >15 seconds over control, or a platelet count <50,000/mm<sup>3</sup>. Amyloidosis is not a contraindication unless the liver is very massively enlarged or there is an associated bleeding tendency. Liver biopsy is performed via percutaneous, transjugular, laparoscopic, open operative, or ultrasonography-guided or CT-guided fine-needle approaches. Before the procedure, a CBC with platelets and PT measurement should be obtained. Patients should be advised to refrain from consumption of aspirin and nonsteroidal antiinflammatory drugs for 7 to 10 days before the biopsy to minimize the risk of bleeding.

The most common side effect is pain at the biopsy site or right shoulder, usually dull and mild, occurring in roughly 25% of patients. Moderate-to-severe pain with or without hypotension usually manifests within the first 3 hours of the procedure. Serious bleeding occurs in <0.3% of patients, although asymptomatic subcapsular or intrahepatic hematomas are probably more common.

## Noninvasive Markers of Fibrosis

Numerous investigators have examined noninvasive tests for assessing hepatic fibrosis. The two most widely investigated tools are the FibroTest (Biopredictive, Paris, France) and FibroScan (Echosens, Paris, France). The FibroTest, called *FibroSure* in the United States, is a composite of five serum biochemical markers (alpha-2-macroglobulin, apolipoprotein A1, haptoglobin, gamma-glutamyltranspeptidase, and bilirubin) associated with hepatic fibrosis. The FibroScan uses an ultrasound-based technique known as transient elastography to measure the speed of propagation of elastic waves through the liver. Both tests have been validated by multiple studies in various liver diseases. Acoustic resonance force imaging and MR elastography are alternative imaging techniques with comparable test characteristics for the assessment of advanced fibrosis. Limitations include their cost, failed validation, difficulty differentiating intermediate fibrosis stage, and the inability to exclude other conditions. Recent

studies of noninvasive markers as tools to potentially identify portal hypertension and esophageal varices found that liver stiffness measured by elastography, spleen size on ultrasound, and platelet count could be used to identify patients with

portal hypertension in the setting of compensated cirrhosis. Although liver biopsy remains the gold standard for diagnosing cirrhosis, noninvasive tools are being widely adopted, particularly in patients for whom the diagnosis is not in question.

## Chapter Review

### Questions

1. A 62-year-old white male is referred for evaluation of a persistently elevated serum aminotransferase. His medical history is notable for long-standing but well-controlled hypertension and hypercholesterolemia. He has been on amlodipine, 10 mg once daily, and atorvastatin, 20 mg once daily. He drinks two to three glasses of red wine on weekends. On examination, his blood pressure is 139/62 mm Hg, heart rate 78 beats per minute, and he weighs 238 lb with a body mass index of 32. His examination is otherwise normal. His AST is 96 U/L (was normal 2 years ago), ALT 109 U/L (was normal 2 years ago), alkaline phosphatase 66 U/L, bilirubin 0.7 mg/dL, albumin 4.5 mg/dL, and international normalized ratio 1.1. CT scan of the abdomen shows low-density hepatic parenchyma. Which of the following is most likely causing this patient's elevated serum aminotransferase values?
  - A. Treatment with amlodipine
  - B. Nonalcoholic fatty liver disease
  - C. Treatment with atorvastatin
  - D. PBC
  - E. Alcohol use
2. The treatment that you would recommend to the patient in Question 1 would be:
  - A. Stop the amlodipine.
  - B. Stop the atorvastatin.
  - C. Weight loss
  - D. Observation only, no treatment
  - E. Complete abstinence from alcohol
3. A 29-year-old man presents with evidence of ascites and abnormal liver function tests. He denies alcohol consumption but smokes (approximately one pack per day for the past 10 years). He has a history of emphysema diagnosed at the age of 22 years. All viral serologies are negative. His serum alpha-1-antitrypsin level is 72 mg/dL (reference range 100–300 mg/dL). A diagnosis of alpha-1-antitrypsin deficiency is made. Which of the

following phenotypes would most likely lead to this clinical presentation?

- A. Pi MM
  - B. Pi SS
  - C. Pi ZZ
  - D. Pi MZ
4. A 39-year-old woman is found to have the following iron studies: serum iron 184 µg/mL, total iron binding capacity 250 µg/mL, and serum ferritin 285 ng/mL (normal 25–240 ng/mL). Her liver function tests are normal, and she is asymptomatic with a normal physical examination. What is the next test that should be ordered?
    - A. Percutaneous liver biopsy
    - B. Serum B<sub>12</sub> and folate levels
    - C. Glucose tolerance testing
    - D. Gene testing for the hereditary hemochromatosis mutation
    - E. Abdominal CT scan with intravenous contrast
  5. A 42-year-old gardener presents with an 8-month history of bullous lesions on the dorsum of his hands, his forearms, and his neck. He says that his urine is a port wine color. His physical examination is otherwise unremarkable. He reports drinking one to two six-packs of beer every week, and on laboratory examination he has a mildly elevated ALT (1.5 times normal). The most likely diagnosis is:
    - A. Bullous pseudoporphyria
    - B. Hydroa vacciniform
    - C. Bullous systemic lupus erythematosus
    - D. Porphyria cutanea tarda
    - E. Epidermolysis bullosa acquisita

### Answers

1. B
2. C

## Cirrhosis

PATRICIA PRINGLE AND RAYMOND T. CHUNG

**C**irrhosis is a diffuse fibrotic process characterized by the transformation of normal hepatic tissue architecture to one structurally composed of nodules. These regenerative nodules lack normal lobular organization and are ringed by fibrous tissue. Liver injury activates hepatic stellate cells, transforming them into myofibroblasts that secrete excessive extracellular matrix proteins, thus leading to progressive fibrosis. The progression of liver injury to cirrhosis may occur over weeks to decades. The chief complications are ascites, encephalopathy, and variceal bleeding.

Chronic liver disease and cirrhosis result in about 35,000 deaths each year in the United States. Cirrhosis is the eleventh leading cause of death in the United States and is responsible for 1.4% of all US deaths.

### Causes of Cirrhosis

The causes of cirrhosis are shown in [Box 75.1](#). The most common cause of cirrhosis in the United States is hepatitis C. Alcoholic liver disease, once considered to be the predominant cause of cirrhosis in the United States, remains a significant etiologic factor, especially given that its interaction with hepatitis C infection accelerates fibrosis and development of cirrhosis. Nonalcoholic fatty liver disease (NAFLD) is fast gaining attention as a major cause of liver disease, and many believe that with the recent obesity epidemic, it will become the most common cause of cirrhosis in the coming years. Many cases of cirrhosis, previously characterized as “cryptogenic,” appear to have resulted from NAFLD and reviews of studies on cryptogenic cirrhosis reveal that many patients have risk factors for NAFLD: obesity, diabetes, and hypertriglyceridemia. It is postulated that steatosis may regress in some patients as hepatic fibrosis progresses, making the histologic diagnosis of NAFLD as a reason for cirrhosis sometimes difficult. Up to one-third of Americans have NAFLD. About 2% to 3% of Americans have nonalcoholic steatohepatitis (NASH), in which NAFLD is complicated by liver inflammation and fibrosis. It is estimated that 10% of patients with NASH will ultimately develop cirrhosis.

### Clinical Features of Cirrhosis

There is a poor correlation between histologic findings of cirrhosis and degree of hepatic impairment. Some patients

with cirrhosis are completely asymptomatic and have a reasonably long life expectancy. Other individuals have a multitude of the most severe symptoms of end-stage liver disease and, as such, have a limited chance for survival. The clinical features of cirrhosis can be broadly attributed to decreased hepatic synthetic function (e.g., coagulopathy), decreased detoxification capabilities of the liver (e.g., hepatic encephalopathy), or portal hypertension (e.g., variceal bleeding; [Fig. 75.1](#)). Patients with clinically advanced cirrhosis present with ascites, jaundice, hypoalbuminemia, coagulopathy, and encephalopathy. In addition, there is marked muscle wasting, renal dysfunction as manifested by hepatorenal syndrome, and pulmonary abnormalities characterized by hepatopulmonary syndrome, portopulmonary hypertension, and hepatic hydrothorax. There is also an increased risk of hepatocellular cancer in patients with cirrhosis.

### Complications of Cirrhosis

#### Ascites

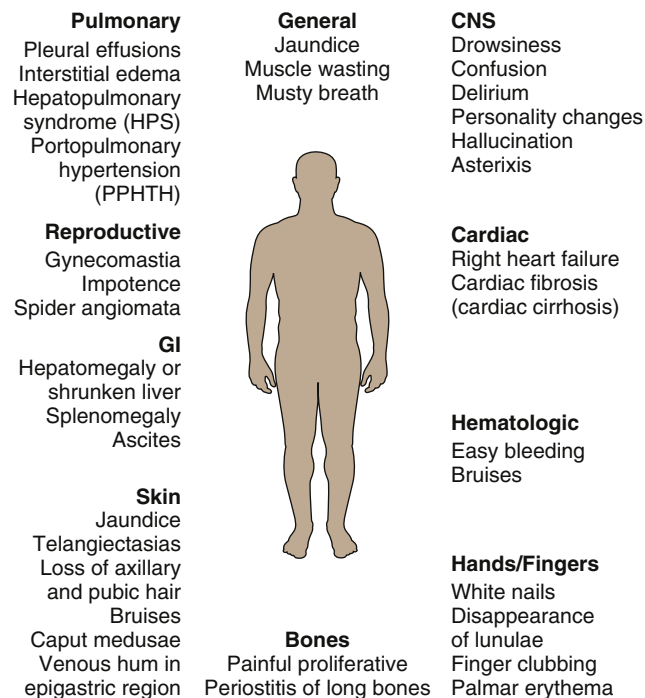

Ascites is defined as an accumulation of excessive fluid within the peritoneal cavity. Ascites formation in patients with cirrhosis is the result of portal hypertension, which, through several mechanisms leads to salt and water retention. Ascites may be a complication of both hepatic and nonhepatic diseases. The most common causes of ascites in North America and Europe are shown in [Table 75.1](#).

#### Diagnostic Evaluation of Ascites

The key steps in the evaluation of ascites include acquiring a thorough history and physical, obtaining an ascitic fluid evaluation, and obtaining special tests. Clinically, ascites is suggested by the presence of abdominal distension, bulging flanks, shifting dullness, and elicitation of a “puddle sign” in patients in the knee-elbow position. A fluid wave may be elicited in patients with massive tense ascites. Ascites may be graded as follows: grade 1, mild, only visible on ultrasound; grade 2, detectable with flank bulging and shifting dullness; and grade 3, gross ascites with marked abdominal distension. On physical examination, the presence of vascular spiders and abdominal wall collaterals are useful in supporting the diagnosis of chronic liver disease as a cause of ascites.

### • BOX 75.1 Causes of Cirrhosis in the United States

Hepatitis C (26%)  
 Alcoholic liver disease (21%)  
 Hepatitis C plus alcoholic liver disease (15%)  
 Cryptogenic causes (18%)  
 Hepatitis B, which may be coincident with hepatitis D (15%)  
 Miscellaneous (5%)  
 Autoimmune hepatitis  
 Primary biliary cirrhosis  
 Secondary biliary cirrhosis (associated with chronic extrahepatic bile duct obstruction)  
 Primary sclerosing cholangitis  
 Hemochromatosis  
 Wilson disease  
 Alpha-1-antitrypsin deficiency  
 Granulomatous disease (e.g., sarcoidosis)  
 Type IV glycogen storage disease  
 Drug-induced liver disease (e.g., methotrexate, alpha-methylidopa, amiodarone)  
 Venous outflow obstruction (e.g., Budd-Chiari syndrome, venoocclusive disease)  
 Chronic right-sided heart failure  
 Tricuspid regurgitation

• **Fig. 75.1** Clinical manifestations of cirrhosis. CNS, Central nervous system; GI, gastrointestinal.

Paracentesis is routine for new-onset ascites in patients on admission and in patients who have a clinical deterioration. A diagnostic tap is performed with a 22-gauge 1.5-inch needle, whereas a therapeutic tap is performed with a 15- to 18-gauge needle. There is an approximate 1% complication rate with paracentesis, mainly abdominal wall hematomas. A popular option for the tap site is the left lower quadrant

Reprinted with permission from Runyon BA, Montano AA, Antillon MR, et al. The serum-ascites albumin gradient is superior to the exudate-transudate concept in the differential diagnosis of ascites. *Ann Intern Med.* 1992;117:215–220.

of the abdomen, two fingerbreadths medial and cephalad to the anterior superior iliac spine. Tests are in [Table 75.2](#).

Serum-ascites albumin gradient (SAAG) is a useful initial test because it distinguishes ascites caused by portal hypertension from nonportal hypertensive causes. The SAAG is calculated by subtracting the ascitic fluid albumin value from the serum albumin value; it correlates directly with portal pressure. The specimens should be obtained relatively simultaneously. The accuracy of the SAAG results is approximately 97% in classifying ascites. Ascites with a SAAG gradient of >1.1 g/dL is termed *high-albumin-gradient* or *portal hypertensive* ascites. In contrast, ascites with a SAAG gradient of <1.1 g/dL is known as *low-albumin-gradient* or *nonportal hypertensive* and is associated with peritoneal diseases ([Table 75.3](#)). For patients with high-albumin-gradient

ascites, total protein can help further delineate portal hypertensive etiologies. An ascitic protein level of  $\geq 2.5$  g/dL is suggestive of cardiac ascites, sinusoidal obstruction syndrome, or early Budd-Chiari syndrome; whereas a level  $< 2.5$  g/dL indicates cirrhotic ascites, late Budd-Chiari syndrome, or massive liver metastases.

Chylous ascites, caused by obstruction of the thoracic duct or cisterna chyli, most often is as a result of malignancy (e.g., lymphoma) but occasionally is observed postoperatively and following radiation injury. Chylous ascites also may be observed in the setting of cirrhosis. The ascites triglyceride concentration is  $> 110$  mg/dL. In addition, ascites triglyceride concentrations are greater than those observed in plasma. Ascitic fluid with  $> 250$  polymorphonuclear (PMN) cells/mm<sup>3</sup> defines neutrocytic ascites and spontaneous bacterial peritonitis (SBP). Many cases of ascites fluid with  $> 1000$  PMN/mm<sup>3</sup> (and certainly  $> 5000$  PMN/mm<sup>3</sup>) are associated with appendicitis or a perforated viscus with resulting bacterial peritonitis. Appropriate radiologic studies must be performed in such patients to rule out surgical causes of peritonitis. Lymphocyte-predominant ascites raises concerns about the possibility of underlying malignancy or tuberculosis (TB). Similarly, grossly bloody ascites may be observed in malignancy and TB. Bloody ascites is seen infrequently in uncomplicated cirrhosis. A common clinical dilemma is how to interpret the ascites PMN count in the setting of bloody ascites. We recommend subtraction of 1 PMN for every 250 red blood cells in ascites to ascertain a corrected PMN count.

Special testing includes an abdominal ultrasound (ultrasound with Doppler can help assess the patency of hepatic vessels), cytology for peritoneal cancer (often requires a large volume for preparation of a cell block), cardiac echo for suspected cardiac ascites, hepatic portal venous gradient testing, and TB smear and culture. Upper gastrointestinal (GI) endoscopy for screening of large varices is also an option. Factors associated with worsening of ascites include excess fluid or salt intake, malignancy, venous occlusion (e.g., Budd-Chiari syndrome), progressive liver disease, and SBP.

### Treatment of Ascites

Therapy for ascites should be tailored to the patient's needs. Options are shown in Table 75.4. Some patients with mild ascites respond to sodium restriction or diuretics taken once or twice per week. Other patients require aggressive diuretic therapy, careful monitoring of electrolytes, and occasional hospitalization to facilitate even more intensive diuresis. The development of ascites refractory to medical therapy has poor prognostic implications, with 20% to 50% of patients dying within 6 months.

### Complications of Ascites

#### Spontaneous Bacterial Peritonitis

SBP is observed in 10% to 30% of patients hospitalized with ascites. The syndrome arises most commonly in patients whose low-protein ascites ( $< 1$  g/dL) contains low levels of complement resulting in decreased opsonic activity. The

three most common signs of SBP (abdominal pain, fever, and leukocytosis) are seen in only 70% of persons with SBP, and some argue that paracentesis should be performed in all patients with cirrhosis who have ascites at the time of hospitalization. SBP appears to be caused by the translocation of GI tract bacteria from the intestines to mesenteric lymph nodes, followed by rupture of lymphatics or bacteremia causing subsequent infection of ascitic fluid. The most common causative organisms are *Escherichia coli*, *Streptococcus pneumoniae*, *Klebsiella* species, and other gram-negative enteric organisms.

Classic SBP is diagnosed by the presence of neutrocytosis, which is defined as  $> 250$  PMN cells/mm<sup>3</sup> of ascites in the setting of a positive ascites culture. Culture-negative neutrocytic ascites is observed more commonly. The yield of ascites culture studies may be increased by directly inoculating 10 mL of ascites into aerobic and anaerobic culture bottles at the patient's bedside. Both conditions represent serious infections that carry a 10% to 30% mortality rate.

The most commonly used regimen in the treatment of SBP is a 5-day course of intravenous third-generation cephalosporin, such as cefotaxime at 1 to 2 g intravenously every 8 hours. Oral ofloxacin can be used as an alternative in milder cases. Some authorities have advised repeat paracentesis in 48 to 72 hours to document a decrease in the ascites PMN count to  $< 250$  cells/mm<sup>3</sup>, but this is not necessary in typical SBP.

Once SBP develops, patients have a 70% chance of redeveloping the condition within 1 year. Prophylactic antibiotic therapy can reduce the recurrence rate of SBP to 20%. Some of the regimens used in the prophylaxis of SBP include norfloxacin at 400 mg orally every day and trimethoprim-sulfamethoxazole at one double-strength tablet 5 days per week.

Therapy with norfloxacin at 400 mg orally twice per day for 7 days can reduce serious bacterial infection and mortality in patients with cirrhosis who have GI bleeding. Furthermore, a metaanalysis of four randomized trials found that primary prophylaxis of SBP (e.g., with norfloxacin 400 mg/d orally) in patients with cirrhosis and low-protein ascites ( $< 1.5$  g/dL) reduced bacterial infections and mortality.

#### Massive Ascites

Patients with massive ascites may experience abdominal discomfort, depressed appetite, and decreased oral intake. Diaphragmatic elevation may lead to symptoms of dyspnea. Pleural effusions may result from the passage of ascitic fluid across channels in the diaphragm.

Umbilical and inguinal hernias are common in patients with moderate and massive ascites. The use of an elastic abdominal binder may protect the skin overlying a protruding umbilical hernia from maceration and may help prevent rupture and subsequent infection. Timely large-volume paracentesis also may help to prevent this disastrous complication. Umbilical hernias should not undergo elective repair unless patients are significantly symptomatic or their hernias are irreducible. As with all other surgeries in patients

**TABLE 75.4 Treatment Options for Diuretic-Responsive and Diuretic-Resistant Ascites**

Conventional Treatment Options	Key Features
<b>Abstinence From Alcohol</b>	
Sodium restriction	First-line therapy Dietary sodium restriction <2000 mg sodium per day.
Diuretics	Second-line therapy Spironolactone (Aldactone) blocks the aldosterone receptor at the distal tubule. Dose 100–400 mg once per day. May be used as a solo agent, but adding furosemide may speed diuresis and avoid hyperkalemia. Alternative is eplerenone, but more expensive. Furosemide (Lasix) should be used in combination with spironolactone. Furosemide blocks sodium reuptake in the loop of Henle. Dosed at 40–160 mg/d in 1–2 divided doses. Avoid intravenous furosemide if possible because it may precipitate acute kidney injury. Starting doses: 100 mg/d spironolactone and 40 mg/d furosemide. This ratio usually maintains normokalemia.
<b>Options for Diuretic-Resistant Ascites</b>	
Large-volume paracentesis	Indicated when aggressive diuretic therapy is ineffective in controlling ascites (~5%–10% of patients).  Several large randomized, controlled trials have shown that repeated large-volume paracentesis (4–6 L) is safer and more effective for the treatment of tense ascites compared with larger-than-usual doses of diuretics. Procedure-associated risks include a 1% chance of significant abdominal-wall hematoma, 0.01% chance of hemoperitoneum, and a 0.01% chance of iatrogenic infection related to paracentesis. The only absolute contraindication to paracentesis is clinically evident fibrinolysis and disseminated intravascular coagulation.  Controversy around whether to use sPA with a tap. One option is to reserve sPA for taps >5 L.
Vasopressin V2 receptor antagonist, e.g., satavaptan	May provide diuresis and correction of hyponatremia, but caution is warranted given possible rapid correction of hyponatremia and increased mortality. Also very expensive.
Transjugular intrahepatic portosystemic shunt	A flexible metal prosthesis is used to bridge a branch of the hepatic and portal veins and is effective in reducing sinusoidal pressure.  The procedure is performed percutaneously under radiologic guidance and obviates the need for surgery.  It is recommended that coagulopathy (INR >2 and platelet count <50 × 10 <sup>9</sup> /L) be corrected first if indicated and that paracentesis be performed in patients with tense ascites before the procedure.  Four randomized, controlled studies have compared TIPS with large-volume paracentesis in refractory ascites. All four studies showed better control of ascites with TIPS, but only one study showed a survival benefit.  The rate of procedure-related complications is 10% and of procedure-related mortality is 2%. Procedure-related complications include neck hematomas, hemobilia, puncture of the liver capsule causing intraabdominal bleeding, and shunt occlusion.  Absolute contraindications for TIPS insertion include serum bilirubin >85 μmol/L (5 mg/dL), INR >2, functional renal disorder with serum creatinine >250 μmol/L (2.8 mg/dL), intrinsic renal disease with urine protein >500 mg/24 hours or active urinary sediment, grade III or IV hepatic encephalopathy, cardiac disease, portal vein thrombosis, noncompliance with sodium restriction, or the presence of carcinoma that is likely to limit the patient's lifespan to <1 year. Relative contraindications include dental sepsis, spontaneous bacterial peritonitis, and active infection (pneumonia or urinary tract infection).
Liver transplantation	Liver transplantation is the only definitive treatment for ascites and the only treatment that has been clearly shown to improve survival.  Patients with cirrhosis who develop ascites should be assessed for possible liver transplantation because of their poor prognosis.  Patients who develop renal dysfunction (GFR <50 mL/min) do much worse after liver transplantation (80% vs. 50% survival at 15 months).

TABLE  
75.4

Treatment Options for Diuretic-Responsive and Diuretic-Resistant Ascites—cont'd

Conventional Treatment Options	Key Features
	Other poor prognostic indicators include mean arterial pressure <82 mm Hg, urinary sodium excretion of <1.5 mEq/d, plasma norepinephrine levels of >570 pg/mL, poor nutritional state, presence of hepatomegaly, and serum albumin <25 g/L.
<i>GFR</i> , Glomerular filtration; <i>INR</i> , international normalized ratio; <i>sPA</i> , salt-poor albumin; <i>TIPS</i> , transjugular intrahepatic portosystemic shunt.	

with cirrhosis, herniorrhaphy carries multiple potential risks, such as intraoperative bleeding, postoperative infection, and liver failure because of anesthesia-induced reductions in hepatic blood flow. However, these risks become acceptable in patients with severe symptoms from their hernia. Urgent surgery is necessary in the patient whose hernia has been complicated by bowel incarceration.

### Portal Hypertension

The normal liver has the ability to accommodate large changes in portal blood flow without appreciable alterations in portal pressure. Portal hypertension results from a combination of increased portal venous inflow and increased resistance to portal blood.

The portal hypertension of cirrhosis is caused by the disruption of hepatic sinusoids. However, portal hypertension may be observed in a variety of noncirrhotic conditions. Prehepatic causes include splenic vein thrombosis and portal vein thrombosis. These conditions are commonly associated with hypercoagulable states and with malignancy (e.g., pancreatic cancer).

Intrahepatic causes of portal hypertension are divided into presinusoidal, sinusoidal, and postsinusoidal conditions. The classic form of presinusoidal disease is caused by the deposition of *Schistosoma* oocytes in presinusoidal portal venules, with the subsequent development of granulomata and portal fibrosis. Schistosomiasis is the most common noncirrhotic cause of variceal bleeding worldwide. *Schistosoma mansoni* infection is described in Puerto Rico, Central and South America, the Middle East, and Africa. *Schistosoma japonicum* is described in the Far East. *Schistosoma haematobium*, observed in the Middle East and Africa, can produce portal fibrosis, but more commonly, it is associated with urinary tract deposition of eggs. The classic sinusoidal cause of portal hypertension is cirrhosis. The classic postsinusoidal condition is an entity known as venoocclusive disease. Obliteration of the terminal hepatic venules may result from ingestion of pyrrolizidine alkaloids in comfrey tea or Jamaican bush tea and following the high-dose chemotherapy that precedes bone marrow transplantation.

Posthepatic causes of portal hypertension may include chronic right-sided heart failure, tricuspid regurgitation, and obstructing lesions of the hepatic veins and inferior vena cava. These latter conditions, and the symptoms they produce, are termed *Budd-Chiari syndrome*. Predisposing

conditions include hypercoagulable states, tumor invasion into the hepatic vein or inferior vena cava, and membranous obstruction of the inferior vena cava. Inferior vena cava webs are observed most commonly in South and East Asia and are postulated to be caused by nutritional factors.

Symptoms of the Budd-Chiari syndrome are attributed to decreased outflow of blood from the liver, with resulting hepatic congestion and portal hypertension. These symptoms include hepatomegaly, abdominal pain, and ascites. Cirrhosis only ensues later in the course of disease. Differentiating the Budd-Chiari syndrome from cirrhosis by history or physical examination may be difficult. Thus the Budd-Chiari syndrome must be included in the differential diagnosis of conditions that produce ascites and varices. A possible clue may come from the analysis of the ascitic fluid. The SAAG is usually >1.1, but the ascitic fluid has a high protein content unlike that of cirrhotic ascites. Hepatic vein patency is checked most readily by performing an abdominal ultrasound with Doppler examination of the hepatic vessels. Abdominal CT scan with intravenous contrast, abdominal MRI, and visceral angiography also may provide information regarding the patency of hepatic vessels.

### Hepatorenal Syndrome

This syndrome represents a continuum of renal dysfunction that may be observed in patients with cirrhosis and is caused by the vasoconstriction of large and small renal arteries and the impaired renal perfusion that results. The syndrome may represent an imbalance between renal vasoconstrictors and vasodilators. Plasma levels of a number of vasoconstricting substances are elevated in patients with cirrhosis and include angiotensin, antidiuretic hormone, and norepinephrine. Renal perfusion appears to be protected by vasodilators, including prostaglandins E<sub>2</sub> and I<sub>2</sub> and atrial natriuretic factor. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit prostaglandin synthesis. They may potentiate renal vasoconstriction, with a resulting drop in glomerular filtration. Thus the use of NSAIDs is contraindicated in patients with decompensated cirrhosis.

Most patients with hepatorenal syndrome are noted to have minimal histologic changes in the kidneys. Kidney function usually recovers when patients with cirrhosis and hepatorenal syndrome undergo liver transplantation.

Hepatorenal syndrome progression may be slow (type II) or rapid (type I). Type I disease frequently is accompanied by

rapidly progressive liver failure. Hemodialysis offers temporary support for such patients. These individuals are salvaged only by performance of liver transplantation. An exception to this rule is the patients with severe alcoholic hepatitis, who spontaneously recover both liver and kidney function. In type II hepatorenal syndrome, patients may have stable or slowly progressive renal insufficiency. Many such patients develop ascites resistant to management with diuretics.

According to the 2015 International Ascites Club criteria, hepatorenal syndrome is diagnosed in patients with cirrhosis, ascites and acute kidney injury, no response after two days of diuretic withdrawal and volume expansion, no recent use of nephrotoxic medications, no shock, and no macroscopic signs of structural kidney injury (proteinuria, hematuria, abnormal renal ultrasound). Acute kidney injury here is defined as an increase by  $\geq 0.3$  mg/dL in  $< 48$  hours or a 50% increase in serum creatinine from a baseline within  $\leq 3$  months.

Nephrotoxic medications, including aminoglycoside antibiotics, should be avoided in patients with cirrhosis. Patients with early hepatorenal syndrome may be salvaged by aggressive expansion of intravascular volume with albumin and fresh frozen plasma and by avoidance of diuretics. Several treatment regimens have been studied, including terlipressin and albumin; midodrine, octreotide, and albumin; and norepinephrine and albumin, with mixed success.

## Hepatic Encephalopathy

Hepatic encephalopathy is a syndrome observed in some patients with cirrhosis that is marked by personality changes, intellectual impairment, and a depressed level of consciousness. The diversion of portal blood into the systemic circulation appears to be a prerequisite for the syndrome. Indeed, hepatic encephalopathy may develop in patients who do not have cirrhosis and who undergo portocaval shunt surgery.

### Clinical Features of Hepatic Encephalopathy

The symptoms of hepatic encephalopathy may range from mild to severe and may be observed in as many as 50% to 80% of patients with cirrhosis. Symptoms are graded on the following scale:

- Grade 0: subclinical; normal mental status, but minimal changes in memory, concentration, intellectual function, coordination
- Grade 1: mild confusion, euphoria or depression, decreased attention, slowing of ability to perform mental tasks, irritability, disorder of sleep pattern (i.e., inverted sleep cycle)
- Grade 2: drowsiness, lethargy, gross deficits in ability to perform mental tasks, obvious personality changes, inappropriate behavior, intermittent disorientation (usually to time)
- Grade 3: somnolent but arousable, unable to perform mental tasks, disorientation to time and place, marked confusion, amnesia, occasional fits of rage, speech is present but incomprehensible
- Grade 4: coma, with or without response to painful stimuli

Patients with mild and moderate hepatic encephalopathy demonstrate decreased short-term memory and concentration on mental status testing. Findings on physical examination include asterixis and fetor hepaticus.

### Laboratory Abnormalities in Hepatic Encephalopathy

An elevated arterial or free venous serum ammonia level is the classic laboratory abnormality reported in patients with hepatic encephalopathy. Elevated blood ammonia alone does not add diagnostic or prognostic value; however, a normal value should prompt diagnostic reevaluation. Serial ammonia measurements are inferior to clinical assessment in gauging improvement or deterioration in patients under therapy for hepatic encephalopathy. No utility exists for checking the ammonia level in a patient with cirrhosis who does not have evidence of encephalopathy.

Some patients with hepatic encephalopathy have the classic but nonspecific electroencephalogram (EEG) changes of high-amplitude low-frequency waves and triphasic waves. EEG may be helpful in the initial workup of a patient with cirrhosis and altered mental status when ruling out seizure activity may be necessary.

CT scan and MRI studies of the brain may be important in ruling out intracranial lesions when the diagnosis of hepatic encephalopathy is in question.

### Common Precipitants of Hepatic Encephalopathy

Some patients with a history of hepatic encephalopathy may have normal mental status when under medical therapy. Others have chronic memory impairment in spite of medical management. Both groups of patients are subject to episodes of worsened encephalopathy. Common precipitants of worsening mental status are diuretic therapy, renal failure, GI bleeding, infection, electrolyte disorder, and constipation. Medications, notably opiates, benzodiazepines, antidepressants, and antipsychotic agents, also may worsen encephalopathy symptoms.

Nonhepatic causes of altered mental function must be excluded in patients with cirrhosis who have worsening mental function. Precipitants of hepatic encephalopathy should be corrected (e.g., metabolic disturbances, GI bleeding, infection, and constipation).

### Treatment of Hepatic Encephalopathy

Lactulose is helpful in patients with the acute onset of severe encephalopathy symptoms and in patients with milder, chronic symptoms. This nonabsorbable disaccharide stimulates the passage of ammonia from tissues into the gut lumen and inhibits intestinal ammonia production. Initial lactulose dosing is 30 mL orally once or twice daily. Dosing is increased until the patient has 2 to 4 loose stools per day. Dosing should be reduced if the patient complains of diarrhea, abdominal cramping, or bloating. Higher doses of lactulose may be administered via either a nasogastric tube or rectal tube to hospitalized patients with severe encephalopathy. Other cathartics, including colonic lavage solutions,

that contain polyethylene glycol (PEG; e.g., Go-Lytely) also may be effective in patients with severe encephalopathy.

Rifaximin is a nonabsorbable antibiotic that received approval by the US Food and Drug Administration in 2010 for the treatment of chronic hepatic encephalopathy and to reduce the risk of overt hepatic encephalopathy in patients with advanced liver disease. The dosing is 550 mg twice daily and can be added on to lactulose therapy to prevent hepatic encephalopathy recurrence. Rifaximin can decrease colonic levels of ammoniagenic bacteria with resulting improvement in hepatic encephalopathy symptoms.

Neomycin and other antibiotics (e.g., metronidazole) also serve as second-line agents. They work by decreasing the colonic concentration of ammoniagenic bacteria. Neomycin dosing is 250 to 1000 mg orally 2 to 4 times daily. Treatment with neomycin may be complicated by ototoxicity and nephrotoxicity.

Other chemicals capable of decreasing blood ammonia levels are L-ornithine-L-aspartate (available in Europe) and sodium benzoate.

Low-protein diets were historically recommended for patients with cirrhosis. High levels of aromatic amino acids contained in animal proteins were believed to lead to increased blood levels of the false neurotransmitters tyramine and octopamine, with resulting worsening of encephalopathy symptoms. However, 75% of patients with hepatic encephalopathy suffer from moderate-to-severe protein-calorie malnutrition with associated loss of muscle mass. Sarcopenia is a negative prognostic indicator in patients with cirrhosis. There is now consensus that low-protein nutrition should be avoided for patients with hepatic encephalopathy. Amino acids from animal protein may promote the maintenance of lean body mass more than they affect encephalopathy.

## Pulmonary Abnormalities in Cirrhosis

### Hepatopulmonary Syndrome

In hepatopulmonary syndrome (HPS), pulmonary arteriovenous anastomoses result in arteriovenous shunting. HPS is characterized by the symptom of platypnea (dyspnea that is relieved when lying down and worsens when sitting or standing up). HPS is a potentially progressive and life-threatening complication of cirrhosis that can be detected most readily by echocardiographic visualization of late-appearing bubbles in the left atrium following the injection of agitated saline. Patients can receive a diagnosis of HPS when their A-a gradient is  $\geq 20$  mm Hg and  $P_{aO_2}$  is  $< 70$  mm Hg. Some cases of HPS may be corrected by liver transplantation. Otherwise, supplemental oxygen is recommended to treat hypoxemia, but no medications have shown a significant and sustained improvement in outcomes.

### Portopulmonary Hypertension

The etiology of portopulmonary hypertension (PPHTN) is unknown. It is defined as the presence of a mean pulmonary artery pressure  $> 25$  mm Hg in the setting of a normal pulmonary capillary wedge pressure. Patients who develop

severe PPHTN may require aggressive medical therapy in an effort to stabilize pulmonary artery pressures and to decrease their chance of perioperative mortality in the setting of liver transplantation.

### Hepatic Hydrothorax

This condition results in the formation of pleural effusions in patients with cirrhosis. In most patients, there is concurrent ascites. In all patients with cirrhosis, the presence of pleural effusions should induce a concern that liver disease is the major culprit. Effusions are often right sided (85%–90%) but can also be left sided or bilateral. Therapy is geared toward the liver disease and management of ascites. Chest tubes are contraindicated.

## Hepatocellular Cancer

Hepatocellular carcinoma (HCC) occurs in 10% to 25% of patients with cirrhosis in the United States and is most often associated with hemochromatosis, alpha-1-antitrypsin deficiency, hepatitis B, hepatitis C, and alcoholic cirrhosis. HCC is observed less commonly in primary biliary cirrhosis and is a rare complication of Wilson disease. Regardless, current guidelines suggest that all patients with cirrhosis irrespective of cause should be screened for HCC. Recommended screening is ultrasonography every 6 months. Cholangiocarcinoma occurs in approximately 10% to 15% of patients with primary sclerosing cholangitis, some of whom may have cirrhosis as a result.

## Prognosis of Cirrhosis

Gauging prognosis in cirrhosis is important. Two scoring systems have been used (Table 75.5). These are the Child-Turcotte-Pugh (CTP) system and the Model for End-Stage Liver Disease (MELD) scoring system. Epidemiologic work shows that the CTP score may predict life expectancy in patients with advanced cirrhosis. A CTP score of  $\geq 10$  is associated with a 45% chance of death within 1 year. The MELD scoring system has been used by liver transplant programs in the United States to assess the relative severities of patients' liver diseases. The 3-month mortality statistics are associated with the following MELD scores: MELD score of  $< 9$ , 2.9% mortality; MELD score of 10 to 19, 7.7% mortality; MELD score of 20 to 29, 23.5% mortality; MELD score of 30 to 39, 60% mortality; and MELD score of  $> 40$ , 81% mortality. The addition of serum sodium concentration to the MELD may improve the predictive accuracy.

## Treatment of Cirrhosis

The management of cirrhosis consists of specific treatment for the underlying cause of cirrhosis and usually later for the inevitable complications of cirrhosis. Treatment of specific causes can be quite varied: for example, prednisone and azathioprine for autoimmune hepatitis, antiviral agents for hepatitis B and C, phlebotomy for hemochromatosis,

**TABLE 75.5** Child-Turcotte-Pugh Scoring System for Cirrhosis

Clinical Variable	1 Point	2 Points	3 Points
Encephalopathy	None	Stages 1–2	Stages 3–4
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	<2	2–3	>3
Bilirubin in PBC or PSC (mg/dL)	<4	4–10	10
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time: seconds prolonged or INR	<4 s or INR <1.7	4–6 s or INR 1.7–2.3	>6 s or INR >2.3

INR, International normalized ratio; PBC, primary biliary cholangitis; PSC, primary sclerosing cholangitis.

Child class A, 5–6 points; child class B, 7–9 points; child class C, 10–15 points.

From Child CG, Turcotte JG. Surgery and portal hypertension. In: Child CG, ed. *The Liver and Portal Hypertension*. Philadelphia: Saunders; 1964:50–64.

ursodeoxycholic acid for primary biliary cirrhosis, and penicillamine, trientine, and zinc for Wilson disease. Once cirrhosis develops, treatment is aimed at the management of complications such as ascites, hepatic encephalopathy, and variceal bleeding. Managing nutrition and pruritus are also important. Many patients complain of anorexia, which may be exacerbated by the mechanical effects of ascites on the GI tract. Patients frequently benefit from the addition of commonly available liquid and powdered nutritional supplements to the diet to ensure adequate calories and protein in their diets. Zinc deficiency is commonly observed in patients with cirrhosis. Zinc may be effective in the treatment of muscle cramps and is adjunctive therapy for hepatic encephalopathy. Pruritus is a common complaint in

both cholestatic liver diseases (e.g., primary biliary cirrhosis) and noncholestatic chronic liver diseases (e.g., hepatitis C). Mild itching may respond to treatment with antihistamines. Cholestyramine is the mainstay of therapy for the pruritus of liver disease. Other medications that may provide relief against pruritus include ursodeoxycholic acid, ammonium lactate 12% skin cream, naltrexone (an opioid antagonist), rifampin, gabapentin, and ondansetron. Patients with severe pruritus may require institution of ultraviolet light therapy or plasmapheresis, although data to support these treatments are limited. Patients with chronic liver disease should also receive vaccination to protect them against hepatitis A. Other protective measures include vaccination against hepatitis B, pneumococci, and influenza.

## Chapter Review

### Questions

- A 47-year-old woman is diagnosed with chronic hepatitis C, genotype 1. A liver biopsy shows grade 2/4 inflammation and stage 1/4 fibrosis. Which of the following is false regarding her management?

  - She can be treated with PEGylated interferon, ribavirin, and boceprevir.
  - Obtain an ultrasound and alpha-fetoprotein to screen for hepatocellular cancer.
  - There is no need to screen for esophageal varices given the low fibrotic content.
  - She should be vaccinated against hepatitis A and B if she is not immunoprotected.
- A 42-year-old man presents with new-onset ascites. Evaluation of the aspirate shows the following: albumin of 3.6 g/dL; total protein of 7.0 g/dL; and cell count, 500 white blood cell (WBC) count with 95% lymphocytes. A serum albumin on the same day is 4.0 g/dL. Cultures of the ascitic fluid for bacteria and acid-fast bacilli are negative. What is the best management option?

  - Treat with a third-generation cephalosporin for SBP.
  - Institute low-salt diet and diuretics for cirrhotic ascites.
  - Obtain a Doppler ultrasound to rule out Budd-Chiari syndrome.
  - Perform a peritoneal biopsy.
- A 46-year-old Caucasian male is seen because of mildly elevated aminotransferases. Alanine aminotransferase (ALT) is 67 U/L (normal 9–50 U/L), and aspartate aminotransferase (AST) is 49 U/L (normal 7–45 U/L). Examination is remarkable for an enlarged liver, but otherwise there is no evidence of advanced liver disease. A subsequent evaluation shows the following: hepatitis B surface antigen, nonreactive; hepatitis C virus antibody, nonreactive; antinuclear antibody (ANA), negative; anti-smooth muscle antibody (ASMA), negative; thyroid-stimulating hormone, normal; iron 250 µg/dL; total iron-binding capacity 300 µg/dL; and ferritin 1200 ng/mL. Complete blood count shows WBC of 5600/µL, hematocrit (HCT) of 46%, and platelet count of 190,000/µL. A genetic test for hemochromatosis returns negative. What would you do next?

  - Obtain an MRI to quantify hepatic iron.
  - Perform a liver biopsy.
  - Tell him he has hemochromatosis, and begin phlebotomy.
  - Repeat the genetic test.

4. Which of the following is true about SBP?
- Ampicillin and gentamicin combination is first-line therapy for SBP.
  - The combination of antibiotic and albumin is superior to antibiotic alone for ascitic fluid sterilization.
  - Cultures in SBP usually grow multiple gram-negative and gram-positive organisms.
  - The risk of renal impairment can be reduced by treatment with antibiotics and albumin infusion.
5. A 54-year-old woman is seen because of fatigue and pruritus. She denies any prior medical issues and is taking no medications. Examination shows an enlarged liver. Laboratory data show the following: normal electrolytes, ALT 45 U/L (normal 9–50 U/L), AST 27 U/L (normal 7–45 U/L), alkaline phosphatase 860 mg/dL (normal 36–118 mg/dL),

albumin is 3.4 mg/dL, total protein is 5.0 g/dL, and cholesterol is 330 mg/dL. WBC is 4600/ $\mu$ L, HCT 38.0%, and platelet count 120,000/ $\mu$ L.

Which of the following serologic tests is most likely to be diagnostic?

- ASMA
- ANA
- Alpha-1-antitrypsin levels
- Antimitochondrial antibodies

## Hepatitis B and C

DARRICK K. LI AND RAYMOND T. CHUNG

The hepatotropic viruses comprise a diverse group of pathogens that together represent a leading cause of morbidity and mortality worldwide. These most prominently include the hepatitis viruses (hepatitis A–E), a significant and growing cause of acute and chronic liver disease in developing and developed nations, as well as other viruses that more infrequently cause liver disease including cytomegalovirus, Epstein-Barr virus, HIV, and the herpes simplex viruses. In 2013 an estimated 1.5 million individuals around the world died of viral hepatitis and its complications, making it the seventh leading cause of death internationally. As such, the treatment and prevention of these diseases are an extremely important area of interest and study worldwide. This chapter will discuss the diagnosis and management of the two most important causes of viral hepatitis, hepatitis B and hepatitis C.

### Hepatitis B

Hepatitis B virus (HBV) is one of the most successful viruses on the planet and is estimated to infect over 500 million people worldwide directly leading to approximately 600,000 deaths yearly. The prevalence of HBV varies significantly across the globe ranging from areas of low prevalence (<2%), including Western Europe, the United States, Canada, Brazil, areas of low-intermediate prevalence (2%–4%), including Australia, Eastern Europe, Northern Africa, and the Middle East, areas of high-intermediate prevalence (5%–7%), including the Eastern and Southern African continent, central Asia, and China, to areas of high prevalence (>8%), which includes mainly sub-Saharan Africa (Fig. 76.1). In the United States, the number of individuals with chronic HBV infection is currently estimated to be between 800,000 to 2.2 million and is gradually increasing, primarily because of migration of individuals from global regions with intermediate-to-high prevalence of HBV.

HBV is a blood-borne pathogen that can be found at very high titers in the blood, particularly in the acute phases of infection. As such, contact with infected blood presents significant risk for transmission of infection. HBV also exists in other secretions including saliva, tears, semen, and cervical secretions but does not exist in the urine or stool. The mode of transmission varies globally with prevalence rates.

In high prevalence areas, the most common route of transmission is perinatal infection via vertical transmission. In contrast, in low prevalence areas, the most common routes of transmission include unprotected sexual intercourse and intravenous drug use.

### Virology

HBV is a member of the Hepadnavirus family and is a small DNA virus with a partially double-stranded 3.2 kb genome. At least 10 genotypes (A–J) have currently been identified based on polymorphisms in the HBV genome. The HBV genome encodes for several proteins, which include: (1) a surface antigen (HBsAg) expressed on the exterior of all viral particles; (2) a nucleocapsid or core antigen (HBcAg); (3) an early antigen (HBeAg), a protein of unknown function highly associated with active replication and high infectivity; (4) a viral polymerase gene; and (5) the *HBx* gene, a regulatory protein that is required for the HBV life cycle but whose precise role has yet to be identified.

The life cycle of HBV has been well described in the literature and will be briefly summarized here. The HBV virion initially attaches to the hepatocyte via the sodium (Na) taurocholate cotransporting polypeptide receptor and is brought into the cell. There, repair of the partially double-stranded DNA genome is performed by as of yet unidentified enzymes. The DNA is then transported to the nucleus where it assumes a highly stable covalently closed circular form (cccDNA). cccDNA is used as a template for transcription by host RNA polymerase II, which results in a pregenome that is then translated to produce core, surface, and polymerase protein, the latter of which has reverse transcriptase function. As the capsid is formed, the pregenome is transcribed to form the (–) strand DNA, followed by the creation of the (+) strand DNA. However, before completion of a fully double-stranded DNA genome, the partially double-stranded genomic material is packaged with capsid and surface antigens to form mature virions. These are then released by the cell via exocytosis to continue the cycle of infection.

### Natural History and Clinical Manifestations

#### Acute Hepatitis B Virus Infection

After initial host infection by HBV, there is typically a 1 to 4 months' incubation period before the development

• **Fig. 76.1** Global prevalence of hepatitis B infection. (From Centers for Disease Control and Prevention. *Infectious diseases related to travel: hepatitis B* [website]. <http://wwwnc.cdc.gov/travel/yellowbook/2016/infectious-diseases-related-to-travel/hepatitis-b>. Accessed July 17, 2016.)

of symptoms. Interestingly, in acute HBV infection, the majority of patients (70%) will have a subclinical asymptomatic course while the remaining 30% have symptomatic infection typified by a nonspecific syndrome characterized by flu-like illness, malaise, fatigue, nausea, vomiting, anorexia, and right upper quadrant tenderness. Jaundice and hepatomegaly are also frequent features of symptomatic infection. During acute infection, serum levels of alanine and aspartate aminotransferases (ALT and AST, respectively) are typically significantly elevated with values commonly up to 1000 to 2000 IU/L with ALT generally being greater than AST. Serum bilirubin will also be elevated in those with icteric hepatitis. In severe infection, the prothrombin time (PT) may also be significantly elevated. In patients who clear their infection, symptoms disappear after 1 to 3 months and laboratory abnormalities typically resolve within 1 to 4 months.

In a small fraction of patients (0.1%–0.5%), fulminant HBV infection occurs, which presents with rapidly progressive symptoms accompanied by encephalopathy, coagulopathy, and other symptoms of acute liver failure. Fulminant HBV infection is thought to be secondary to an exuberant immune response to the offending virus, although risk factors for development of this life-threatening presentation remain unclear.

### Chronic Hepatitis B Virus Infection

Of those who are acutely infected with HBV, only 5% develop chronic infection with the risk of developing chronic HBV being inversely proportional to age. Those patients who develop chronic infection are at higher risk for development of cirrhosis and hepatocellular carcinoma (HCC) and warrant close monitoring.

Chronic HBV infection has been classically organized into four phases of infection of variable duration (Fig. 76.2). However, not all infected patients will experience each phase, reflecting the dynamic interaction between the viral life cycle and the host immune response.

The first phase is called the *immune-tolerant* phase, which is characterized by high viral replication (HBV DNA levels often in excess of  $10^6$  IU/mL) and minimal hepatic inflammation (normal ALT). This phase is almost exclusively seen in patients with perinatally acquired HBV infection. This phase is of variable duration and can last as long as 30 years. With increasing age, there grows a higher propensity for the host to lose immune tolerance and transition to an immune active stage.

The second phase is called the *HBeAg-positive immune-active* phase. In patients with perinatally transmitted HBV, this generally occurs by the third or fourth decade of life. In this phase, the rate of spontaneous HBeAg clearance increases to  $\sim 10\%$  per year and is frequently accompanied by decrease in HBV DNA levels and elevated levels of hepatic inflammation (increases in ALT). This is thought to be secondary to an increase in the amount of immune-mediated destruction of infected hepatocytes. In general, the higher the serum ALT, the more likely seroconversion will occur. The molecular triggers that signal for the transition from immune-tolerant to the immune-active phase remain obscure. This phase is associated with increased risk of development of cirrhosis and hepatocellular carcinoma and as such is one of the clinical scenarios in which antiviral therapy is recommended (see Treatment).

The third phase is the inactive carrier state and is heralded by the seroconversion of HBeAg. This phase is

• **Fig. 76.2** Natural history of chronic hepatitis B (*HBV*) infection. Not all patients chronically infected with *HBV* will experience all four stages of infection (i.e., only 10%–30% of patients who are inactive carriers will progress to HBeAg-chronic hepatitis). *ALT*, Alanine aminotransferase; *Anti-HBe*, hepatitis B early antibody; *Anti-HBs*, hepatitis B surface antibody; *HBeAg*, hepatitis B early antigen; *HBsAg*, Hepatitis B surface antigen.

marked by low or undetectable levels of *HBV* DNA, normal *ALT*, and the appearance of anti-HBe. Typically, there is little to no hepatic necroinflammation, although biopsy may reveal variable amounts of fibrosis, which likely reflect the sequelae of prior liver injury from the immune-active phase of chronic infection. Unfortunately, even after seroconversion of HBeAg, the patient may have a fluctuating course that is characterized by reactivation of *HBV* replication and subsequent episodes of immune-active hepatitis. This can occur with or without HBeAg reversion. In the latter case, this likely occurs through selection of precore or core promoter mutations that allow for viral replication in the absence of HBeAg production. So-called HBeAg-negative chronic hepatitis is characterized by evidence of hepatic inflammation and moderately elevated *HBV* DNA levels. Importantly, patients with HBeAg-negative chronic hepatitis are at even higher risk of progression to cirrhosis and development of HCC than those in the immunoinactive stage.

The fourth phase is resolution of the infection, which is marked by seroconversion of HBsAg. This typically occurs at a rate of ~0.5% per year. Clearance of HBsAg reduces the risk of progression to cirrhosis and further hepatic decompensation events.

### Extrahepatic Manifestations

Extrahepatic manifestations associated with *HBV* infection are thought to result from the deposition of circulating immune complexes produced in response to viral

infection. These include a constellation of serum sickness-like illness (fever, rash, polyarthritis) that typically occurs before the onset and subsiding with the appearance of jaundice. Nephrotic syndrome caused by membranous or membranoproliferative glomerulonephritis is another such manifestation but typically occurs in children with active viral replication. The medium-vessel vasculitis polyarteritis nodosa is also associated with *HBV* infection and usually manifests within the first 6 months of infection with fever, rash, abdominal pain, renal disease, eosinophilia, and polyarthritis.

### Hepatitis D

The hepatitis D virus (HDV) was identified in the 1970s as a nuclear antigen that was distinct from HBsAg, HBeAg, and HBeAg in the hepatocytes of some HBsAg carriers. It was quickly identified to be a passenger virus that requires concurrent *HBV* infection for replication and transmission. It is a small RNA virus that has more in common with plant viruses including viroids than with other animal viruses. Clinically, HDV coinfection presents with a severe hepatitis with liver injury. Moreover, coinfection with HDV carries with it a higher risk for fulminant hepatic failure. Biochemically, initial coinfection can present with a biphasic pattern to *ALT* elevation, with the first peak being from *HBV* replication and the second from HDV infection. The establishment of chronic HDV infection results in an accelerated presentation of cirrhosis and hepatic decompensation, including the development of HCC. Interestingly, if

chronic HDV infection is established, HBV DNA levels are typically low as HDV suppresses HBV replication. The diagnosis of HDV is made with detection of anti-HD IgG and/or IgM antibodies. HDV polymerase chain reaction (PCR) can also be performed to establish the presence of chronic infection.

## Diagnosis

Different forms of HBV infection are associated with characteristic patterns of serology studies. A number of laboratory tests are routinely used to assist in the diagnosis of HBV infection (Table 76.1) and help to define different infective states.

HBsAg is the hallmark of HBV infection (acute or chronic) and is the first serologic marker to appear after an acute infection. Serum detection of HBsAg occurs 1 to 10 weeks after acute exposure and may be detectable even before the development of symptoms. In patients who ultimately clear the infection, HBsAg disappears within 4 to 6 months and is followed by the appearance of the hepatitis B surface antibody (anti-HBs), which confers long-term immunity. However, during seroconversion, there is frequently a window period of several weeks to months during which HBsAg is undetectable and anti-HBs is also undetectable (see later). To detect infection during the window period, hepatitis B core antibody (anti-HBc) IgM is often the only evidence of infection. However, in a minority of patients acutely infected with HBV, HBsAg persists without seroconversion.

If HBsAg positivity persists for >6 months, the patient is then considered to have chronic HBV infection. Coexistence of HBsAg and anti-HBs has also been reported and typically indicates ineffective neutralizing antibody (Ab) activity and, as such, patients with this serologic signature should still be considered a chronic carrier of HBV. Patients who have acquired immunity via vaccination are positive for anti-HBs but are negative for HBsAg and anti-HBc.

Anti-HBc is detectable in the serum during acute infection and chronic infection, as well as cleared infection. In contrast, HBcAg is an intracellular antigen that is expressed within infected hepatocytes and is not detectable in the serum. During acute infection, anti-HBc is predominantly produced as IgM antibodies and becomes detectable 9 to 21 weeks after an acute infection. IgM anti-HBc is typically indicative of acute infection but can remain detectable up to 2 years after infection and may also increase in titer during reactivation flares in chronic infection. IgG anti-HBc becomes predominant in chronic infection and does not confer any protection against viral activity.

HBeAg is a secretory protein that results from posttranslational processing of the precore protein and is considered a marker of HBV infectivity and replication. As such, the presence of HBeAg is associated with higher levels of HBV DNA as well as elevated levels of ALT signifying liver inflammation, although this is not the case in patients with vertically transmitted HBV that are HBeAg+. Seroconversion of HBeAg to anti-HBe occurs early in patients with acute infection, often before HBeAg seroconversion and is usually

**TABLE 76.1 Serologic Interpretation of Hepatitis B Virus Infection States**

HBsAg	Anti-HBs	HBeAg	Anti-HBe	Anti-HBc (IgM)	Anti-HBc (IgG)	HBV DNA	ALT	Interpretation

associated with a decrease in HBV DNA levels and remission of active liver disease. A subset of patients will continue to have active liver disease despite seroconversion of HBeAg or absence of HBeAg. These patients are most likely infected with HBV with mutations or premature stop codons in the promotor region of the precore coding sequence, which decreases or completely abolishes production of HBeAg.

Assessment of HBV DNA levels with high-sensitivity PCR-based assays is frequently performed, most commonly in patients with chronic infection. Evaluation of HBV DNA levels helps the clinician in deciding whether to start antiviral therapy, to assess response to therapy, and to monitor for virologic breakthrough. HBV DNA is also useful in several other circumstances including in the window period to distinguish between acute and chronic hepatitis as well as in fulminant hepatitis where HBV DNA may become detectable before HBsAg.

Most patients do not require routine screening for hepatitis B infection. However, screening is suggested in a number of patient populations, in particular those that are born in

#### • BOX 76.1 Populations for Hepatitis B Virus Screening

Patients born in a country with high or intermediate prevalence of chronic hepatitis B infection

Family, sexual, or household contact with someone with hepatitis B infection

Adults at high risk of infection (i.e., intravenous drug use, multiple sexual partners, MSM, sex workers, incarceration)

Diagnosis of another infection with similar mode of acquisition (i.e., HCV, HIV)

Patients with abnormal liver function tests and/or evidence of acute or chronic liver disease

Patients with hepatocellular carcinoma

Patients undergoing chemotherapy or immunosuppressive therapy

Patients undergoing hemodialysis

Pregnant women (as part of routine antenatal care)

HCV, Hepatitis C virus; MSM, men who have sex with men.

areas with high rates of endemic infection (i.e., Asia, Africa, Central America, Eastern Europe) and those that are at high risk because of behaviors (i.e., intravenous drug users, sex workers, etc.). These and other populations who should be routinely screened for HBV are listed in [Box 76.1](#).

### Management

Currently, there are six approved antiviral therapies for the treatment of chronic hepatitis B infection in adults ([Table 76.2](#)). These antivirals can be grouped into two categories, interferon (IFN) and the nucleos(t)ide analogues (NAs).

#### Acute Hepatitis B

The treatment of acute HBV infection is largely supportive because 95% of patients infected with HBV will spontaneously seroconvert. However, there are several instances in which treatment should be considered. These include fulminant hepatitis B infection (in which case liver transplantation may be necessary), severe infection with associated coagulopathy and jaundice for >4 weeks, infection of immunocompromised patients, elderly patients, and those with preexisting liver disease. If treatment is initiated, the recommended antiviral is tenofovir or entecavir and should be continued for at least 3 months after HBsAg seroconversion. IFN should not be given because of the risks of worsening hepatic necroinflammation.

#### Chronic Hepatitis B

The goal of antiviral therapy in the treatment of chronic HBV infection is to prevent morbidity and mortality caused by liver-related complications. A number of factors have shown to be associated with high risk of liver-related complications and have thus guided identification of populations that most warrant the initiation of antiviral therapy. Strong risk factors for complications include elevated serum ALT and HBV DNA. Other important risk factors include older age, male sex, a family history of HCC, alcohol use,

**TABLE 76.2** Approved Antiviral Therapies for Hepatitis B Virus Infection

Antiviral	Dose	Viral Resistance	Side Effects
PEG-IFN-2a	180 µg weekly	None	Flu-like symptoms, fatigue, mood disturbances, cytopenias, autoimmune disorders
Lamivudine	100 mg daily	High (15%–30% per year)	Pancreatitis, lactic acidosis
Tenofovir disoproxil fumarate (TDF)	300 mg daily	Minimal (none identified)	Nephropathy, Fanconi syndrome, osteomalacia, lactic acidosis
Tenofovir alafenamide (TAF)	25 mg daily	Minimal (none identified)	Similar to TDF but lower frequency
Entecavir	0.5 or 1.0 mg daily	Minimal (0.2% per year)	Lactic acidosis
Adefovir	10 mg daily	Low (3%–5% per year)	Acute renal failure, Fanconi syndrome, nephrogenic diabetes insipidus, lactic acidosis
Telbivudine	600 mg daily	Low (6% per year)	Myopathy, peripheral neuropathy

PEG-IFN, Pegylated interferon.

HIV infection, diabetes, HBV genotype C, and HBV pre-core and core promoter variants. As such, current recommendations for initiation of antiviral treatment are the following:

1. Treat all patients with immune-active chronic HBV with detectable HBV DNA and evidence of liver injury (i.e., elevation of ALT  $>2\times$  upper limit of normal (ULN) or significant histologic disease on biopsy).
  - a. For HBeAg+ individuals, treat if HBV DNA  $>20,000$  IU/mL.
  - b. For HBeAg- individuals, treat if HBV DNA  $>2000$  IU/mL.
2. Treat all patients with immune-active chronic HBV with cirrhosis if HBV DNA  $>2000$  IU/mL regardless of ALT level.
3. Treat all patients with immune-active chronic HBV with extrahepatic manifestations (independent of liver disease).
4. Treat patients in the immune-tolerant phase if age  $>40$  years and HBV DNA  $\geq 1,000,000$  IU/mL and liver biopsy showing significant necroinflammation or fibrosis.
5. Treat all patients with compensated cirrhosis and low levels of viremia ( $<2000$  IU/mL) regardless of ALT level.
6. Treat all HBsAg+ pregnant women with HBV DNA level  $>200,000$  IU/mL to reduce the risk of vertical transmission.

In terms of selecting an antiviral agent, the most recent guidelines recommend either pegylated IFN (PEG-IFN) or the NAs tenofovir and entecavir as first-line treatment for treatment-naïve patients. The precise choice of antiviral agent should be individualized, considering comorbidities, predicted length of treatment, history of resistance, and financial costs. Head-to-head trials have not definitively shown superiority of one antiviral agent over another with regards to reducing the risk of liver-related complication.

### Interferon

The use of IFN has been a standard in the treatment of HBV for nearly 30 years. This recombinant protein has antiviral, antifibrotic, antiproliferative, and immunomodulatory effects although the precise mechanism of action by which it treats HBV infection is unknown. The suggested treatment course of PEG-IFN (given as a weekly injection of 180  $\mu\text{g}$ ) is 48 weeks, and this yields HBeAg seroconversion rates of  $\sim 20\%$  to  $30\%$  per year and sustained HBV DNA suppression ( $<2000$  IU/mL) in  $\sim 65\%$  who achieve HBeAg seroconversion. Factors associated with a favorable response to IFN therapy include low HBV DNA, ALT elevation  $>2\times$  ULN, female sex, and HBV genotype A or B.

IFN therapy is typically limited by its many side effects, including flu-like illness, myalgias, headache, fatigue, cytopenias, and depression. IFN is contraindicated in patients with autoimmune disease, severe cardiac disease, baseline cytopenias, uncontrolled psychiatric disease, and decompensated cirrhosis.

### Nucleos(t)ide Analogues

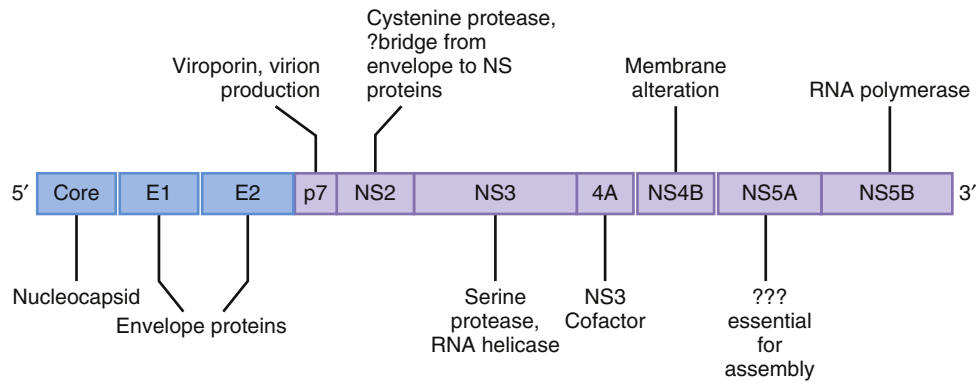

Similar to HIV, HBV replication involves reverse transcriptase activity. As such, NAs were investigated for HBV treatment and found to be effective at suppressing viral replication. These agents have the advantages of being oral medications and being relatively well tolerated with few adverse side effects. However, once therapy with NAs is discontinued, viremia returns in the majority of HBeAg-positive patients who do not achieve seroconversion and in nearly all HBeAg-negative patients. Therefore the duration of NA-based therapy is variable and influenced by a number of factors including HBeAg status, duration of HBV suppression, and presence of cirrhosis and/or hepatic decompensation.

Entecavir is a first-line medication for chronic hepatitis B infection in treatment-naïve patients and has an extremely low rate of resistance in this population ( $\sim 1\%$  in 5 years of treatment). Side effects are rare and mild and generally include headache, abdominal pain, and diarrhea. Notably, the development of resistance rises considerably if the patient has previously been treated with lamivudine and has developed resistance.

Tenofovir is the most recent NA to have been approved for the treatment of chronic hepatitis B infection and is a first-line agent in treatment-naïve patients as well as patients who have exposure to other NAs. Peripartum administration of tenofovir has also been reported in a 2016 paper by Pan et al. in the *New England Journal of Medicine* to reduce the rate of mother-to-child transmission among mothers with a high viral load of hepatitis B. It also has an extremely low rate of drug resistance, and, to date, no resistance mutations have been identified. Tenofovir is renally cleared. As such, a notable side effect is renal insufficiency, caused by buildup of the drug in the proximal tubule cells, an effect that is potentiated by drugs that interact with the transporters that help to shuttle the drug into tubular lumen. This is more common in the older form of tenofovir known as tenofovir disoproxil fumarate (TDF). The FDA approved tenofovir alafenamide fumarate (TAF) in 2016 for the treatment of chronic hepatitis B. TAF has demonstrated an improved side effect profile, with lower incidence of renal toxicity and worsened bone density compared with TDF.

The other NAs now have limited use, especially given the availability of oral agents with extremely low rates of viral resistance as described earlier. Lamivudine was previously commonly used for HBV treatment but has fallen out of favor because of its high rate of drug resistance. It may still have a role in individuals who are coinfecting with HBV and HIV. Adefovir was previously used for its activity against lamivudine-resistant HBV strains as well as for its relatively lower rate of drug resistance compared with lamivudine but has essentially been supplanted with the introduction of the more potent tenofovir. Telbivudine also has an unacceptable rate of virologic resistance over time.

Several special populations also deserve mention. For individuals coinfecting with HIV, treatment of HBV will need to be coordinated with HIV therapy and will require dual agent therapy with tenofovir and either lamivudine or emtricitabine, which have potent antiviral activity against both

• **Fig. 76.3** Genomic organization and proteins of the hepatitis C virus. E, Envelope; NS, nonstructural.

viruses and limit emergence of HIV resistance. For patients coinfecting with HDV, PEG-IFN is the only effective treatment. Finally, in pregnant women, tenofovir (category B) and lamivudine (category C) have been the most extensively studied agents and have been found to be extremely safe.

Besides treatment with antivirals, patients with chronic HBV infection should also be counseled regarding behaviors to limit other sources of liver injury including cessation of alcohol use and avoidance of exposures that predispose them to the contraction of other viruses that can hasten disease progression including hepatitis C and HIV (i.e., unprotected sex, intravenous drug use, etc.). Other management considerations include the need for hepatitis A vaccination as well as screening of all sexual and household contacts. Any contacts who are seronegative should be vaccinated. Finally, patients with chronic HBV infection are at high risk for developing HCC and should undergo regular screening with ultrasonography. Currently, guidelines recommend surveillance in Asian men age >40 years, Asian women age >50 years, patients with HBV and cirrhosis, Africans and African Americans, and patients with a family history of HCC.

## Hepatitis C

After the discovery of hepatitis A and hepatitis B, it became clear that a significant number of transfusion-related cases of hepatitis were the result of a third uncharacterized agent that was initially termed *non-A, non-B hepatitis*. The identity of this agent was not discovered until researchers in the late 1980s identified it as a small lipid-enveloped virus that was ultimately termed the *hepatitis C virus* (HCV).

HCV infects 185 million individuals globally (or nearly 3% of the world's population), leading to >700,000 deaths annually from cirrhosis or HCC worldwide. Moreover, estimates of US prevalence of HCV number roughly 3.5 million individuals. Given the proclivity of HCV to establish chronic infection, this makes HCV the leading cause of chronic liver disease currently in the United States.

HCV is primarily transmitted percutaneously through the blood with extremely low rates of sexual and maternal

transmission. HCV is also found in saliva, tears, semen, ascitic fluid, and cerebrospinal fluid, although transmission via contact with these fluids is case reportable. In developed countries, the majority of HCV infections are likely the result of the use of contaminated needles in association with illicit drug use. The overall incidence of HCV associated with illicit drug use in the United States may have decreased; however, incidence remains high in urban areas and outbreaks of HCV in various cities across the country in young individuals age 20 to 29 years have been reported. The incidence of transfusion-related HCV infection has plummeted with the onset of virus inactivation protocols that have become standard in transfusion centers and blood banks. Worldwide, the most common route of transmission is nosocomial in relation to poor medical sanitation practices.

## Virology

HCV is a member of the Flavivirus family (which also includes the yellow fever and Dengue viruses) and is an enveloped (+)-strand RNA virus. The genome is approximately 9.6 kb in length and encodes for a single large polyprotein, which is ultimately cleaved to form at least 10 proteins by cellular and viral proteases. These include three structural proteins comprising the nucleocapsid protein (C) and two envelope proteins (E1 and E2), as well as at least seven nonstructural proteins, which include two proteins required for virion production (p7 and NS2) as well as five proteins that form the cytoplasmic viral replication complex (NS3, NS4A, NS4B, NS5A, and NS5B) (Fig. 76.3).

Significant parts of the HCV life cycle remain unclear and are subjects of active study although the following model synthesizes much of what is known to date. HCV virions enter the hepatocyte via interaction with a number of coreceptors including CD81, claudin 1, occludin, and SR-B1 and are endocytosed into the cell. Following entry, the endosome becomes acidified that changes the conformation of the envelope proteins, releasing the viral (+)-strand RNA genome into the cytoplasm, which become associated with the endoplasmic reticulum (ER). The RNA then becomes the template for the production of viral proteins. The envelope proteins are secreted into the lumen of the ER

while the core protein remains cytoplasmic. The replication complex of NS3, NS4A, NS4B, NS5A, and NS5B then forms membranous webs derived from the ER membrane and directs transcription of a (–)-strand genome, which then becomes the template for further production of (+)-strand genomes, which are then packaged with the structural proteins to form mature virions, which are then released.

Given its central role in the viral life cycle, a number of the protein components of the viral replication complex have been a target for many of the effective antivirals that have recently been developed, in particular NS3, NS5A, and NS5B (see [Management](#)). The NS3 protein functions as the key viral protease and requires NS4A as a cofactor for its function. NS3 is responsible for a number of the polypeptide processing events including the cleavage of the NS3/NS4A, NS4A/NS4B, NS4B/NS5A, and NS5A/NS5B junctions. NS5A is a membrane-bound RNA-binding protein whose exact role remains unclear but seems to play multiple essential roles in the regulation of viral replication, assembly, and exit. NS5B is the viral RNA-dependent RNA polymerase and the catalytic core of the viral replication machinery.

Of note, the HCV NS5B polymerase has the property of being extremely error prone because it lacks proof-reading capability. This leads to the rapid accumulation of genetic diversity and has led to the rise of at least six separate HCV genotypes. These genotypes have important consequences for treatment because there are emerging differences in the response rate of various genotypes to various antiviral regimens (see [Management](#)). The genotypes also have geographic variability: genotype 1 is the most widespread and is predominantly seen in North America; genotype 2 is also widespread, found principally in Central and West Africa; genotype 3 is found primarily in Asia; genotype 4 is found in the Middle East and Northern Africa; genotypes 5 and 6 are rare and can be found in regions of Africa and Asia.

## Natural History

### Acute Hepatitis C

Symptomatic infection upon initial exposure is uncommon, although when it occurs it is usually characterized by a non-specific viral prodrome of nausea, malaise followed by right upper quadrant pain, and jaundice. These symptoms can persist for several weeks before resolving. Fulminant hepatitis C infection is extremely rare.

### Chronic Hepatitis C

Approximately 75% of patients will continue to have persistent viremia at 6 months whereas the remainder are able to clear the infection. Why some patients develop persistent viremia and chronic infection while others do not remains a topic of intense research. Polymorphisms within and around genes for human leukocyte antigen (*HLA*) genes, *λ-IFN*, and *interleukin (IL)-28B* have been recently discovered that suggest that these genetic loci

play central roles in the effectiveness of the immune response to HCV infection. Individuals who develop persistent viremia and chronic HCV infection are frequently asymptomatic but at substantially higher risk for developing hepatic fibrosis leading to cirrhosis. Once chronic infection has been established, HCV can persist in the host for decades. Of these patients, approximately 5% to 20% will develop cirrhosis over the next 20 years. Of these, 10% to 20% of HCV cirrhotics will present with some form of hepatic decompensation (i.e., ascites, esophageal varices, coagulopathy, hepatic encephalopathy, or HCC) within 5 years.

### Extrahepatic Manifestations of Hepatitis C Virus Infection

HCV infection is strongly associated with a number of extrahepatic complications that include hematologic and dermatologic manifestations. Up to 50% of patients with chronic HCV infection have detectable circulating cryoglobulins, and this can lead to clinical manifestations, specifically in the form of type II cryoglobulinemia. However, only a minority develop true cryoglobulinemic vasculitis, which typically presents with arthralgias, palpable purpura, and, in severe cases, ischemic skin lesions. A membranoproliferative glomerulonephritis can also be associated with HCV-infected patients with cryoglobulinemia and typically presents with a nephrotic syndrome-like picture. HCV-infected patients are also at higher risk of developing hematologic malignancies including B-cell non-Hodgkin lymphomas, diffuse large B-cell lymphoma, and primary hepatic lymphoma. Porphyria cutanea tarda, a dermatosis that is characterized by photosensitivity, hyperpigmentation, and a predisposition to forming vesicles and even bullae with minor trauma, is also strongly associated with chronic HCV infection.

## Diagnosis

The primary means by which a diagnosis of HCV infection is secured is the detection of antibodies to recombinant HCV proteins including NS3, NS4, and NS5 sequences (HCV Ab) as well as detection of serum HCV RNA by PCR-based assays. HCV Ab immunoassays have undergone several generations of refinement and currently exhibit a sensitivity and specificity of >98% for HCV infection. In 1998 given increasing awareness of risk factors for exposure to the virus, the Centers for Disease Control and Prevention began recommending screening individuals with various HCV risk factors, including intravenous drug use, those who received blood transfusions before 1992, and all persons born between 1945 and 1965. A full list of screening recommendations from the US Public Health Service Guidelines for HCV is found in [Box 76.2](#).

Detection of circulating HCV RNA is also important in the diagnosis of HCV infection because it may help the clinician differentiate between cleared and chronic

### • BOX 76.2 Individuals Who Should Be Screened for Hepatitis C Infection

Persons born from 1945 to 1965  
 Persons who have ever used intravenous drugs  
 Persons with elevated aminotransferases  
 Persons who received transfusions or organ transplants before July 1992  
 Persons with percutaneous or heavy mucosal exposure to HCV-positive blood  
 Children born to HCV-infected women  
 Persons at high risk for HCV not otherwise specified (i.e., hemodialysis, incarcerations, unregulated tattoos)

HCV, Hepatitis C virus.

infection as well as acute infection before the development of antibodies. After exposure to HCV, HCV RNA can be detected in serum within days of the initial exposure, which may occur 1 to 4 weeks before elevations in liver aminotransferases and 8 to 10 weeks before the development of Abs toward HCV. As such, in patients who present acutely with viral hepatitis, in addition to HCV Ab, HCV RNA should also be sent. Moreover, HCV RNA should be sent in cases of suspected infection in patients with underlying immunodeficiencies (i.e., HIV) that may blunt the production of HCV Ab. If positive for either HCV Ab or HCV RNA, initiation of antiviral therapy can be considered (see [Management](#)), and the patient should be monitored for the development of chronic infection and persistent viremia or clearance.

HCV genotype should also be sent in cases of confirmed infection to aid in making decisions regarding specific antiviral regimens (see [Management](#)).

Staging of liver fibrosis is also an important part of the overall workup of HCV infection. At this point, liver biopsy remains the gold standard to assess the level of liver injury in patients with chronic HCV. However, liver biopsy is limited by relative insensitivity because of sample bias and complications including severe bleeding. Given these limitations, a number of noninvasive tests have been developed to help identify patients with significant fibrosis and who are therefore at risk for hepatic decompensation events. These include scoring systems based on readily available serum tests including the Fibrosis-4 (age, AST, ALT, platelet count) and the AST to platelet ratio index (AST, ULN for AST, platelet count) scoring systems that correlate scores with predicted levels of fibrosis. More recently, transient elastography (Fibroscan), which uses an ultrasonic shear wave to evaluate liver stiffness, was approved for use in 2013 and has increasingly been used to evaluate fibrosis. Further radiographic techniques including MR elastography are being studied to provide clinicians with more noninvasive means to assess for fibrosis.

## Management

The goal of HCV therapy is the achievement of permanent clearance of the virus (defined as undetectable HCV RNA using highly sensitive assays), also known as sustained virologic response (SVR). SVR has been shown to be associated with dramatic reductions in all-cause mortality and progression of liver disease. Within the last 5 years, the therapeutic landscape of HCV has undergone a sea change with the introduction and rapid proliferation of direct acting antiviral agents (DAAs) and approval of all-oral IFN-free DAA regimens that now promise superb (>90%) SVR rates.

Since their introduction in 1986, IFN-based therapies had been the backbone of HCV therapy. However, despite advancement and refinement of IFN-based regimens over the past several decades, relatively low SVR rates were observed. In addition, the probability of SVR varied largely with viral genotype and viral load. Furthermore, IFN itself was poorly tolerated by patients because of frequent side effects including debilitating malaise, fever, and flu-like illness.

Significant advances in our understanding of the molecular virology, life cycle, and pathogenesis of HCV since it was first discovered have catalyzed the development of the first DAAs. These agents were the first-generation NS3-4A protease inhibitors, telaprevir and boceprevir, which achieved SVR rates of 65% to 75% when used together with PEG-IFN and ribavirin. As such, they were approved by the US Food and Drug Administration (FDA) for use in triple therapy for HCV genotype 1 in 2011. Simeprevir, a once daily NS3-4A protease inhibitor, was approved in 2013 to be used in combination with PEG-IFN and ribavirin for treatment of HCV genotype 1, achieving comparable SVR rates as its predecessors with better tolerability. The approval of NS3-4A inhibitors was followed by the development of several compounds targeting other stages of the HCV life cycle. A major advance was the development of an NS5B inhibitor, sofosbuvir, which has a high barrier to resistance and provided the therapeutic backbone for the approval of the first IFN-free antiviral regimens for HCV in 2013.

With these DAAs in hand, the field became interested in developing additional all-oral IFN-free regimens using two or more classes of DAAs. This concept was realized with the FDA's approval of the combination of sofosbuvir and ledipasvir (an NS5A inhibitor) in 2014, a once-daily coformulation for the treatment of HCV genotype 1 that achieved SVR rates of 94% to 99%. Numerous other DAA combinations have been tested, and several have been approved for the treatment of various HCV genotypes with ever-shortening treatment courses. In 2016 an additional milestone was achieved with the approval of the combination sofosbuvir/velpatasvir, the first available pangenotypic HCV treatment.

A list of current FDA-approved DAAs and combination pills for the treatment of chronic HCV is provided in [Table 76.3](#).

Current recommendations for the treatment of chronic HCV infection are changing frequently to keep up with the constant development of new and more effective DAA combinations. Suggested treatment regimens differ in terms of drug combination and duration based on a number of factors including viral genotype, the absence or presence of cirrhosis, presence or absence of NS5A resistance-associated variants, drug-drug interactions, and treatment status. For simplicity, the recommended regimens for treatment-naïve patients as of September 2017 are included here ([Table 76.4](#)). For the most up-to-date guidelines that reflect the most recent clinical data, the reader is encouraged to go to [www.hcvguidelines.com](http://www.hcvguidelines.com).

Regarding acute HCV infection, in the majority of cases, given the self-limited nature of the initial symptomatic infection, close monitoring without antiviral treatment is recommended. HCV RNA should be checked every 4 to 8 weeks to monitor for clearance of infection versus persistent viremia and the establishment of chronic HCV infection. If persistent viremia exists at 6 months, the patient should be treated with DAA-based therapy as discussed previously. However, in select instances, the benefits of treating during the acute infection may outweigh the benefits of simply monitoring for HCV clearance. These include, but are not limited to, situations where the risk of loss to follow-up is high or where the patient is at high risk of decompensation (i.e., underlying cirrhosis). In these instances, the same regimens that are used for chronic HCV infection should be used.

Patients with chronic HCV infection should also be counseled regarding behaviors to limit further liver injury including cessation of alcohol and intravenous drug use. Other management considerations include regular screening for HCC with ultrasonography in all patients infected with chronic HCV infection with concurrent advanced fibrosis or cirrhosis.

	Yes	Velipasvir (100 mg)/sofosbuvir (400 mg) daily	12	Class I, Level A	
		Daclatasvir (60 mg) + sofosbuvir (400 mg) daily	24	Class IIa, Level B	
4	No	Paritaprevir (150 mg)/ritonavir (100 mg)/ombitasvir (25 mg) daily + dasabuvir (250 mg) twice daily + ribavirin	12	Class I, Level A	
		Velipasvir (100 mg)/sofosbuvir (400 mg) daily	12	Class I, Level A	
		Elbasvir (50 mg)/grazoprevir (100 mg) daily	12	Class I, Level A	
		Ledipasvir (90 mg)/sofosbuvir (400 mg) daily	12	Class I, Level A	
		Yes	Paritaprevir (150 mg)/ritonavir (100 mg)/ombitasvir (25 mg) daily + dasabuvir (250 mg) twice daily + ribavirin	12	Class I, Level A
			Velipasvir (100 mg)/sofosbuvir (400 mg) daily	12	Class I, Level A
	Elbasvir (50 mg)/grazoprevir (100 mg) daily		12	Class IIa, Level B	
	5 and 6	Either	Ledipasvir (90 mg)/sofosbuvir (400 mg) daily	12	Class IIa, Level B
			Velipasvir (100 mg)/sofosbuvir (400 mg) daily	12	Class I, Level A
Ledipasvir (90 mg)/sofosbuvir (400 mg) daily			12	Class IIa, Level B	

Strength of recommendation assessments are based on scientific evidence and expert opinion. For further information on how each recommendation is evaluated, please refer to [www.hcvguidelines.com](http://www.hcvguidelines.com).

## Chapter Review

### Questions

1. A 35-year-old male who recently emigrated to the United States from Ghana presents for an annual physical examination. He reports that he has been feeling well and does not have any acute complaints. His physical examination is unremarkable. As part of routine screening, you check hepatitis B serologies including HBsAg, anti-HBs, anti-HBc (total immunoglobulins). You find the following results:

HBsAg	Positive
Anti-HBs	Negative
Anti-HBc (total)	Positive

What should be your next step?

- Initiation of antiviral therapy with 300 mg daily of tenofovir disoproxil fumarate and screening of his household members
  - Check liver function tests (LFTs), HBeAg, anti-HBe, and HBV DNA
  - Check LFTs, HBeAg, anti-HBe, HBV DNA, HAV, HCV, and HIV serologies
  - Liver biopsy
2. A 45-year-old Chinese female presents to your office because although she was born in the United States, her mother was recently diagnosed with chronic hepatitis B infection and new hepatocellular carcinoma. She is asymptomatic and her physical examination is unremarkable. She is concerned that she may also be infected. You obtain LFTs and viral serologies, and you find the following results:

HBsAg	Positive
Anti-HBs	Negative
Anti-HBc (total)	Positive
Anti-HBc (IgM)	Negative
Anti-HBe	Positive
HBV DNA	$1.04 \times 10^6$ IU/mL
HAV IgG	Positive
HCV Ab	Negative
HIV	Negative
ALT	15 IU/L

What should be your next step?

- Initiation of antiviral therapy with 0.5 mg daily of entecavir
  - Liver biopsy
  - Monitoring with LFTs and HBV DNA every 6 months
  - Abdominal ultrasound and serum alpha-fetoprotein
3. A 28-year-old presents to the emergency department with malaise, abdominal tenderness, and recent onset of jaundice. On physical examination, he appears ill and jaundiced but answers questions appropriately and is in no acute distress. He denies any recent ingestions or use of over-the-counter medications. You obtain laboratory studies, which reveal:

ALT	2057 IU/L
AST	1631 IU/L
Total bilirubin	9.4 mg/dL
International normalized ratio	1.7
HBeAg	Positive
Anti-HBe	Negative
Anti-HBc (total)	Positive
Anti-HBc (IgM)	Positive
HBsAg	Positive
Anti-HBs	Negative
HBV DNA	$3.5 \times 10^5$ IU/mL

What should be your next step?

- Start *N*-acetylcysteine and admit for workup and expedited evaluation for liver transplant.
  - Admit for workup and monitoring but no antiviral treatment.
  - Admit for workup and initiation of antiviral therapy with nucleos(t)ide analogues.
  - Discharge home with close follow-up with primary care physician.
4. A 24-year-old male intravenous drug user presents with several weeks of fatigue and malaise and new-onset jaundice. His past medical history is notable for HIV infection for which he is on antiretroviral therapy. He reports taking six to eight tablets of acetaminophen daily for pain. You obtain a number of laboratory tests, which reveal:

ALT	1477 IU/L
AST	936 IU/L
Total bilirubin	6.1 mg/dL
HAV IgM	Negative
HAV IgG	Positive
HBsAg	Negative
HBsAb	Positive
HCV Ab	Negative
HIV-1/2 Ab	Positive
CD4+	370

What is the most likely diagnosis?

- Acute HBV infection
  - Acetaminophen toxicity
  - Wilson disease
  - Acute HCV infection
5. A 57-year-old female with no significant medical history presents for a routine annual physical examination. She reports feeling well, and her physical examination is unremarkable. She consents to routine HCV screening based on her age. Several days later, you receive the results and find:

HCV Ab	Positive
HCV RNA	$5.3 \times 10^5$ IU/mL

You inform her of these results and ask her to come back into the office for follow-up and discussion of therapy.

She denies any history of intravenous drug use but does report being transfused with blood in her childhood after being in a motor vehicle accident. You obtain a right upper quadrant ultrasound, which revealed evidence of cirrhosis. Additional laboratory studies show normal liver synthetic function and HCV genotype 3. She is eager to start treatment. What antiviral treatment would you recommend for her?

- A. Velpatasvir/sofosbuvir daily for 12 weeks
- B. Ledipasvir/sofosbuvir daily for 12 weeks

- C. Sofosbuvir and ribavirin daily for 24 weeks
- D. PEG-IFN, ribavirin, and sofosbuvir for 24 weeks

### Answers

- 1. C
- 2. B
- 3. B
- 4. D
- 5. A

# Board Simulation: Gastroenterology

MUTHOKA MUTINGA AND ROBERT BURAKOFF

## Questions

- A 57-year-old woman presents with a 2-month history of pruritus and mild fatigue. Her skin examination reveals excoriations but no visible rash. Laboratory examination reveals an alkaline phosphatase elevated to 3× normal, with otherwise normal liver biochemical tests. Her thyroid-stimulating hormone is also elevated, and she has a positive antithyroid microsomal antibody test. What is the most likely diagnosis, and what treatment is indicated?

  - Primary sclerosing cholangitis; ursodiol
  - Primary biliary cirrhosis; prednisone
  - Primary sclerosing cholangitis; liver transplantation
  - Primary biliary cirrhosis; ursodiol
  - Congenital hepatic fibrosis; liver transplantation
- A 45-year-old man with long-standing gastroesophageal reflux disease (GERD) and occasional symptoms of nausea undergoes an esophagogastroduodenoscopy (EGD) for further evaluation. He is noted to have long segment Barrett esophagus confirmed with biopsies. Which of the following is associated with a decreased risk of development of neoplasia in Barrett esophagus?

  - Advancing age
  - Treatment with statins
  - Tobacco use
  - Central obesity
  - Increasing length of Barrett esophagus
- A 55-year-old man presents with a 4-month history of intermittent, watery diarrhea, severe heartburn, and epigastric pain. He is diagnosed with four duodenal ulcers on endoscopic evaluation. He denies aspirin or nonsteroidal antiinflammatory drug (NSAID) use. Gastric antral biopsy testing for *Helicobacter pylori* bacteria is negative. His symptoms fail to respond to an acid suppression regimen consisting of omeprazole, 20 mg twice daily. A fasting serum gastrin level is 1850 pg/mL. Which of the following is true of his likely diagnosis?

  - The patient most likely has a somatostatinoma.
  - Omeprazole may falsely lower serum gastrin levels.
  - The tumor responsible for this disorder is most often located in the duodenum.
  - The tumor responsible for this disorder is usually benign.
  - The duodenal ulcers will not respond to any level of acid suppression therapy.
- A 22-year-old woman who was recently diagnosed with ileal Crohn disease returns for routine follow-up. Her symptoms are well controlled with adalimumab. She has done some research on the internet about her disease and is curious to learn more about extraintestinal manifestations of Crohn disease. Which of the following is an extraintestinal manifestation of Crohn disease?

  - Paget disease
  - Sicca syndrome
  - Thyroiditis
  - Rosacea
  - Renal calculi
- A patient with well-compensated cirrhosis caused by alcohol abuse is found to have large esophageal varices on upper endoscopy. There is no history of prior upper gastrointestinal (GI) bleeding. What is the appropriate therapy to prevent future variceal bleeding?

  - Ursodiol
  - Interferon
  - Nonselective beta-blocker
  - Endoscopic sclerotherapy
  - Proton pump inhibitor therapy (e.g., omeprazole)
- Ascites is classified according to the serum ascites albumin gradient (SAAG), which is calculated by subtracting the albumin level in the ascites from that in the serum. Which of the following conditions is associated with low gradient (SAAG <1.1 mg/dL ascites)?

  - Budd-Chiari syndrome
  - Cirrhosis caused by hepatitis C

- C. Peritoneal carcinomatosis  
 D. Congestive heart failure  
 E. Acute alcoholic hepatitis
7. A 47-year-old woman presents with a 4-month history of watery diarrhea and 24-lb weight loss. Laboratory examination is notable for mild iron deficiency anemia and a low serum calcium level. Stool cultures and examination for ova and parasites are unremarkable. Thyroid laboratory testing is normal. A colonoscopy is performed, and the examination is normal, including inspection of the terminal ileum and histologic evaluation of random colon biopsies to assess for microscopic colitis. A tissue transglutaminase antibody is strongly positive.  
 Which of the following statements regarding this disorder is true?  
 A. Adherence to dietary modification increases the risk of small intestinal lymphoma.  
 B. This disease is less common in patients with diabetes mellitus.  
 C. This disease is seen most commonly in patients of Mediterranean background.  
 D. Small intestinal biopsies are likely to reveal villous atrophy, crypt hyperplasia, and increased intraepithelial lymphocytes.  
 E. There is no association with autoimmune thyroid disease.
8. A 35-year-old woman is found to have abnormal results of iron studies on a routine physical examination. Her liver biochemical tests are normal, and her physical examination is unremarkable. She does not consume alcohol or over-the-counter medications or supplements. Her iron studies are as follows:  
 Serum iron 186 µg/dL  
 Total iron binding capacity (TIBC) 255 µg/dL  
 Serum ferritin 300 ng/mL (normal 25–240 ng/mL)  
 What is the next test that should be ordered to facilitate the diagnosis?  
 A. Percutaneous liver biopsy  
 B. Serum B<sub>12</sub> and folate levels  
 C. Glucose tolerance testing  
 D. Gene testing for hereditary hemochromatosis  
 E. Abdominal CT scan with intravenous contrast
9. A 19-year-old woman is seen in your office to establish primary care. She reports that her mother had colon cancer at age 42 years, her maternal aunt had uterine cancer at age 38 years, and her maternal grandfather had colon cancer at age 49 years. You suspect Lynch syndrome. Which of the following is a feature of this syndrome?  
 A. The mean age of first developing colon cancer is in the late 50s.  
 B. There is a predominance of proximal colon cancers.  
 C. The incidence of synchronous colon cancer is estimated low.  
 D. It is unusual to have a family history of extracolonic malignancies.  
 E. The disorder is transmitted in an autosomal recessive fashion.
10. A 64-year-old businessman is seen in a travel medicine clinic. He thinks he may be traveling to a hepatitis E endemic area and is interested in learning more about this illness. Which of the following statements regarding hepatitis E is true?  
 A. The virus is endemic in India and Southeast Asia.  
 B. The clinical features of hepatitis E are similar to those of hepatitis C.  
 C. The virus is transmitted primarily via percutaneous blood exposure.  
 D. Hepatitis E is associated with a low rate of fulminant hepatic failure in pregnant women.  
 E. An effective vaccine is widely available to prevent hepatitis E.
11. A 23-year-old man with confirmed GERD after 24-hour intraesophageal pH-testing is seen for follow-up in your office. He was initially referred to you by an ear, nose, and throat specialist who had seen him for evaluation of a persistent sore throat. You review with him other atypical manifestations of GERD, such as which of the following?  
 A. Pulmonary sarcoidosis  
 B. Uveitis  
 C. Chronic diarrhea  
 D. Nocturnal asthma  
 E. Irritable bowel syndrome
12. A 46-year-old man presents with a complaint of intermittent dysphagia for 10 years. He reports that food “sticks in my chest” approximately 1 or 2 times per month and that he needs to either wash down the bolus with water or regurgitate it. He has symptoms only with solid foods, primarily meat, rice, and bread. He has never had difficulty swallowing liquids. He has had no symptoms of odynophagia and has not experienced weight loss.  
 What is the most likely cause of his symptoms?  
 A. Schatzki ring  
 B. Esophageal cancer  
 C. Achalasia  
 D. Diffuse esophageal spasms  
 E. Peptic stricture of the esophagus
13. A 54-year-old African man undergoes EGD for evaluation of dyspepsia. Diffuse antral gastropathy is noted, and chronic *H. pylori* infection is suspected. Which of the following is a potential sequela of chronic gastric *H. pylori* infection?  
 A. Gastric cancer  
 B. Eosinophilic gastroenteritis  
 C. GI stromal tumor (GIST)  
 D. Duodenal adenocarcinoma  
 E. Carcinoid tumors of the small intestine

14. A 21-year-old presents for routine health examination. His family history is notable for colon cancer in his mother (age 45 years), maternal uncle (age 52 years), and maternal grandmother (age 56 years). The patient is asymptomatic, routine laboratory tests are normal, and the physical examination including a test for occult blood in the stool is unremarkable. Which of the following represents appropriate recommendations for colorectal cancer screening for this patient?
- Colonoscopy every 3 to 5 years beginning at age 40 years
  - Colonoscopy no less than every 10 years beginning at age 50 years
  - Colonoscopy every 2 years beginning at age 21, then annually beginning at age 40 years
  - Annual flexible sigmoidoscopy beginning at puberty
15. A 42-year-old man with a 15-year history of inflammatory bowel disease presents with new-onset jaundice, right upper quadrant pain, and fever. An ultrasound reveals a dilated common bile duct, and an endoscopic retrograde cholangiopancreatography (ERCP) reveals multiple strictures of the common bile duct (CBD) and intrahepatic bile ducts. A distal CBD stricture is dilated, and the patient's symptoms resolve, although his serum alkaline phosphatase remains persistently elevated at 3× the upper limit of normal. Which of the following statements regarding this disorder is true?
- This disorder is more commonly associated with Crohn disease than ulcerative colitis.
  - Liver biopsy is the definitive diagnostic test for this disorder.
  - Ursodiol has been proven to be effective in treating this disorder.
  - The risk of cholangiocarcinoma is greatly increased in this disorder.
  - This disorder will not recur after liver transplantation.
16. An 86-year-old man develops abdominal cramps, watery diarrhea, and low-grade fever. Within 2 days his stools become bloody, and he feels weak and light headed. He is seen in your office, and his examination is notable for a temperature of 100.8°F and mild orthostasis. His abdomen is diffusely tender, but no peritoneal signs are present. He has bloody stool in the rectal vault and a fine petechial rash on his lower extremities. Laboratory studies reveal a hematocrit of 27%, platelet count of 48,000/μL, and creatinine of 3.5 mg/dL (his prior laboratory values had been within the normal range). Which of the following statements regarding this disorder is true?
- The hematologic and renal complications of this disorder are common in young children and the elderly.
  - The illness is primarily transmitted through the ingestion of poorly cooked rice and pasta products.
  - Antibiotics are effective in preventing complications in this illness.
  - The diarrhea is usually severe and protracted.
  - The disease is caused by gram-positive bacteria.
17. A 38-year-old landscaper presents with a 6-month history of bullous lesions on the dorsum of his hands, forearms, and neck. His physical examination is otherwise unremarkable. He consumes 6 to 12 beers daily. On laboratory examination, he has a mildly elevated alanine aminotransferase (ALT) (1.5× normal). He reports being rejected as a blood donor but is unsure why. Which of the following statements about this patient and his condition is true?
- Abstinence from alcohol rarely improves the skin lesions.
  - He is unlikely to have evidence of chronic hepatitis C.
  - He is likely to have had a history of episodes of severe abdominal pain.
  - Phlebotomy is the accepted treatment for this disorder.
18. A 58-year-old woman is seen in your office with complaints of a 5-year history of progressive dysphagia for liquids and solids. She describes occasional nocturnal regurgitation of food. An upper GI series reveals a dilated esophagus with beak-like narrowing at the level of the gastroesophageal junction. An upper endoscopy reveals no mass or stricture, but there is some resistance to passage of the endoscope through the lower esophageal sphincter (LES), and some liquid and particulate residue is present in the esophagus despite confirmed prepcedure fasting. Esophageal manometry is notable for high normal basal LES pressure, failure of the LES to relax with swallows, as well as aperistalsis of the esophageal body. Which of the following is not an appropriate management option for her disease?
- Pneumatic dilation
  - Surgical resection of the distal esophagus
  - Surgical myotomy
  - Botulinum toxin (Botox) injection of the lower esophageal sphincter
19. A 35-year-old woman presents with evidence of ascites and elevated hepatic transaminases. She does not drink alcohol. All viral serologic tests are negative. She is not overweight and has no history of autoimmune disorders. Of note, she has a history of emphysema diagnosed in her 20s despite absence of a history of tobacco use. Which of the following phenotypes would most likely lead to this clinical presentation?
- Pi MM
  - Pi SS
  - Pi ZZ
  - Pi MZ

20. A 39-year-old man presents with brisk hematochezia for 4 hours. In the emergency department, his blood pressure is 92/62 mm Hg, and heart rate is 100 beats per minute in the supine position. Rectal examination reveals red blood and no palpable masses. Anoscopy is limited, revealing red blood in the rectal vault without a visible source of bleeding. His hematocrit is 33% (his baseline hematocrit 1 year ago was 45%). The platelet count and coagulation tests are normal. He denies aspirin, NSAID, or anticoagulant use and has had no recent upper GI symptoms such as abdominal pain or nausea. A nasogastric tube is placed and yields clear fluid. He has no history of liver disease, abdominal or gastric surgery, or prior history of GI bleed. Which one of the following would likely be an unusual cause of such severe GI hemorrhage?
- Colonic arteriovenous malformations (AVMs)
  - Duodenal ulcer
  - Internal hemorrhoids
  - Colonic diverticula
  - Meckel diverticulum
21. A 35-year-old man with Crohn disease presents to your office with complaints of intense epigastric pain of several hours' duration. He reports heavy alcohol use the night before. His medications include 6-mercaptopurine (6-MP) and oral mesalamine. Laboratory tests are notable for lipase 400 U/L (normal, <60 U/L), total bilirubin 2.5 mg/dL, direct bilirubin 0.5 mg/dL, aspartate aminotransferase (AST) 17 U/L, ALT 25 U/L, and alkaline phosphatase 72 U/L. His lactate dehydrogenase and hematocrit are within normal limits. What is the likely explanation for the elevated total bilirubin level?
- Hepatotoxicity from 6-MP
  - Alcoholic hepatitis
  - Gilbert syndrome
  - Biliary obstruction caused by gallstones
22. A 24-year-old woman who is contemplating pregnancy undergoes abdominal ultrasound imaging for evaluation of intermittent right upper quadrant pain. She is noted to have a focal liver lesion. A benign etiology is suspected, and further testing is pursued. Which of the following focal liver lesions should be monitored with imaging during pregnancy?
- Hepatic adenoma
  - Hepatic hemangioma
  - Hepatic cyst
  - Focal nodular hyperplasia
23. A 33-year-old with severe asthma requiring periodic oral steroid therapy is noted to have candidal esophagitis on endoscopic evaluation of odynophagia. In addition to steroid therapy, which of the following medical conditions may predispose to the development of candidal esophagitis?
- Diabetes insipidus
  - Idiopathic gastroparesis
  - GERD
  - Achalasia
24. A 62-year-old with decompensated cirrhosis caused by prior alcoholism is hospitalized for evaluation and management of worsening ascites and peripheral edema. There have been no recent changes in medications including diuretic doses. However, he is noted to have an elevated creatinine of 1.8 mg/dL (his creatinine was 0.9 mg/dL 1 month ago). Which of the following is a criterion for the hepatorenal syndrome?
- Proteinuria >2000 mg/dL with no evidence of parenchymal renal disease
  - History of shock or other factors that may compromise renal function
  - Chronic or acute liver disease with advanced hepatic failure and portal hypertension
  - Active urine sediment containing red cells and red cell or other casts
  - Improvement of renal function after diuretic withdrawal and plasma expansion
25. A 57-year-old man with chronic diarrhea, significant weight loss, and arthralgia undergoes both an upper endoscopic and colonoscopic examination, preceded by extensive stool and laboratory tests as well as abdominal CT scan imaging, all of which are unrevealing for the cause of his symptoms. Biopsy results are pending, but Whipple disease is suspected. Which of the following statements regarding Whipple disease is true?
- Congo red staining is helpful in detecting the bacteria within macrophages.
  - Women are more commonly affected than men.
  - Arthralgia is an uncommon symptom.
  - Valvular heart disease may occur.
  - Lymphadenopathy is rarely noted on physical examination.

### Answers

1. D. Primary biliary cirrhosis (PBC) is a cholestatic liver disease most commonly affecting middle-aged women. It often presents with symptoms of fatigue and pruritus, although many patients are detected in the asymptomatic phase on routine laboratory testing. The typical early laboratory abnormality is an elevated alkaline phosphatase with otherwise normal liver biochemical tests. There is a close association between PBC and autoimmune thyroid disease and other autoimmune disorders. Ursodiol, a synthetic bile acid, is currently the only treatment known to retard the progression of this disease, which, left untreated, will lead to end-stage liver disease requiring transplantation. Some experts are also using colchicine to limit fibrosis, and methotrexate in refractory cases, but the role of these medications is unproven. (Ali AH, Lindor KD. Primary biliary cirrhosis. *Lancet*. 2015;386:1565–1575.)

2. B. Barrett esophagus is characterized by specialized columnar metaplasia of the esophagus that develops as the result of chronic acid reflux and is associated with an increased risk of developing esophageal adenocarcinoma. Recent studies suggest that the annual incidence of adenocarcinoma in patients with Barrett esophagus is 0.1% to 0.4%. Some risk factors for development of adenocarcinoma in Barrett esophagus include male gender, white race, age  $\geq 50$  years, intraabdominal distribution of body fat, elevated body mass index, tobacco use, and increasing length of Barrett esophagus. Epidemiologic data suggest that aspirin and other NSAIDs may reduce the risk of development of adenocarcinoma in Barrett esophagus, likely caused by inhibition of cyclooxygenase. Statin therapy has also been associated with a decreased risk of development of neoplasia in Barrett esophagus. (Shaheen NJ, Falk GW, Iyer PG, et al. ACG clinical guideline: diagnosis and management of Barrett's esophagus. *Am J Gastroenterol*. 2016;111(1)30–50.)

3. C. The findings of multiple duodenal ulcers, diarrhea, and a fasting serum gastrin of  $>1000$  are highly suggestive of Zollinger-Ellison syndrome resulting from a gastrinoma of the GI tract. Gastrinomas are most often located in the duodenum and pancreas, and most are malignant.

Interpretation of serum gastrin levels is complicated by the frequent use of proton pump inhibitors, which can falsely elevate gastrin levels, although not to the degree seen in Zollinger-Ellison syndrome. The ulcer diathesis will often respond to high-dose proton pump inhibitors (e.g., omeprazole, 40 mg twice daily), but the only definitive treatment is resection of the secretory tumor. (Ito T, Igarashi H, Jensen RT. Zollinger-Ellison syndrome: recent advances and controversies. *Curr Opin Gastroenterol*. 2013;29(6):650–661.)

4. E. Crohn disease (and ulcerative colitis) can be associated with a wide variety of extraintestinal manifestations that may result in significant morbidity and some mortality among certain groups of patients. Uveitis, sacroiliitis, and erythema nodosum are all autoimmune phenomena that frequently occur in patients with inflammatory bowel disease. Renal calculi are overly represented among patients with Crohn disease. Enhanced colonic absorption of oxalate can predispose patients with ileal Crohn disease to develop calcium oxalate containing renal calculi. Thyroiditis, Paget disease, sicca syndrome, and rosacea are not clearly associated with Crohn disease. (Brown SR, Coviello LC. Extraintestinal manifestations associated with inflammatory bowel disease. *Surg Clin North Am*. 2015;95(6):1245–1259.)
5. C. Patients with portal hypertension and large esophageal varices benefit from prophylactic therapy to prevent GI hemorrhage. Currently, pharmacologic prophylaxis with nonselective beta-blockers (propranolol, nadolol,

or timolol) is recommended. Endoscopic sclerotherapy has been shown to be ineffective and possibly harmful when used for prophylaxis of variceal hemorrhage. Interferon, ursodiol, and acid inhibition therapy have no role in the prevention of variceal bleeding. Nonselective beta-blockers are associated with an increased risk of mortality in patients with decompensated cirrhosis and should not be used in these patients. (Ilyas JA, Kanwal F. Primary prophylaxis of variceal bleeding. *Gastroenterol Clin North Am*. 2014;43(4):783–794.)

6. C. The SAAG differentiates between ascites caused by portal hypertension (formerly known as transudative ascites) and that caused by nonportal hypertensive states (formerly known as exudative ascites) with 97% accuracy. Low-gradient ascites (SAAG  $<1.1$ ) is seen in peritoneal carcinomatosis, tuberculous peritonitis, pancreatitis, and fungal infections of the peritoneum. The remaining answers are all associated with high-gradient ascites (SAAG  $>1.1$ ) caused by portal hypertension. (Huang LL, Xia HH, Zhu SL. Ascitic fluid analysis in the differential diagnosis of ascites: focus on cirrhotic ascites. *J Clin Transl Hepatol*. 2014;2(1):58–64.)
7. D. The constellation of symptoms, evidence of nutrient malabsorption, and positive tissue transglutaminase antibody are all consistent with a diagnosis of celiac sprue. This disorder primarily affects people of Northern European descent rather than those of Mediterranean ancestry. The disease is associated with both diabetes mellitus and autoimmune thyroid disease. The characteristic histologic features include flattening of the small intestinal villi (villous atrophy), deepening of duodenal crypts (crypt hyperplasia), and the presence of increased intraepithelial lymphocytes. Treatment involves elimination of gluten from the diet. Remember that gluten is present in barley, bulgur, couscous, farina, oats, rye, semolina, spelt, and wheat among others but is not present in arborio or basmati rice, beans, brown rice, cassava, corn, sweet potato, and others.

Not only does this ameliorate symptoms, but there is some evidence suggesting that a gluten-free diet may decrease the risk of small intestinal lymphoma, which is seen with increased frequency in celiac disease. (Kelly CP, Bai JC, Liu E, et al. Advances in diagnosis and management of celiac disease. *Gastroenterology*. 2015;148(6):1175–1186.)

8. D. This patient's iron saturation is 73% (iron saturation = serum iron/TIBC). An iron saturation of  $>55\%$  is suggestive of an iron overload syndrome, and this finding should initiate the workup for hereditary hemochromatosis. One might expect the serum ferritin to be higher in a patient with hemochromatosis; however, a 35-year-old female may lose enough blood from menstruation to keep her total body iron relatively low. The next test to obtain is the hemochromatosis genetic test (HFE gene analysis), which looks for

the two most common mutations seen in hereditary hemochromatosis (the major mutation C282Y and minor mutation H63D). In a young, asymptomatic patient with normal liver function tests, a liver biopsy is not necessary. Phlebotomy therapy can be started based on a positive genetic test alone, if iron overload is present. There is also no need to search for occult glucose intolerance in the young patient without symptoms. CT scanning is not yet sensitive enough to determine the presence or degree of hepatic iron overload and should not be used to diagnose hemochromatosis. (Pietrangelo A. Iron and the liver. *Liver Int.* 2016;36(suppl 1):116–123.)

9. B. Hereditary nonpolyposis colon cancer is a syndrome characterized by an increased risk of colonic malignancy caused by a defect in certain DNA mismatch repair genes that normally correct base-pair mismatches during DNA replication. The disorder is transmitted in an autosomal dominant fashion with high degree of penetrance. The mean age of presentation with cancer is 40 years. Synchronous colon cancer (a second colon cancer found at the time of the index colon cancer) is common, and there is a predominance of proximal tumors (60%–80% are beyond/proximal to the splenic flexure). In some kindreds (Lynch syndrome II), there is an increased incidence of extracolonic malignancies including ovarian, endometrial, and gastric cancers. (Kastrinos F, Stoffel EM. History, genetics, and strategies for cancer prevention in Lynch syndrome. *Clin Gastroenterol Hepatol.* 2014;12(5):715–727.)
10. A. Hepatitis E is a common cause of epidemic hepatitis in Africa and Asia and is seen in the United States primarily in returned travelers and immigrants from endemic areas. It is transmitted via the fecal-oral route and is associated with large outbreaks caused by contaminated water systems. In general, it is a self-limited icteric illness with a similar clinical course to hepatitis A. An important exception to this generally benign course is the observation that pregnant women infected with hepatitis E have a high rate of fulminant hepatic failure, up to 25% in some series from India and Pakistan. There is currently no widely available vaccine to prevent hepatitis E. (Perez-Garcia MT, Garcia M, Suay B, et al. Current knowledge on hepatitis E. *J Clin Transl Hepatol.* 2015;3(2):117–126.)
11. D. In recent years, several clinical syndromes have been shown to be associated with GERD. These include hoarseness and chronic laryngitis, chronic nonproductive cough, nocturnal asthma, and noncardiac chest pain. In such cases, the presence of acid reflux can be confirmed with a 24-hour intraesophageal pH monitor. Alternatively, an empirical trial of a proton pump inhibitor can be used, and symptomatic response can be assessed after 12 weeks of therapy. There is no association between simple gastroesophageal reflux and pulmonary sarcoidosis, uveitis, chronic diarrhea, or irritable bowel syndrome (IBS). Use of magnesium-based antacids can cause diarrhea in patients with GERD, and proton pump inhibitor therapy may be independently associated with IBS type symptoms. (Patel DA, Harb AH, Vaezi MF. Oropharyngeal reflux monitoring and atypical gastroesophageal reflux disease. *Curr Gastroenterol Rep.* 2016;18(3):12.)
12. A. This patient likely has a Schatzki ring, a fibrous ring in the lower esophagus that causes intermittent obstructive symptoms. The key features of this disorder are intermittent dysphagia to solids with normal swallowing in between. Patients often report choking on meat or large pieces of bread and may need to regurgitate at times. Both esophageal cancer and a peptic stricture would result in progressive dysphagia for solids, whereas achalasia causes dysphagia for both solids and liquids early in its course. Esophageal spasms tend to present with episodes of chest pain and dysphagia. A Schatzki ring is treated with endoscopic esophageal dilation, resulting in excellent relief of symptoms, although there is a small rate of recurrence. (Kaindlstorfer A, Pointner R. An appraisal of current dysphagia diagnosis and treatment strategies. *Expert Rev Gastroenterol Hepatol.* 2016;10(8):929–942.)
13. A. Infection with *H. pylori*, a gram-negative urease-producing bacterium that colonizes the gastric mucosa, may lead to a variety of pathologic conditions. It is clearly associated with duodenal ulcer disease, and treatment of infection reduces the risk of ulcer recurrence by >80%. Chronic gastritis caused by *H. pylori* can lead to atrophic gastritis and hypochlorhydria over decades. This rarely may predispose to gastric but not duodenal carcinoid tumors. There is a clear relationship between chronic *H. pylori* infection and gastric adenocarcinoma, such that the World Health Organization has declared *H. pylori* a class I carcinogen. There is also an interesting association between mucosa-associated lymphoid tissue lymphoma and *H. pylori*. Some studies have shown tumor regression after eradication of this organism. There is as yet no known association linking *H. pylori* infection with eosinophilic gastroenteritis, GIST tumors, or carcinoma of the small intestine. (Doorakkers E, Lagergren J, Engstrand L, et al. Eradication of *Helicobacter pylori* and gastric cancer: a systematic review and meta-analysis of cohort studies. *J Natl Cancer Inst.* 2016;108(9).)
14. C. The history meets the criteria for Lynch syndrome as follows: (1) three relatives with colorectal cancer (CRC)—one must be a first-degree relative of the other two; (2) one or more CRC cases occurring before the age of 50 years; (3) CRC involving at least two generations; (4) familial adenomatous polyposis (FAP) syndrome must be excluded. Screening of family members in kindreds with Lynch syndrome should consist of colonoscopy every 2 years beginning at age 21 years until age 40 years, and annually thereafter. Genetic testing to identify

mismatch repair gene mutations (e.g., *MSH2*, *MLH1*, and *MSH6*) is available.

Annual flexible sigmoidoscopy beginning at age 12 years is recommended for screening in FAP syndrome.

Genetic testing to identify adenomatous polyposis coli gene mutations in this syndrome is also available.

Patients at moderate risk of colon cancer, such as those with a first-degree relative with adenomatous polyps or colon cancer at age <60 years, should have screening colonoscopies performed every 3 to 5 years, beginning at age 40 years.

Colonoscopy no less than every 10 years, beginning at age 50 years, is recommended for patients at average risk for colorectal cancer.

(Turgeon DK, Ruffin MT 4th. Screening strategies for colorectal cancer in asymptomatic adults. *Prim Care*. 2014;41(2):331–353.)

15. D. This patient has primary sclerosing cholangitis (PSC), an inflammatory disorder of the biliary tree that leads to progressive stricturing of both small and large bile ducts, with recurrent bouts of cholangitis and eventual progression to biliary cirrhosis. It is strongly associated with inflammatory bowel disease (IBD). As many as 70% to 80% of patients with PSC have coexisting IBD (ulcerative colitis > Crohn disease), although only 2.4% to 7.5% of patients with IBD will develop PSC. The diagnosis of PSC is made on ERCP. Liver biopsy has a low diagnostic yield. Ursodiol has not been shown to alter the prognosis in patients with PSC, although it may relieve symptoms of pruritis. Cholangiocarcinoma will develop in 7% to 15% of patients with PSC and is a common cause of mortality in these patients. Liver transplantation is effective in end-stage PSC, although there is some risk of recurrence in the transplanted liver. Total colectomy in ulcerative colitis will not result in resolution of PSC. (Eaton JE, Talwalkar JA. Primary sclerosing cholangitis: current and future management strategies. *Curr Hepat Rep*. 2013;12(1):28–36.)

16. A. This patient has the hemolytic uremic syndrome (HUS), a sequela of infection with the gram-negative bacterium, *Escherichia coli* O157:H7, the enterohemorrhagic *E. coli* strain. The disease is transmitted via poorly cooked meat products and begins as a syndrome of fever, abdominal cramps, and watery diarrhea. It progresses to frankly bloody diarrhea over a period of days and is generally self-limited. However, in very young children and in the elderly, a syndrome of renal failure, thrombocytopenia, and hemolytic anemia may develop, which may be fatal. Antibiotics have not been shown to prevent this complication; in fact, antibiotic therapy may promote the development of HUS, and therefore antibiotics are currently not recommended for the treatment of *E. coli* O157:H7 colitis. (Keir LS. Shiga toxin associated hemolytic uremic syndrome. *Hematol Oncol Clin North Am*. 2015;29(3):525–539.)

17. D. The patient has porphyria cutanea tarda (PCT), a disorder of heme breakdown and porphyrin metabolism. It is characterized by bullous lesions on sun-exposed areas that heal with scarring. Most patients with PCT have elevated liver biochemical tests, and many are found to have chronic hepatitis C. In addition, there is a strong association with alcohol ingestion, and abstinence from alcohol may lead to a regression of the skin manifestations of PCT. The mainstay of treatment is phlebotomy, which greatly reduces iron stores and improves the lesions and liver abnormalities seen in PCT. Unlike acute intermittent porphyria, there is no abdominal pain syndrome associated with PCT. (Dedaria B, Wu GY. Dermatologic extrahepatic manifestations of hepatitis C. *J Clin Transl Hepatol*. 2015;3(2):127–133.)

18. B. The patient has a classic history, imaging studies, and manometric findings for achalasia. Upper endoscopy is required to rule out adenocarcinoma of the proximal stomach or distal esophagus or even tumors in the mediastinum that invade the area of the lower esophagus and which may mimic achalasia (pseudo-achalasia). Achalasia is thought to result from progressive loss of ganglion cells within the myenteric plexus of the distal esophagus. Most patients present between the ages of 30 and 50 years. The most common presenting symptom is dysphagia. Initially the dysphagia occurs with solids, but then liquid dysphagia develops later in the clinical course. Other common symptoms include chest pain and nocturnal regurgitation of undigested food.

Resection of the distal esophagus is not a treatment for achalasia. Oral medical therapy for achalasia (e.g., isosorbide and nifedipine) is associated with poor symptom response (<50% response at 1 year). Botulinum toxin injections into the muscles of the LES are associated with approximately 60% response at 1 year, although repeated injections are often necessary. Balloon dilation has a better long-term response rate (60%–90% at 1 year) but carries a risk of esophageal perforation (up to 4%). Surgical therapy includes open myotomy of the LES (>90% response at 1 year) and laparoscopic myotomy of the LES (90% response at 1 year). There is an approximately 10% incidence of postsurgical symptomatic reflux in these patients. (Gunasingam N, Perczuk A, Talbot M, et al. Update on therapeutic interventions for the management of achalasia. *J Gastroenterol Hepatol*. 2016;31(8):1422–1428.)

19. C. This patient has alpha-1-antitrypsin deficiency. Alpha-1-antitrypsin is a protease inhibitor synthesized almost exclusively in the liver. It is responsible for inhibiting neutrophil-derived proteases, especially neutrophil elastase. There are over 75 different protease inhibitor (Pi) alleles. The normal alpha-1-antitrypsin phenotype is Pi MM. The most common pathologic phenotype causing both liver and lung disease is the Pi

ZZ variant, in which serum alpha-1-antitrypsin activity level is <15% of normal. Pi SZ heterozygotes may rarely develop cirrhosis, whereas Pi MZ heterozygotes usually do not develop cirrhosis unless there is some other cofactor for liver disease such as heavy alcohol use or chronic viral hepatitis. The pathophysiology of liver injury is controversial but is hypothesized to be caused by altered degradation of retained alpha-1-antitrypsin in the hepatocyte. (Teckman JH, Jain A. Advances in alpha-1-antitrypsin deficiency liver disease. *Curr Gastroenterol Rep*. 2014;16(1):367.)

20. C. Lower GI bleeding is severe and hemodynamically significant (e.g., resting tachycardia, postural hypotension) in 15% of patients. Approximately 15% to 20% of patients with severe, ongoing hematochezia and anemia have an upper GI source of bleeding. A nasogastric aspirate that is clear or nonbloody does not exclude an upper GI tract bleed unless bile is present. Meckel diverticulum is the most common cause of lower GI bleeding in children, although it may rarely cause lower GI hemorrhage in adults. Diverticular hemorrhage occurs in 3% to 5% of persons with colonic diverticuli. Bleeding from AVMs is usually subacute, although 15% of patients present with acute, massive hemorrhage. Hemorrhoids are unlikely to be associated with massive lower GI bleeding in a patient without significant coagulopathy or portal hypertension. (Ghassemi KA, Jensen DM. Lower GI bleeding: epidemiology and management. *Curr Gastroenterol Rep*. 2013;15(7):333.)
21. C. This patient has acute pancreatitis manifested by marked elevation of lipase. Alcohol is a common cause of acute pancreatitis. Patients with Crohn disease are at an increased risk for development of gallstones; these gallstones may lead to pancreatitis if they temporarily occlude the pancreatic duct outflow. Abrupt elevations of transaminases (ALT and AST), alkaline phosphatase, as well as both direct and total bilirubin are clues to a diagnosis of gallstone pancreatitis. 6-MP and azathioprine can cause pancreatitis in 3% of patients and, if stopped immediately, rarely lead to severe pancreatitis and are unlikely to lead to chronic pancreatitis. In addition, 6-MP and azathioprine can cause drug-induced hepatitis, typically characterized by elevated transaminases. Alcoholic hepatitis usually results in elevation of AST out of proportion to ALT, and if bilirubin elevation is present, the direct bilirubin is also elevated.
- This patient's mild indirect hyperbilirubinemia with normal transaminases and normal alkaline phosphatase are suggestive of Gilbert syndrome (a common, benign, congenital condition resulting from impaired bilirubin conjugation) rather than an obstructive biliary process. It is typically manifested in the setting of acute illness or prolonged fasting. (Banks PA. Acute pancreatitis: landmark studies, management decisions, and the future. *Pancreas*. 2016;45(5):633–640.)
22. B. Hepatic adenomas are benign epithelial tumors, typically solitary and primarily seen in young women. They are strongly associated with oral contraceptives, anabolic androgens, and glycogen storage disease and less strongly associated with pregnancy and diabetes. Current recommendations are that hepatic adenomas should be monitored during pregnancy for growth, using ultrasound imaging. Hepatic adenomas that are >5 cm should be referred for resection before pregnancy. Other focal liver lesions such as hemangiomas, hepatic cysts, and focal nodular hyperplasia do not require routine imaging for surveillance during pregnancy. (Vijay A, Elaffandi A, Khalaf H. Hepatocellular adenoma: an update. *World J Hepatol*. 2015;7(25):2603–2609.)
23. D. *Candida albicans* is the most common infectious esophagitis in the general population. *C. albicans* is considered part of the normal oral flora. Esophageal infection first involves colonization of the esophageal mucosal surface followed by mucosal invasion as a result of impaired host defense. Risk factors for candidal esophagitis include diabetes mellitus, adrenal dysfunction, immunosuppression, nonhematologic malignancies, advanced age, alcoholism, and radiation therapy for thoracic malignancies. Conditions that compromise normal immune function such as HIV infection and hematologic malignancies are also associated with increased risk of candidal esophagitis. Lastly, esophageal stasis caused by conditions such as achalasia and scleroderma of the esophagus increase the risk of developing candidal esophagitis. Idiopathic gastroparesis is not associated with increased risk of developing candida esophagitis. (O'Rourke A. Infective oesophagitis: epidemiology, cause, diagnosis and treatment options. *Curr Opin Otolaryngol Head Neck Surg*. 2015;23(6):459–463.)
24. C. The hepatorenal syndrome (HRS) is characterized by rapid decline of renal function in patients with advanced liver failure and portal hypertension, and is a diagnosis of exclusion. The impaired renal function occurs as a result of arterial vasodilation and compensatory activation of endogenous vasoconstrictive systems. Based on clinical outcomes, two types of HRS have been described. Type I HRS is characterized by rapid and progressive reduction of renal function resulting in a doubling of the initial serum creatinine to a level >2.5 mg/dL or a 50% reduction of the initial 24-hour creatinine clearance to a level <20 mL/min, in less than 2 weeks. Type II HRS does not have as rapidly progressive course. Mild proteinuria to a maximum of 500 mg/dL may be seen in HRS. No evidence of obstructive uropathy or parenchymal renal disease, such as glomerulonephritis, should be present. (Busk TM, Bendtsen F, Moller S. Hepatorenal syndrome in cirrhosis: diagnostic, pathophysiological, and therapeutic aspects. *Expert Rev Gastroenterol Hepatol*. 2016;10:1153–1161.)

25. D. Whipple disease, a rare chronic systemic illness, is caused by a gram-positive actinomycete, *Tropheryma whipplei*. The disease primarily causes small intestinal malabsorption and is fatal if untreated. The bacteria form round or sickle-shaped inclusions in macrophages and can be detected with periodic acid-Schiff staining, not Congo red staining (used to detect amyloid deposits). For unknown reasons Whipple disease occurs predominantly in middle-aged Caucasian men (86%). Common symptoms include weight loss (90%), diarrhea (>70%), and arthralgia (>70%).

Cardiac involvement occurs in about 30% of affected persons and can include valvular heart disease, congestive heart failure, and pericarditis. Both hyperpigmentation of sun-exposed skin and lymphadenopathy are frequent physical findings. Central nervous system manifestations occur in about 5% of patients and include dementia, meningoencephalitis, ataxia, mild clonus, and cerebellar symptoms. Prolonged treatment (12 months) with antibiotics is required. (Schwartzman S, Schwartzman M. Whipple's disease. *Rheum Dis Clin North Am*. 2013;39(2):313–321.)

# 78

## Gastroenterology Summary

NORTON J. GREENBERGER

This chapter focuses on a potpourri of topics regarding liver disease that are popular subjects for the boards and that have not been covered in detail in the other chapters in this section.

### Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a slowly progressive cholestatic disease of the liver. The etiology is unknown; however, several lines of evidence point to an autoimmune mechanism, including the presence of autoantibodies, abnormalities in both cellular and humoral immunity, and the association with several other autoimmune diseases. The major pathology of this disease is a destruction of the small-to-medium bile ducts, which leads to progressive cholestasis and often end-stage liver disease. Key features of the disease are shown in [Box 78.1](#).

PBC is more common in women and those of northern European descent. Onset is usually in middle age (see [Box 78.1](#)), and one in four patients with PBC is discovered incidentally. Most patients develop symptoms over 5 to 20 years. The most common clinical presentation is with fatigue and pruritus. In the early stages of the disease, the physical examination is normal, but later in its course, features consistent with cirrhosis and portal hypertension are common. There are several associated systemic abnormalities ([Box 78.2](#)).

The main laboratory findings with PBC are (1) liver test abnormalities such as elevated aminotransferases including alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and gamma-glutamyl transpeptidase (GGTP) and (2) antimitochondrial antibodies (AMAs). AMAs are detected in 90% to 95% of patients with a specificity of 98% for PBC. AMAs target different components, mainly enzymes, in the mitochondria. The presence of anti-M2, anti-M4, anti-M8, and anti-M9 correlate with the severity of PBC.

There are four stages of PBC:

- Stage 1 (portal stage of Ludwig): portal inflammation, bile duct abnormalities, or both are present.
- Stage 2 (periportal stage): periportal fibrosis is present, with or without periportal inflammation or prominent enlargement of the portal tracts with seemingly intact newly formed limiting plates.

- Stage 3 (septal stage): septal fibrosis with active inflammation, passive paucicellular septa, or both are present.
- Stage 4 (cirrhosis): nodules with various degrees of inflammation are present.

Treatment is summarized in [Box 78.1](#). The overarching goals of treatment are to slow the progression rate of the disease and to alleviate the symptoms. Liver transplantation appears to be the only lifesaving procedure. Ursodeoxycholic acid (UDCA) is the major medication used to slow the progression of the disease. On the other hand, glucocorticoids, cyclosporine, methotrexate, colchicine, and azathioprine are unproven or do not alter the natural progression of PBC.

#### • BOX 78.1 Key Features of Primary Biliary Cirrhosis

##### Description

95% of patients are women

##### Manifestations

Asymptomatic  
Dermatologic  
Pruritus  
Hyperpigmentation  
Musculoskeletal  
Fatigue  
Rheumatoid arthritis (10%)  
Sjögren syndrome  
Hypercholesterolemia  
Xanthomatous peripheral neuropathy

##### Criteria for Diagnosis

Increased serum alkaline phosphatase 95%  
Positive antimitochondrial antibody 95%  
Liver biopsy: provides information on stage of disease, i.e., I–IV (cirrhosis)

##### Treatment

Ursodeoxycholic acid (UDCA), 13–15 mg/kg  
Metaanalysis trials: long-term >2 years  
Improvement in liver biochemical tests  
Reduction/delay in disease progression  
Possible improvement in transplant-free survival  
UDCA more effective in early disease  
Patient with advanced disease and complications should be referred for transplantation

### • BOX 78.2 Primary Biliary Cirrhosis: Associated Systemic Abnormalities

Pruritus  
 Metabolic bone disease  
 Hypercholesterolemia  
 Malabsorption and steatorrhea  
 Vitamin (fat-soluble) deficiency: vitamins A, D, E, K  
 Hypothyroidism (20% of patients)  
 Anemia  
 Xanthelasma in primary biliary cirrhosis  
 Osteoporosis

Obeticholic acid is an isomer of human bile acid UDCA. It can be used in combination therapy with UDCA in PBC patients with an inadequate response to UDCA alone—that is, persistent elevation in alkaline phosphatase levels >2 times the upper limit of normal after 1 year of UDCA.

### Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic liver disease characterized by cholestasis with inflammation and fibrosis of the intrahepatic and extrahepatic bile ducts (Box 78.3). The etiology is unknown; however, several lines of evidence point to an autoimmune mechanism, including the strong association with inflammatory bowel disease (IBD) and the presence of autoantibodies—antineutrophil cytoplasmic antibodies (ANCA), anticardiolipin (aCL) antibodies, and antinuclear antibodies (ANAs). PSC may lead to cirrhosis of the liver with portal hypertension.

The mean age of onset is age 40 years. In contrast to PBC, there is a predilection for men. Approximately 75% to 80% of patients have IBD—mostly ulcerative colitis rather than Crohn disease. Clinical features in those patients who are symptomatic (20%–40% are asymptomatic) include fatigue, jaundice, pruritus, and right upper quadrant pain.

The key laboratory findings are abnormal liver tests. The most striking abnormality is the serum ALP, which is usually 3 to 5 times reference range values and cholestatic in nature (ALP fraction is liver disease in origin rather than bone disease in origin). The serum GGTP level is also elevated. There is a modest increase in serum aminotransferase and bilirubin levels. Also seen are abnormalities on MR cholangiopancreatography (MRCP) or endoscopic retrograde cholangiopancreatography (ERCP) that include multiple strictures and dilations of the intrahepatic and extrahepatic biliary ducts.

As with PBC, there are four stages of PSC:

- Stage 1: portal hepatitis, degeneration of bile ducts with inflammatory cell infiltrate
- Stage 2: extension of disease to periportal area with prominent bile ductopenia
- Stage 3: septal fibrosis and necrosis
- Stage 4: frank cirrhosis

### • BOX 78.3 Key Features of Primary Sclerosing Cholangitis

#### Clinical Features

75% of patients have inflammatory bowel disease (IBD) especially ulcerative colitis  
 Asymptomatic with elevated serum alkaline phosphatase  
 IBD patients with a persistently elevated serum alkaline phosphatase  
 Jaundice with obstructive types liver tests (especially men age 30–40 years)  
 Fatigue and pruritus  
 Right upper quadrant abdominal pain, fever, chills, sweat

#### Criteria for Diagnosis

Demonstration of multifocal strictures and dilatation of intrahepatic/extrahepatic bile ducts by MR cholangiopancreatography (MRCP) or endoscopic retrograde cholangiopancreatography (ERCP). Liver biopsy supports the diagnosis with typical findings:

- Include fibrosis with obliteration of small bile ducts and “onion skin pattern” stages I–IV (cirrhosis)

Small duct primary sclerosing cholangitis (PSC)

- Typical presentation, however ERCP/MRCP examinations do not show typical bile duct abnormalities, but liver biopsy specimens demonstrate characteristic histologic features
- Delayed/reduced likelihood of disease progression and cholangiocarcinoma

#### Differential Diagnosis

Cholangiocarcinoma develops in 8%–15% of PSC patients  
 Infectious cholangiopathy (microsporidium, cryptosporidium) in AIDS patients  
 Autoimmune pancreatitis with bile duct stricturing

#### Complications

Fatigue, pruritus, deficiency of fat-soluble vitamins (A, D, E, K)  
 Metabolic bone disease  
 PSC increased risk of colon carcinoma patients with ulcerative colitis  
 Cholangiocarcinoma: difficult diagnosis—brush cytology 1 Ca/19–9

#### Treatment

No effective treatment; high-dose ursodeoxycholic acid 20 mg/kg → equivocal improvement in liver tests

PSC is a chronic progressive disease with no curative medical therapy. The goals of medical management are to treat the symptoms and to prevent or treat the known complications. Liver transplantation is the only effective therapy and is indicated in end-stage liver disease.

PSC–autoimmune hepatitis (AIH) overlap syndrome is diagnosed by use of a modified AIH score and has been demonstrated in 8% of 113 PSC patients from the Netherlands, 1.4% of 211 PSC patients from the United States, and 17% of 41 PSC patients from Italy. Patients with PSC–AIH overlap syndrome have cholangiographic abnormalities characteristic of PSC but serologic features of AIH.

**TABLE 78.1****Acute Versus Chronic Hepatitis**

Acute Hepatitis	Chronic Hepatitis
Toxins (e.g., acetaminophen) Viral: A–E, cytomegalovirus, Epstein-Barr virus, herpes simplex virus, varicella zoster virus Autoimmune hepatitis Vascular compromise Fulminant Wilson disease	Toxins Viral: B and C Metabolic: nonalcoholic fatty liver disease Genetic <ul style="list-style-type: none"> <li>Hemochromatosis</li> <li>Alpha-1-antitrypsin deficiency</li> <li>Wilson disease</li> </ul> Immune <ul style="list-style-type: none"> <li>Autoimmune hepatitis</li> <li>Celiac sprue</li> </ul> Vascular <ul style="list-style-type: none"> <li>Budd-Chiari syndrome</li> <li>Right-sided heart failure</li> <li>Venoocclusive disease</li> </ul>

## Hepatitis

*Hepatitis* refers to inflammation of the liver. The pathologic target is the hepatocyte (in contrast to cholangitis wherein the target is mostly biliary ductal cells). In hepatitis, the predominant abnormality is the serum aminotransferase (ALT and AST) elevations rather than the ALP. Hepatitis can be acute or chronic (Table 78.1). Its causes can be either infectious or noninfectious. Infectious etiologies include viral, bacterial, fungal, and parasitic organisms. In the United States, viral hepatitis is most commonly caused by hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV). These three viruses can all result in an acute disease process with symptoms of nausea, abdominal pain, fatigue, malaise, and jaundice. HBV and HCV can also lead to chronic infection. Chronically infected liver may progress to cirrhosis and/or develop hepatocellular carcinoma.

## Autoimmune Hepatitis

Autoimmune hepatitis is characterized by progressive hepatocellular inflammation and necrosis, with progression to cirrhosis (Box 78.4). Its etiology is unknown. However, as for PBC and PSC, several lines of evidence point to autoimmune mechanisms, including histopathologic evidence of cell-mediated immunity (hepatic histopathologic lesions composed predominantly of cytotoxic T cells and plasma cells), presence of autoantibodies (i.e., nuclear, smooth muscle, thyroid, liver), and association with other autoimmune diseases.

Autoimmune hepatitis mostly affects women (70%–80%) and has a predilection for Caucasians of northern European ancestry with a high frequency of human leukocyte antigen (HLA)-DR3 and HLA-DR4 markers. It has a bimodal distribution—10 to 30 years and 40 to 50 years. Autoimmune hepatitis clinical syndromes include acute hepatitis (fever, hepatic tenderness, and jaundice), chronic hepatitis (asymptomatic but with abnormal liver tests [LFTs] and fatigue, pruritus, and abdominal pain), or

### • BOX 78.4 Key Features of Autoimmune Hepatitis

#### Spectrum of Presentations

Asymptomatic with abnormal liver tests  
 Acute onset of jaundice  
 Chronic liver disease with jaundice and hepatosplenomegaly  
 Fulminant hepatic failure

#### Extrahepatic Manifestations

Thyroiditis  
 Celiac sprue  
 Hemolytic anemia  
 Idiopathic thrombocytopenic purpura  
 Ulcerative colitis  
 Diabetes mellitus

#### Criteria for Diagnosis

Female sex  
 Alkaline phosphatase/alanine transaminase or aspartate transaminase increase >1.5  
 Antinuclear antibody, antismooth muscle antibody, antiactin LKM (liver, kidney, microsome) antibodies, (+) >1:40  
 (–) Test for antimitochondrial antibody  
 (–) Test for drugs, viral hepatitis markers, alcohol history  
 ↑ serum globulins >1–2 × upper limit of normal  
 Liver histology: interface hepatitis, lymphoplasmacytic infiltrate

#### Treatment

Corticosteroids + azathioprine (steroid sparing) preferred Rx or corticosteroids alone if concerns about azathioprine, i.e., cytopenias, malignancy, thiopurine methyltransferase deficiency  
 85% of patients respond; indicators of poor response: serum bilirubin does not decrease to <15 mg/dL after 2 weeks of treatment

well-established cirrhosis. There are protean disease associations (Box 78.5).

Autoimmune hepatitis is a treatable condition with steroids and/or immunosuppressive agents (azathioprine). Without therapy, most patients die within 10 years of disease onset. Treatment with appropriate pharmacologic agents improves survival significantly (see Box 78.4).

### • BOX 78.5 Autoimmune Hepatitis Disease Associations

Hematologic complications  
 Hypersplenism  
 Autoimmune hemolytic anemia  
 Coombs-positive hemolytic anemia  
 Pernicious anemia  
 Idiopathic thrombocytopenic purpura  
 Eosinophilia

Gastrointestinal complications  
 Inflammatory bowel disease  
 Proliferative glomerulonephritis  
 Fibrosing alveolitis  
 Pericarditis and myocarditis

Endocrinologic complications  
 Graves disease and autoimmune thyroiditis  
 Juvenile diabetes mellitus

Rheumatologic complications  
 Rheumatoid arthritis and Felty syndrome  
 Sjögren syndrome  
 Systemic sclerosis  
 Mixed connective-tissue disease  
 Erythema nodosum

Leukocytoclastic vasculitis  
 Febrile panniculitis  
 Lichen planus  
 Uveitis

## Infectious Causes of Hepatitis

HAV, HBV, HCV, hepatitis D (HDV), and hepatitis E (HEV) cause 95% of cases of acute viral hepatitis observed in the United States. HCV is the most common cause of chronic hepatitis. The clinical stages or phases of disease with the viral hepatitis are listed subsequently:

#### Phase 1: Viral replication

Patients are asymptomatic during this phase.  
 Laboratory studies demonstrate serologic and enzyme markers of hepatitis.

#### Phase 2: Prodromal phase

Patients experience anorexia, nausea, vomiting, alterations in taste, arthralgias, malaise, fatigue, urticaria, and pruritus. Some develop an aversion to cigarette smoke.

When seen by a health care provider during this phase, patients are often diagnosed as having gastroenteritis or a viral syndrome.

#### Phase 3: Icteric phase

Patients may note dark urine, followed by pale-colored stools.

In addition to the predominant gastrointestinal symptoms and malaise, patients become icteric and may develop right upper quadrant pain with hepatomegaly.

#### Phase 4: Convalescent phase

Symptoms and icterus resolve.  
 Liver enzymes return to normal.

The key features of hepatitis A to E are listed in [Boxes 78.6–78.10](#) and [Table 78.2](#).

### • BOX 78.6 Key Features of Hepatitis A

- Single-stranded RNA virus
- Causes mostly acute and occasionally relapsing episodes of hepatitis
- Formerly responsible for between 20% and 40% of acute hepatitis in the United States before immunization available; now <5%
- Does not result in chronic liver disease; liver abnormalities can persist for 3 months
- Fulminant liver failure is very rare but possible, particularly in setting of preexisting chronic liver disease; at least one study has reported high mortality rates in the setting of chronic hepatitis C virus infection
- Transmission by the fecal-oral route with incubation period ranging from 2–8 weeks with an average of 4 weeks
- Presence of IgM antibodies to hepatitis A virus signifies acute infection
- IgG antibodies suggest prior infection or vaccination and thus immunoprotection
- Postexposure treatment with IgG effective if given within 2 weeks
- Postexposure IgG treatment does not decrease effectiveness of vaccination

## Chronic Hepatitis

Chronic hepatitis is defined as inflammation of the liver lasting at least 6 months. Common causes include hepatitis B and C viruses and drugs. Many patients are asymptomatic until the liver has become severely damaged. Chronic hepatitis can result in cirrhosis and portal hypertension. The differential diagnosis for chronic hepatitis is shown in [Box 78.1](#).

## Wilson Disease

Wilson disease is a rare autosomal recessive inherited disorder of copper metabolism. The condition is characterized by excessive deposition of copper in the liver, brain, and other tissues. The major physiologic aberration is excessive absorption of copper from the small intestine and decreased excretion of copper by the liver. The genetic defect, localized to chromosome arm 13q, affects the copper-transporting adenosine triphosphatase (ATPase) gene (*ATP7B*) in the liver. Patients with Wilson disease usually present with liver disease during the first decade of life or with neuropsychiatric illness during the third decade. The diagnosis is confirmed by measurement of serum ceruloplasmin, urinary copper excretion, and hepatic copper content as well as the detection of Kayser-Fleischer rings. Key features are depicted in [Box 78.11](#).

## Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is characterized by predominantly macrovesicular hepatic steatosis that occurs in individuals even in the absence of consumption of alcohol in amounts considered harmful to the liver. Patients who have the classic triad of obesity, type 2 diabetes mellitus, and

### • BOX 78.7 Key Features of Hepatitis B

Double-stranded DNA virus

Cause of both acute and chronic hepatitis

Common disease, with an estimated worldwide prevalence of 350 million and 250,000 annual deaths; most prevalent in Asia and sub-Saharan Africa

- 1.25 million cases in United States with 70,000 new infections/year
- 30% infections symptomatic, 70% subclinical
- 95% of adults recover, 3.5% of adults and 95% of children do not have an immune response adequate to clear the infection
- Modes of transmission are blood-borne and sexual

Definitions:

- Chronic hepatitis B: HBsAg (+) >6 months
- HBeAg (+) chronic hepatitis B: serum HBV-DNA >20,000 IU/mL
- HBeAg (-) chronic hepatitis B: serum HBV-DNA >2000 IU/mL
- In both HBeAg (+) and HBeAg (-) chronic hepatitis there is intermittent or persistent ↑ ALT/AST levels, and liver biopsies show chronic hepatitis
- Inactive carrier state: HBsAg (+) >6 months
  - Serum HBV/DNA <20,000 IU/mL
  - Persistently normal ALT/AST
  - Liver biopsy shows absence of significant hepatitis (low necroinflammatory score)
- Resolved hepatitis B: previous known acute/chronic hepatitis B now HBsAg (-)
  - Undetectable serum HBV-DNA
  - HBsAg or HBsAb and HBeAb (+)

ALT, Alanine transaminase; AST, aspartate transaminase; HBeAg, hepatitis e B antigen; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

### • BOX 78.8 Key Features of Hepatitis C

Previously known as non-A, non-B hepatitis, hepatitis C virus (HCV) is an RNA virus.

Approximately 3% of US population is HCV antibody positive; 1.7% are HCV RNA positive. HCV RNA should be evaluated in HCV antibody-positive persons before a diagnosis is rendered.

Antibodies to HCV do not confer protective immunity.

Responsible for both acute (rare) and chronic (common) hepatitis.

Less than 20% of infected patients are symptomatic during acute infection.

The modes of transmission are both percutaneous and sexual. Intravenous drug use is the most common mode of acquisition in the United States.

An estimated 80%–85% progress to chronic hepatitis.

Extrahepatic manifestations:

- Cryoglobulinemia with palpable purpura, arthralgias, leukocytoclastic vasculitis, and glomerulonephritis.
- Porphyria cutanea tarda, a blistering rash most prominent in the sun-exposed areas of the body.

Variable natural history, but rate of fibrosis affected by alcohol intake.

HCV genotypes 1a and 1b are most common in the United States, but genotypes 2 and 3 are more easily treated with currently available therapies.

Progression to cirrhosis in 20%–30% after 20 years.

HCV is currently the most common indication for liver transplantation in the United States.

Prior therapy for HCV was a combination of interferon, protease inhibitors, and ribavirin for 6–12 months.

Current therapy consists of direct acting antiviral NS5A or NS5B inhibitors in combination with a nucleotide polymerase inhibitor.

Examples of such combination therapy include the following: sofosbuvir + simeprevir; ledipasvir + sofosbuvir; daclatasvir + sofosbuvir. Recent studies have indicated that adding ribavirin to these regimens does not add additional benefit. These new regimens will largely replace current interferon and ribavirin-based regimens. The aforementioned two drug oral regimens have effected cure rates in greater than 90% of patients with hepatitis C.

Potential side effects of treatment with new antiviral with or without ribavirin.

### • BOX 78.9 Key Features of Hepatitis D

- A defective RNA virus that is dependent on coinfection with hepatitis B virus (HBV)
- Transmitted percutaneously or sexually
- May be transmitted with HBV (coinfection) or during active HBV (superinfection)
- Acute hepatitis D virus may result in rapid progression in hepatitis leading to fulminant hepatitis

### • BOX 78.10 Key Features of Hepatitis E

- RNA virus
- Fecal-oral transmission
- Highest prevalence in Asia, Central America, Africa
- Clinical disease similar to hepatitis A
- Incubation period of 2 weeks to 2 months
- Fulminant hepatitis common during pregnancy with mortality rates reported at 15%–25%
- Rarely progresses to chronic hepatitis
- Suspect in patients with acute hepatitis simulating hepatitis A but hepatitis A antibody (hepatitis A virus–IgM) is negative
- Take careful travel history; hepatitis E found in Mexico, Egypt, South America, Pakistan, South Africa
- Check hepatitis E antibody (IgM) to confirm diagnosis

### • BOX 78.11 Key Features of Wilson Disease

#### Criteria for Diagnosis

- Kayser-Fleischer rings, may also see sunflower cataracts
- ↓ Serum ceruloplasmin <20 mg/dL (low predictive value)
- ↑ Urine copper >100 µg/24-hour urine
- 25% need penicillamine challenge to have abnormal level
- Liver biopsy showing liver copper content >250 µg/g liver
- Usual age at presentation (5–40 years)

#### Special Features

- Can present simulating autoimmune hepatitis
- Fulminant liver failure
- Release of copper causes Coombs-negative intravascular hemolysis
- Rapidly progressive renal failure
- Coagulopathy unresponsive to vitamin K
- May show stigmata of advanced liver disease with markedly decreased serum albumin cholesterol, prolonged international normalized ratio
- These patients require liver transplantation

#### Caveat

- Screen patients age <40 years with signs of chronic liver disease for Wilson disease

#### Treatment: Lifelong Therapy Required

- Penicillamine: monitor urine copper excretion
- Trientine for patients unable to tolerate penicillamine
- Zinc has also been used for maintenance therapy

**TABLE 78.2 Interpretation of Hepatitis B Serologic Tests**

	Example Markers of Viral Hepatitis B Tests			Interpretations
	HBsAg	HBsAb	HBcAb	
1	+	–	–	Acute viral hepatitis
2	+	–	–	Acute viral hepatitis carrier (normal aminotransferases) Chronic hepatitis B (abnormal liver tests)
3	–	+	–	Remote infection immunization
4	–	+	–	Remote infection
5	+	+	+	Infection with more than one strain of hepatitis B (IVDA, renal dialysis)
6	–	–	+	“Window phase” hepatitis B Remote infection False positive

*HBcAb*, Hepatitis B core antigen; *HBsAb*, hepatitis B surface antibody; *HBsAg*, hepatitis B surface antigen; *IVDA*, intravenous drug abuse.

### • BOX 78.12 Key Features of Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) spectrum includes steatosis, steatohepatitis, fibrosis, cirrhosis  
75%–80% of patients with “cryptogenic cirrhosis”  
Patients with metabolic syndrome have a 75% likelihood of having steatohepatitis

Metabolic syndrome

D = Dyslipidemia

R = Insulin resistance

O = Obesity

P = Elevated blood pressure

Laboratory clues to diagnosis of NAFLD

↑ Alanine transaminase (ALT) serum ALT/aspartate

transaminase ratio >2:1 (opposite of alcoholic liver disease)

Treatment

Weight loss

Rx diabetes

Rx hypercholesterolemia

Vitamin E, pioglitazone

dyslipidemia (i.e., patients with the metabolic syndrome) are prone to develop NAFLD. The likelihood of having NAFLD is directly proportional to body weight. NAFLD is being increasingly recognized as a major cause of liver-related morbidity and mortality. Key features are shown in [Box 78.12](#).

### • BOX 78.13 Key Features of Alcoholic Liver Disease

#### Spectrum

Asymptomatic (with abnormal liver tests) to steatohepatitis, severe alcoholic hepatitis, cirrhosis, liver failure

#### Peripheral Manifestations

Spider angiomata, palmar erythema, gynecomastia, parotid enlargement, Dupuytren contractures, paucity axillary and pubic hair, testicular atrophy

Triad of parotid enlargement, gynecomastia, and Dupuytren sign indicative of chronic alcohol use

Decompensated cirrhosis

- Jaundice
- Ascites
- Encephalopathy
- Bleeding varices (can make a diagnosis of portal hypertension with triad of splenomegaly, ascites, ↑ venous collateral abdominal wall)

Can make a diagnosis of cirrhosis with two physical findings and two laboratory findings

- Ascites and asterixis
- Serum albumin <2.8 g/dL, international normalized ratio >1.6

Laboratory abnormalities in alcoholic liver disease

↑ Aspartate transaminase

↑ Alanine transaminase (ALT): ALT ratio >3:1

↑ Mean corpuscular volume

↑ Gamma-glutamyl transpeptidase

#### Treatment

Prednisone and pentoxifylline may be transiently effective

## Alcoholic Liver Disease

Alcoholic hepatitis is a syndrome of progressive inflammatory liver injury associated with long-term heavy intake of ethanol. It is characterized by a variable constellation of symptoms, which may include feeling unwell, hepatomegaly, ascites, and modest elevation of LFTs. Alcoholic hepatitis can vary from mild, with only liver enzyme elevation, to severe liver inflammation. Patients who are severely affected present with subacute onset of fever, hepatomegaly,

leukocytosis, marked impairment of liver function (e.g., jaundice, coagulopathy), and manifestations of portal hypertension (e.g., ascites, hepatic encephalopathy, variceal hemorrhage). However, milder forms of alcoholic hepatitis often do not cause any symptoms. On histopathology, the liver exhibits characteristic centrilobular ballooning necrosis of hepatocytes, neutrophilic infiltration, megamitochondria, and Mallory hyaline inclusions. Steatosis (fatty liver) and cirrhosis frequently accompany alcoholic hepatitis. Key features are shown in [Box 78.13](#).

## Cardiovascular Disease

# 79

## Cardiac Examination

JOSEPH LOSCALZO

In this era of high technology and expensive testing, there is nothing more important than a thorough history and physical examination in the process of medical care. A focused cardiac history allows the clinician to establish a differential diagnosis. The physical examination is used not only as an overall assessment of the cardiovascular system but also, more specifically, to pursue those diagnoses in the historical differential that can be confirmed or refuted by the physical findings. Critical physical examination findings are rarely uncovered unless the clinician is specifically probing for given physical characteristics and knows what would be expected in the face of disease. Only by applying skilled history and physical examination techniques can the clinician determine the rank order of the differential diagnoses and order those tests most likely to answer the question with the least inconvenience, pain, and cost to the patient.

### General

The patient's general appearance is often overlooked. This can include the degree of discomfort the patient manifests, respiratory rate and labored breathing, and key physical examination findings that may direct more specific investigations. This might include dramatic jugular venous distension while in the seated position, suggesting a high right atrial pressure because of restrictive heart disease or constrictive pericarditis. It might also include a head bob or body titubations associated with severe aortic regurgitation. Patients with endocrinopathies often display characteristic facial and body habitus changes as seen in thyroid-related myxedema or adrenal gland dysfunction and related Cushing syndrome. Similarly, patients with Marfan syndrome or Ehlers-Danlos syndrome have a typical morphologic appearance allowing recognition well before detailed examination begins. Finally, end-stage heart disease with overall cachexia colors not only the assessment of the nature of the heart disease and its severity but also the prognosis for the patient.

Although this chapter concentrates on the cardiac examination, many clues to the cardiac diagnosis come from examination of other organs. In fact, by the time the skilled clinician listens to the heart, the probable heart disease

diagnosis has already been established. We, therefore, begin our examination evaluating other organ systems that may give a clue to the cardiovascular diagnosis.

### Eye Examination

Frequently, findings in the eye suggest elevated cholesterol and other lipoproteins, including xanthelasma, xanthoma, and arcus senilis. Xanthelasmas are yellow to orange plaques on the eyelids or medial canthus. Xanthomas are nodules or deposition of lipid-laden histiocytes, which may be evident around the eyes. Arcus senilis, or arcus cornealis, is a yellow-gray ring found in the outer periphery of the cornea. This is usually caused by a deposit of fatty granules in the cornea. Other band keratopathies may be caused by deposits such as copper in Wilson disease. Patients with sarcoidosis or other inflammatory conditions may have secondary iritis. Excessively blue sclera may be a clue to osteogenesis imperfecta or connective tissue disorders such as lupus erythematosus. Suffusion (beety redness and congestion) of the eyelids may be seen in individuals with excessively elevated hemoglobin levels. Proptosis (or exophthalmos) is a protrusion of one or both eyes. Although this may be familial or congenital and occasionally caused by retroorbital tumors, it is more typically bilateral in thyroid disease (usually Graves disease). Ptosis of the lids is occasionally a feature of Kearns-Sayre syndrome, which is associated with muscular dystrophy.

Funduscopy examination of the eyes is also of benefit and is often overlooked despite the availability of ophthalmoscopes in most examination rooms. Funduscopy examination may reveal papilledema or bulging of the optic nerve compatible with elevated intracranial pressures and occasionally malignant hypertension. More frequent would be chronic changes of hypertension, including atrioventricular (AV) nicking, and of more severe forms of arterial hypertension, including hemorrhage and exudates. Findings of neovascularization may be an indication of microvascular complications of diabetes. A Roth spot is a rounded white retinal spot with surrounding hemorrhage seen in bacterial endocarditis or hemorrhagic conditions. Hollenhorst plaques are refractile atheromatous emboli that appear in the retinal arterioles and usually originate from the carotid arteries or great vessels. Lipemia retinalis refers to creamy-colored

retinal vessels found in severe hypertriglyceridemia (hyperchylomicronemia). Each of the findings noted earlier may trigger more intensive investigation of suspected etiologies responsible for these physical characteristics.

## Oral Cavity

The mouth should be examined in general to determine the size of the oropharynx and the degree of obstruction of the passageway by the tongue. Relatively narrow passageways, particularly in patients who are obese or have short squat necks, should trigger an assessment of obstructive sleep apnea. The high arched palate of an individual with Marfan syndrome can help confirm that diagnosis. The tongue and lips should be examined for central cyanosis, an indication of arteriovenous mixing in the heart, as opposed to peripheral cyanosis caused by low cardiac output and/or central mixing. The tongue should be examined to ensure that it is not excessively large with dental indentations compatible with amyloidosis or smooth related to iron deficiency anemia. Gingival decay is often an indicator of coronary artery disease and/or bacterial infection, including endocarditis. The lips may also indicate capillary hemangiomas compatible with Osler-Weber-Rendu (hereditary hemorrhagic telangiectasias) syndrome.

## General Skin Examination

The skin may be bronzed, particularly in non-sun-exposed areas, in individuals with hemochromatosis. Patients with amyloidosis display capillary fragility of the skin and will have “pinch purpura.” In addition, individuals with amyloidosis who have had their heads in a dependent position (initially described after proctoscopy) may have periorbital purpura caused by spontaneous capillary hemorrhage. Extensor tendons should be evaluated for tuberous xanthomas; these are often found in individuals with excess lipoproteins. The Achilles tendon is particularly notable as an area to examine, as are the extensor tendons on the hand. Tuberous xanthomas may also appear as lipid-laden plaques on any skin surface but particularly over the elbows. Patients with hyperthyroid myxedema have a doughy consistency to their skin and a unique lower extremity edema, which is partially pitting but poorly responsive to diuresis. Patients with growth hormone excess-related acromegaly have similar edema as well as a doughy consistency to enlarged hands and feet. Striae are thin bands of skin that are initially red and transition to purple or white over time. These often appear in the abdomen or over the shoulders. These changes appear caused by overextension of the skin or with metabolic syndromes such as Cushing syndrome or disease. These changes may be seen in individuals who have had excessive weight loss or decrease in muscle mass (as in bodybuilders). Excessive laxity of the skin tissue along with features suggestive of Marfan syndrome may lead to the diagnosis of Ehlers-Danlos syndrome. Patients with scleroderma have virtually wrinkleless faces and tight skin over

the digits, often with digital ulceration in more advanced forms. Cyanosis of the periphery may be caused by low cardiac output or right-to-left shunting. Characteristic findings are also seen in the peripheral embolic phenomena associated with endocarditis. Osler nodes are tender and painful lesions, usually on the pads of the fingers and toes, because of infected microemboli. Janeway lesions are nontender, slightly raised erythematous macules or hemorrhages, similarly from peripheral embolic phenomena.

## Skeleton and Joints

The general habitus of an individual with a connective tissue syndrome such as Marfan syndrome is characterized by excessive height and excessive arm span-to-height ratio. There is general hypermobility of joints, particularly fingers and elbows. Patients often have a straightened back and high arched palate. Less dramatic findings may be associated with myxomatous degeneration of the mitral valve (mitral valve prolapse) in the absence of a specific genetic abnormality of fibrillin. Patients who have suffered from rickets have bowed tibias, and those with Paget disease may have similar deformities and skeletal warmth because of increased blood flow and excessive metabolic activity in the affected skeletal region. Findings of rheumatoid arthritis in the hands may signal the investigator to evaluate the patient for pericardial disease or accelerated atherosclerotic disease, as found in many individuals with long-standing inflammatory states. Inflammatory irritation of many joints (polyarticular) may be found in gout, pseudogout, or other conditions, such as sarcoidosis. Clubbing of the digits is expected in individuals with cyanotic congenital heart disease, advanced chronic obstructive pulmonary disease, severe hepatic disease, or inflammatory bowel disease. This requires three features, including loss of the unguo-phalangeal angle, appearance of a clubbed terminal digit when viewed from above, and a soft spongy cuticle compatible with increased capillary flow and activity.

## Thyroid Gland

The thyroid gland should not be ignored and can be examined with the ends of the examiner's digits addressing the gland from the front or with both hands from the back of the patient. The examination is enhanced by having the patient swallow while the thyroid is examined because some portions of the thyroid may fall below the clavicular margin at rest. General enlargement may be seen in inflammatory states, including thyroiditis or Graves disease, and focal nodules may signal the potential for hyperactivity, hypothyroidism, or thyroid malignancy.

## Jugular Venous Pressure

The jugular venous pressure (JVP) can be accurately assessed by physical examination and clearly defines the right atrial pressure. The internal jugular vein is best used to assess the

“phasic” character of the right atrial pressure because there are no valves between the right atrium and the right internal jugular vein. The external jugular vein, found lateral to the internal jugular vein, is a better measure of the mean right atrial pressure because there are usually valves that dampen the phasic pressure. One must ensure that venous valves or other mechanical obstructions in the external jugular vein are not prohibiting an accurate assessment of the external jugular system. This is often the case in individuals who have indwelling cardiac fibrillators or pacemakers on the side of the neck being examined. The internal jugular vein is located just lateral to the margin of the lateral head of the sternocleidomastoid muscle. In patients with markedly elevated JVP, this is often missed because the clinician does not elevate the head of the patient’s bed to a point where the meniscus of the internal jugular system is seen. One must think of the internal jugular vein as a direct manometer connected to the right atrium. The higher the right atrial pressure, the higher will be the column of blood in the jugular vein. The higher the column of blood in the jugular vein, the higher the patient’s head must be elevated for the meniscus to be seen. Once the top of the meniscus is judged, the investigator should measure vertically from this plane to the midchest, the site of the mid right atrium. This distance in centimeters is equivalent to millimeters of mercury, after conversion for blood to mercury density. The assessment of the height of the right atrial pressure is critical in determining the patient’s volume status or intrinsic disease of the right side of the heart or pulmonary system. Jugular veins that are mildly elevated may become more prominent with hepatojugular reflux. In this maneuver, the investigator applies gentle and persistent pressure for at least 15 to 30 seconds over the right upper quadrant. This compresses the liver and forces blood into the superior vena cava. If the right atrium is already volume overloaded, this excess blood will reflux into the superior vena cava, and the JVP will rise. Positive hepatojugular reflux is an indication of borderline elevation of volume in the right side of the heart.

Specific waveforms are seen in the jugular venous tracing (particularly the internal jugular). These will include an *A* wave, caused by right atrial contraction. This is followed by an *x* descent caused by atrial relaxation and to the movement of the floor of the right atrium toward the apex in systole. There may be a *C* wave, caused by right ventricular contraction causing the tricuspid valve to bulge into the right atrium and also influenced by the reflection of the carotid impulse on the venous system, which lies adjacent to the vein in the vascular sheath in the neck. Next is the *y* descent, caused by tricuspid valve opening and a rapid decline in pressure of the right atrium during rapid ventricular filling. A *V* wave follows and is associated with passive filling in the right ventricle and subsequently right atrium.

With inspiration, the JVP falls because of the negative intrathoracic pressure created in the chest. This negative intrathoracic pressure helps draw blood into the heart. If the patient has constrictive or restrictive heart disease, an increase in venous return will result in excessive volume to

the right atrium, and the venous pressure will rise. This is termed *Kussmaul sign* and is seen in constrictive pericarditis, restrictive heart disease, or conditions of severe volume overload to the right side of the heart.

A giant *A* wave in the neck is caused by atrial contraction against a stenotic or a closed tricuspid valve. The latter may occur because of ventricular premature contraction. A giant *V* wave or giant *S* wave in the neck replaces both the *A* and *V* wave and is seen in patients with significant tricuspid regurgitation. Prominent *x* and *y* descents are seen in individuals with constrictive heart disease.

The components of the venous pulse are timed by coordination with the carotid artery pulse. The investigator looks at the venous pulse wave form in the right neck while placing a finger gently on the carotid artery of the left neck. Waves that will rise before the carotid upstroke are *A* waves, waves that arise after the carotid upstroke are small *v* waves, and single waves that arise in the neck (giant *V* or *S* waves) are caused by tricuspid regurgitation.

Most of what pulsates in the neck is venous as opposed to arterial. The venous pulsation is in the lateral part of the neck whereas carotid pulsations are quite medial, next to the trachea. One should be particularly astute to evaluate pulsating neck wave forms that “tickle the earlobes” and pulsate in coordination with arterial upstroke. This may be a subtle clue that the venous pressure is markedly elevated and should stimulate the clinician to elevate the patient’s head until a clear meniscus is seen and measurements are made. Occasionally, venous pulsations are more easily palpated than seen, and this should be correlated with the carotid pulsation, which is often much deeper, more central, and, in these instances, much lower in volume.

## Carotid Artery Examination

Carotid arteries are of importance to the examination because they are the arterial system closest to the heart. As with many physical findings, the investigator creates his or her own “database” of normal examinations, allowing a more careful assessment of what is abnormal. The carotid arteries should be approached carefully because some individuals may have carotid sinus sensitivity, and examination of the carotids may result in asystole. One should listen to the carotids before touching them to determine whether or not there is evidence of a bruit to indicate carotid artery disease.

Patients with aortic stenosis have typically tardus and parvus carotid pulsations that are characteristically a delay in rate of rise of the carotid and diminished fullness of the carotid pulsation. Patients with aortic stenosis often have thrills that are palpable in the carotid arteries and have transmitted murmurs from the aortic valve into the carotid system. Clearly, atherosclerotic carotid disease can mimic these findings, often a humbling experience to those attempting to discern the severity of an aortic valve problem. Patients with critical aortic stenosis often have an additional finding of an anacrotic shoulder to the upstroke of the carotid

artery. By contrast, patients with aortic regurgitation have bounding carotid arteries with a rapid upstroke and decline. This may be associated with a patient's head bob or general body pulsation with each cardiac contraction. Patients with hypertrophic subaortic stenosis have a bifid and dynamic upstroke. This is characterized by a rapid rate of rise and a falloff in the upstroke, which is then replaced by a secondary rise. This is presumably because of midflow obstruction in the left ventricular outflow tract during systole.

A common finding is that of intrinsic carotid artery disease associated with stiff vessels and atherosclerosis. Because carotid bruits are often faint, the patient and physician should suspend respiration while listening. One must differentiate a carotid systolic bruit from a venous hum, which is a continuous murmur caused by flow through the internal jugular system and return to the thoracic cavity.

## Lung Examination

Before listening to the lungs, the chest cavity should be examined. Patients with congenital heart disease may have overdevelopment of the left or right chest. In addition, the rate of respiration and the labor of breathing should be examined visually before listening. The examiner should always listen to the lungs before the patient takes a deep breath. Some murmurs have transmitted findings that are best heard without the background noise from inspiration. This includes pulmonic stenosis, which radiates from the anterior left sternal border to the left scapula posteriorly. Mitral regurgitation may radiate to the spine or to the top of the head. AV communications may also be heard in the lateral parts of the lungs compatible with congenital or acquired malformations. Coarctation of the aorta may also be heard in the area over the left chest, compatible with the area of narrowing. In addition to the features noted earlier, patients should be examined for evidence of chronic obstructive pulmonary disease as manifested by an increased chest diameter and diminished diaphragm movement. Patients with connective tissue abnormalities may display pectus excavatum or pectus carinatum of the sternum. This gives a caved-in or bird-like chest appearance, respectively. Once the lungs have been inspected and listened to for the aforementioned abnormalities, percussion of the lung cavities should occur. This allows the investigator to determine whether or not there is an elevation of one or both of the diaphragms and whether or not they move normally with inspiration. This may indicate the presence of a pleural effusion, chronic airway disease, or diaphragm paralysis.

The typical cardiac findings in the lungs that are associated with congestive heart failure include rales. Rales reflect excess fluid in the lymphatic, interstitium, and alveolar system. Fine rales may be heard in individuals with interstitial lung disease, which can also be confused with congestive heart failure. Excessive fluid accumulation may result in peribronchial cuffing, which may be associated with audible wheezing caused by airflow turbulence from edema of the medium-sized alveolar passageways. Pleural effusions are

characterized by diminished or absent breath sounds associated with egophony. Egophony is a change in the quality (often enhanced resonance) of a spoken sound ('e' to 'a' change) at the upper level of fluid accumulation in or consolidation of the lungs. Bronchophony or whispered pectoriloquy represents enhanced transmission of (softly) spoken sounds caused by similar mechanisms.

## Abdominal Examination

The abdomen should be inspected to determine whether or not there is ascites. This is evident by often tense distension of the abdominal cavity and a pear-shaped appearance of the abdomen. If there is less tense ascites, the investigator may be able to percuss the abdomen supine and laterally to assess the presence of "shifting dullness." Shifting dullness is a consequence of a change in location of the fluid because of shifts in position. The liver and spleen should be palpated. In the case of each of these organs, the investigator should begin the palpation low in the abdomen so as not to underestimate the size of the organ enlargement. One proceeds from the pelvic brim superiorly until a liver edge or spleen tip is felt; it is best to palpate the spleen beginning in the right lower quadrant and moving then toward the left upper quadrant. The liver or spleen is then percussed over the length of their dullness to determine the size of each organ. Occasionally, the spleen cannot be felt without deep inspiration. In more subtle instances of splenomegaly the investigator may percuss over the left lateral rib cage while the patient takes a deep breath. The change from resonance to dullness indicates a spleen beneath the percussion site and can be used to determine the size of the organ. The liver should also be examined for pulsation. This is sometimes difficult to differentiate from chest wall movement in the case of active cardiac motion. Nonetheless, the investigator can place fingers on both sides of the liver edge and determine whether or not it is expanding. More frequently, however, the heel of the hand is placed against the presumed liver edge or thoracic cavity edge, and one determines a "push back" compatible with regurgitation. Pulsation of the liver is often seen in patients with severe tricuspid regurgitation. Patients with persistently elevated JVP and small livers must be evaluated for cardiac cirrhosis. The liver may also be a site for AV communications, and careful auscultation over the liver for continuous murmurs should be performed. The venous pattern over the abdomen or thorax should be assessed. Prominent veins may indicate obstruction of a more central venous conduit, often by tumor infringement.

## Peripheral Arterial Examination

Every patient should be examined for the presence and quality of the carotid, brachial, radial, ulnar, femoral, popliteal, dorsal pedis, and posterior tibial arteries. The blood pressure should be assessed in both arms, and the femoral arteries should be auscultated for bruits. Palpation of the pulses demonstrates two distinct waves in most individuals.

The first is a percussion wave compatible with blood flow through the artery and the second a tidal wave. The tidal wave is formulated by a backflow of blood from the arterial column, usually associated with variations in peripheral resistance and more prominent in elderly patients. The presence of a pulse in each of the aforementioned sites should be documented as well as its quality. Diminution or absence of pulses is usually associated with intrinsic disease of the arteries. This is mostly manifested in the lower extremities. If the pulse is not adequately felt, capillary refill should be assessed in the digits by compressing the nail bed and determining the rate of refill. Other evidence for peripheral arterial insufficiency should be sought including loss of hair in the legs and ulcerations. These are particularly common in individuals with diabetes, who may have peripheral disease combined with peripheral neuropathy.

Pulse deficits may be found in coarctation or aortic dissections. Individuals with aortic coarctation have diminished lower extremity pulses and a dramatically increased brachial-femoral arterial delay. Patients with significant aortic regurgitation have both Quincke pulse and Duroziez sign. Quincke pulse is the characteristic “winking” of the nail bed in the upper extremities. This is assessed by applying gentle pressure to the nail bed with the examiner’s finger, milking approximately one-third of the color from the nail bed. A positive Quincke is characterized by a systolic blinking of the nail bed compatible with arterial expansion in systole. This is seen in individuals with wide pulse pressures, often chronic aortic regurgitation, but also in sepsis, anemia, and hyperthyroidism. Duroziez sign is assessed in the femoral arteries. The investigator places the diaphragm of the stethoscope over the femoral artery. Compression of the arterial pulse above the stethoscope will result in a systolic bruit. The investigator should compress the femoral artery until flow is virtually absent and then release pressure to establish a clear-cut systolic bruit. Individuals with aortic regurgitation will have not only a systolic bruit but a diastolic flow murmur as well. This excessive “to and fro” movement of the blood column is compatible with those conditions noted previously, particularly aortic regurgitation.

Pulsus paradoxus should be assessed in individuals in whom pericardial tamponade is contemplated. With normal inspiration, there is an increase of blood flow to the right heart and return of blood to the pulmonary circuit from the left atrium. This results in a right-to-left ventricular septal shift and removal of blood from the left atrium, respectively. These maneuvers decrease the amount of blood in the left ventricle, and, therefore with inspiration, the blood pressure may fall by up to 10 to 12 mm Hg. Excessive falls (>12 mm Hg) are seen in patients with pericardial tamponade as well as in patients with severe chronic obstructive pulmonary disease or asthma (which would present with different physical examination features than those with pericardial disease). Evaluation of the pulsus paradoxus is difficult and done correctly by few clinicians. The clinician elevates the blood pressure cuff to above the level of the patient’s systolic blood pressure. The cuff is then deflated

exceedingly slowly. The operator determines the difference in systolic pressure from hearing an occasional systolic beat to every systolic beat. Only if the cuff is deflated slowly will this differentiation be evident. This is impossible to assess in individuals with irregular pulses such as atrial fibrillation or frequent ventricular premature contractions. Very marked pulsus paradoxus can often be appreciated by palpation of the major arteries, particularly the femoral and occasionally the brachial arteries.

Pulsus alternans is the appearance of a pulse with every other heart contraction. This finding is probably caused by altered intracellular calcium handling in the myocardium. Therefore every other heart contraction has enough contractility to manifest a peripheral pulsation. This is usually found in individuals with severe cardiomyopathy. It may be seen more rarely in individuals with a “swinging heart” in the face of massive pericardial effusion.

## Heart Inspection

Before the heart is auscultated, it must be inspected. The operator must evaluate both right and left ventricular activity and size. The patient’s heart should in general be the same size as his or her fist. Therefore the expected point of maximal impulse (PMI) can be assessed by having the patient lay a clenched fist on his or her sternum. The tip of the lateral fist would indicate the expected PMI. This can be assessed by inspection and/or by percussion to confirm the size of the heart.

The patient should be evaluated for right ventricular overload. This is best done by inspection of the lower sternum from the end of the bed or to the right of the patient, at the patient’s body level. Excessive motion of the parasternal region is compatible with right ventricular overload unless the patient is thin with a small and vertically aligned heart, in which case this may be the left ventricular apex. The left ventricle should also be inspected. One must not underestimate the size of the left ventricle. Therefore the clinician gazes laterally across the chest but extends the inspection to the midclavicular and midaxial region to ensure that the PMI is not “over the horizon” of the chest wall.

The investigator should then palpate each ventricle. The right ventricle should be assessed by placing the palm of the right hand on the sternum while gently pressing the top of that hand with the left hand. A “pushback” is felt in the presence of a right ventricular heave. Occasionally, with less intense pressure one can feel extra components to this pushback, which usually represent palpable gallops. The left ventricular PMI is assessed using the fingertips. The flattened right hand is extended to beyond the estimated point at which the maximal impulse is located. The fingers are then dragged back to the PMI to ensure that this is the site of maximal contraction.

The point of the left ventricular maximum impulse should be assessed. Patients with thick hearts, including those with hypertrophic cardiomyopathy, aortic stenosis, or long-standing hypertension, will have forceful contraction of

the left ventricle. Patients with volume overload conditions, such as aortic and mitral regurgitation, will have a very active and often displaced PMI. The activity of the PMI differentiates the volume overload conditions from cardiomyopathy, where the PMI may be displaced but is inactive. If the PMI is not easily felt, the patient should be rolled into the left lateral decubitus position, and the PMI appreciated. Although this does not allow evaluation of the size of the heart, it does provide some indication of ventricular enlargement.

Occasionally in cases of severe mitral regurgitation, there will be a left atrial heave. This is found superior to the right ventricular heave in systole. It is assessed by placing the heel of the hand on the high sternum and assessing the push-back. The heart should also be felt for thrills. Patients with aortic stenosis often have a thrill when  $>50$  mm Hg gradient exists in the outflow tract. This would be present in the aortic region at the left sternal border.

Most underappreciated are palpable and audible gallops from the left ventricle. Fingertips on the PMI should be able to trace the additional rise (S<sub>4</sub>) or fall (S<sub>3</sub>) of the gallop rhythm. If this is not appreciated visually, one can place a tongue blade or cotton swab over the PMI and visualize these extra movements of the PMI signifying gallop rhythms. Once one has “timing” of the gallop, the fingers and ears are more apt to appreciate it. Recall that gallops create subtle pressure against the tympanic membrane and are not sounds such as S<sub>1</sub> or S<sub>2</sub>.

Occasionally a double impulse at the PMI will be seen in individuals who have left ventricular aneurysms.

## Auscultation of the Heart

As noted in our general advice to the clinician, one rarely finds something on the examination that one does not listen for. Therefore if one suspects mitral stenosis, one should listen more closely to the intensity of the first heart sound and the interval sound between S<sub>2</sub> and an opening snap or a diastolic rumble. If one is naïve in the art of physical examination or is unclear as to what the patient might have, it is best to approach auscultation in a systematic fashion. This forces the clinician to listen to each component of the cardiac cycle and determine whether or not it is abnormal and then to piece together the abnormalities into a picture compatible with a disease state.

One must listen for specific findings in certain locations. The aortic valve will be heard at the upper left sternal border. It is, in fact, best heard in the seated position. The pulmonic valve will be just to the left of the aortic valve and will usually be much less intense. The tricuspid valve sounds are always heard at the lower left sternal border. Mitral sounds are generally located at the apex but are transmitted widely across the precordium and back depending on the condition. In describing a murmur, one must determine whether or not it is in systole or diastole, then what the location (aortic, mitral, pulmonic, or tricuspid) is, and where the murmur radiates.

The first heart sound is made up of two components, the closure of the mitral and then the tricuspid valves. In

some individuals in whom there is a delay in the closure, there may be two components of S<sub>1</sub> heard. Tricuspid valve closures are usually soft and indistinct. The second heart sound is also caused by closure of left-sided and right-sided valves, specifically the aortic and pulmonic valves, respectively. The sounds of closure of the aortic valve are usually twice that of the pulmonic valve because of the difference in diastolic pressure forcing the valves shut. Ejection clicks occur after the first heart sound and are usually related to the ejection of blood through a diseased valve or into an enlarged arterial circuit. This may be because of aortic or pulmonic valve or root disease. Mid systolic or late systolic clicks are also “sounds” that are typically heard in individuals with myxomatous degeneration of their mitral valves. This is because of the “wind in the sail” effect as the redundant valve balloons backward in systole. Third heart sounds are occasionally not gallops but are caused by intracardiac or extracardiac noises. These may include (1) a pericardial knock as the heart expands in diastole and strikes a thickened pericardial surface in constrictive pericardial disease and (2) a tumor plop, which may also occur in this time frame as a result of an atrial myxoma shifting into the mitral apparatus in diastole.

An S<sub>3</sub> gallop is created by rapid inflow into the left ventricle through the mitral valve. This may be physiologic in individuals with a great deal of blood flow (young and athletic) or reflect ventricular dysfunction in patients who have diminished blood flow and exceedingly weakened heart muscles (dilated cardiomyopathy). These “sounds” are pressures against one’s tympanic membrane or fingertips and are not sounds like an S<sub>2</sub> or an ejection click. An S<sub>4</sub> gallop occurs just before S<sub>1</sub> and is caused by the rapid influx of blood with atrial systole into the left ventricle. This is usually seen in individuals with left ventricular hypertrophy of any etiology. Specific findings of note with cardiac sounds include the fixed splitting of an S<sub>2</sub>. This may occur with an atrial septal defect or patent foramen ovale. It is secondary to the lack of any change in the amount of blood being ejected from the left and right ventricles during systole with respiration because there is equal filling of the ventricles in diastole with this condition. Wide splitting of the second heart sound may be seen in individuals with right bundle branch block, delayed emptying of the right ventricle because of right ventricular disease, or high pulmonary artery pressures. In normal inspiration, the aortic and pulmonic closure sounds of S<sub>2</sub> widen in timing. This is caused by increased filling of the right ventricle with prolonged ejection and decreased filling of the left ventricle with inspiration. If there is a left bundle branch block, disease of the left ventricle, or increased pressure in the aorta, there may be paradoxical splitting of the second heart sound.

Increased intensity of the first heart sound is usually seen in conditions where the mitral valve remains open longer into diastole before systolic contraction forces it shut. If there is adequate contractility to the left ventricle, the valve will be shut briskly, like slamming a door. This is seen in mitral stenosis when the valve is still mobile, and the high

left atrial pressure keeps the valve open longer until systole forces it shut. The second heart sounds may also reflect changes in pressure. A very loud aortic component is often caused by hypertension. A loud pulmonic closure sound usually reflects pulmonary hypertension and is often a key to determining this diagnosis.

## Specific Valvular Conditions

### Aortic Stenosis

Aortic stenosis is characterized by a thickening of the aortic valve. This may be attributed to bicuspid aortic valve disease, but increasingly it is caused by wear and tear in the tricuspid aortic valve in elderly patients. As our population ages, the number of people with systolic murmurs will increase. It is critical that the investigator be able to distinguish aortic sclerosis, because of age-related thickening of the aortic valve, from aortic stenosis. Although aortic sclerosis is usually benign, it may result in aortic stenosis, and the transition may often be subtle. Signs of significant aortic stenosis include a delay in the peak of the systolic murmur, associated with an increased delay in the carotid upstroke. The later in systole the murmur peaks, the more severe the gradient across the valve. As the valve thickens, the aortic ejection click is often lost, and the aortic component of S2 becomes less marked. Although the murmur becomes progressively louder as the condition worsens, once the ventricle begins to fail, the velocity of flow through the valve will diminish, and the murmur will become less evident. This will not, however, change its timing. Significant aortic stenosis (without left ventricular decompensation) should also be associated with a forceful PMI and on S4 gallop.

### Aortic Regurgitation

Aortic regurgitation may be caused by valvular heart disease (bileaflet disease, endocarditis) or aortic root disease as in Marfan syndrome or atherosclerotic dilation. The murmur of aortic regurgitation that remains close to the sternum without further radiation is called the Proctor Harvey sign. This is usually indicative of aortic root disease. A murmur radiating to the apex is usually more compatible with valvular heart disease. With mild (chronic) aortic regurgitation there is a sustained pressure difference across the aortic valve through diastole. Therefore the murmur may be loud and prolonged. In severe acute aortic regurgitation, however, the aortic contents reflux into the left ventricle more rapidly and equilibration of aortic and ventricular pressures is achieved earlier in diastole because the ventricle has not had time to dilate. Therefore the murmur may not be heard throughout all of diastole. Patients with severe chronic aortic regurgitation have peripheral findings including pistol-shot pulses, bounding carotids, and Quincke and Duroziez signs. Significant aortic regurgitation would be associated with a dynamic PMI and a rapid diastolic filling phase associated with an S3 gallop. Aortic regurgitation will often direct a

jet against the anterior leaflet of the mitral valve. This may result in a diastolic “rumble,” which can be confused with mitral stenosis.

### Mitral Regurgitation

Mitral regurgitation has classically been thought of as a rheumatic process with a holosystolic murmur at the apex. In this condition, the gradient of pressure between the left ventricle and left atrium is persistent throughout all of systole, resulting in the holosystolic nature of the murmur. Increasingly, however, mitral valve disease is not caused by rheumatic heart disease but is attributed to myxomatous degeneration. Myxomatous degeneration may often result in ruptured chordae tendineae or distinct prolapse of an anterior or posterior leaflet segment. Therefore the pressure gradient is often not maintained through systole because of the amount of blood being regurgitated, and the radiation of the murmur is related to the direction of the blood flow jet. In patients with posterior mitral leaflet disorders, the posterior mitral leaflet is not able to close or coapt with the anterior leaflet, and the jet of blood will be ejected anteriorly. Therefore posterior leaflet rupture would sound like a murmur radiating to the outflow tract and is often confused with aortic stenosis. Alternatively, an anterior leaflet defect would not be able to coapt with a posterior leaflet, and the blood would be directed posteriorly. This would be directed to the left atrium, which is adjacent to the spine. Therefore the murmur would radiate up and down the spine and occasionally to the top of the head. Involvement of both leaflets will result in radiation of the murmurs in both directions. Significant mitral regurgitation is associated with volume overload of the left ventricle and an active PMI often with gallop rhythms.

### Tricuspid Regurgitation

Tricuspid regurgitation is often secondary to right ventricular volume and pressure overload and annular dilatation. This may be a reflection of chronic obstructive pulmonary disease or pulmonary arterial hypertension but is usually caused by congestive heart failure. Tricuspid regurgitation is heard exclusively at the lower left sternal border. It does not radiate to any other site and is often subtle. In fact, the findings of a pulsatile jugular vein or pulsatile liver are much more sensitive and specific for tricuspid regurgitation than the murmur itself. With normal inspiratory volume shifts, a tricuspid regurgitant murmur may increase its intensity with inspiration. One must be careful to not have the patient take too deep a breath, which would increase the distance from the stethoscope to the patient's valve.

### Tricuspid Stenosis

Occasionally owing to an inflammatory condition such as carcinoid, the tricuspid valve can become regurgitant and stenotic. In the case of tricuspid stenosis, there is a soft diastolic

murmur in the left sternal border location. This is usually considered because of the JVP findings of a giant *A* wave.

### Pulmonic Stenosis and Regurgitation

Occasionally congenital heart disease will result in pulmonic stenosis or regurgitation, and acquired diseases such as carcinoid may also affect the pulmonary valve and endocarditis. Pulmonic stenosis produces a systolic murmur, usually softer than aortic stenosis, which radiates from the left sternal border lateral to the aortic valve to the scapula. Pulmonic regurgitation may be found in any condition with pulmonary hypertension or pulmonary valve disease and is in a similar location, subtle, and in early diastole. Importantly, all right-sided murmurs and right-sided gallops inverse with inspiration.

### Continuous Murmurs

Continuous murmurs may be heard in any form of AV communication. The examiner is best advised to sharpen his or her auscultatory skills to appreciate the continuous murmur by listening over an AV fistula used for renal dialysis. Continuous murmurs are found when there is communication between the arterial and venous system. This might be in the presence of a patent ductus arteriosus, a coronary artery rupture into the heart, or other congenital conditions. Continuous murmurs may be heard associated with a venous hum and less frequently over peripheral or hepatic AV communications. A continuous murmur must be differentiated from the distinct systolic and diastolic murmurs that might result from combined aortic stenosis and regurgitation or pulmonic stenosis and regurgitation.

### Mitral Stenosis

Mitral stenosis is found almost exclusively with rheumatic heart disease but is occasionally heard in patients with congenital or even severe calcific mitral heart disease. The typical sounds in mitral stenosis are an increased first heart sound, an increasingly loud pulmonic closure sound of S<sub>2</sub>, a shortened S<sub>2</sub> opening snap interval, and a diastolic rumble persisting throughout the length of diastole, occasionally with presystolic accentuation. More significant mitral stenosis causes pulmonary hypertension as demonstrated by an increased pulmonic closure sound and evidence of right ventricular volume and pressure overload. In pure mitral stenosis, the left ventricle is protected and therefore not enlarged. The S<sub>2</sub> opening snap interval can be used to determine the height of the left atrial pressure. The higher the left atrial pressure, the more quickly the pressure will open the mitral valve in diastole, and, therefore the S<sub>2</sub>-opening snap interval will shorten, indicative of more severe mitral stenosis. A rumble is heard virtually exclusively at the apex and often requires exercise or auscultation in the left lateral decubitus position to be recognized.

## Other Congenital Heart Disease Murmurs

### Atrial Septal Defect

Atrial septal defect findings are often subtle and are best characterized by fixed splitting of the second heart sound. There may be a flow murmur associated with diastolic flow through the tricuspid valve caused by left-to-right shunting. There may also be a systolic ejection murmur caused by increased flow through the pulmonary outflow tract. There is no murmur generated from the defect itself.

### Ventricular Septal Defect

A ventricular septal defect results in a nonholosystolic murmur at the left sternal border that usually does not radiate broadly. In cases where this is arising from a muscular defect, the murmur can virtually disappear with Valsalva.

### Innocent Murmur

The clinician will spend a lifetime determining whether or not outflow murmurs are caused by pathologic valvular heart disease or are innocent. Individuals with high flow through any valve can create enough turbulence to cause a murmur. This may be seen in individuals who are highly trained athletes or patients who are pregnant and have increased flow. Virtually all pregnant women will have aortic and/or pulmonic flow murmurs. The innocent murmur tends to be located near the sternum, is “vibratory,” does not radiate, and is not associated with any other findings to suggest organic heart disease.

### Significance of Murmurs

In determining the significance of a murmur, one must determine if it is in systole or diastole. One must also determine its location and whether or not it is reflective of aortic, pulmonic, mitral, or tricuspid disease. Similarly, the radiation of the murmur and its duration will provide clues as to whether it is innocent or caused by organic heart disease.

The loudness of the murmur is also of interest but does not always correlate with the severity of the valvular problem. The murmur loudness has been traditionally determined on a scale of 1 to 6. Grade 1 is barely audible, grade 2 readily audible, grade 3 loud, grade 4 loud of medium intensity with thrill, grade 5 loud and heard with the stethoscope partially off the chest, and grade 6 can be heard without a stethoscope. Each murmur should be judged by its loudness. There is often a discrepancy between the loudness of the murmur and the severity of the problem, however. The patient with critical aortic stenosis and a poor ventricle may have a soft murmur but have both valvular and muscular problems. A patient with wide open aortic regurgitation and high left ventricle end-diastolic pressure may have no murmur or a soft diastolic murmur depending upon its chronicity and left ventricular function.

## Other Sounds

### Pericardial Rub

Occasionally patients may present with chest pain and have a pericardial rub. A rub is generated by the epicardial and pericardial surfaces coming in contact during parts of the cardiac cycle. Traditionally the pericardial rub has three components. These are associated with blood movement in the left ventricle and include a systolic component during contraction, an early diastolic component in ventricular filling, and a late diastolic component with atrial filling. It is unusual for all three components to be heard. Before an investigator can eliminate the diagnosis of pericardial disease, he or she should listen with the patient in the supine, left lateral decubitus, and leaning forward positions. The positional nature of these sounds and the patient's complaints of pain usually help differentiate this diagnosis from others associated with valvular or myocardial disease.

### Maneuvers

Occasionally maneuvers are performed to enhance or differentiate murmurs. For instance, the best way to hear a murmur of aortic regurgitation is to have the patient lean forward, grip hands to increase outflow resistance, take a deep breath in, and then exhale. As the patient is holding his or her breath in expiration, one listens carefully for the aorta regurgitation. Placing the patient's hands behind his head also improves detection. This allows the aorta to swing forward to the chest wall, increases afterload, and diminishes respiratory related interference with auscultation. This maneuver should also be done in any individual with a prosthetic heart valve to rule out aortic regurgitation or early valve degeneration if bioprosthetic.

Elevating the patient's legs increases preload or filling of the left ventricle. This may enhance murmurs on the right side of the heart and diminish murmurs such as that aroused by hypertrophic cardiomyopathy on the left.

Inspiration (natural and not forced) may increase flow to the right side and enhance a murmur of tricuspid or pulmonary regurgitation or stenosis.

Exercise, such as sit-ups, is occasionally used to increase blood flow to enhance murmurs, particularly in mitral stenosis.

Squatting is occasionally used, particularly in congenital heart disease. Squatting is, however, a complex maneuver that simultaneously diminishes preload because of venous obstruction and increases afterload because of squatting and is often complicated by an unusual position making auscultation difficult. Therefore some tend not to perform the squat maneuver.

Valsalva can be performed to enhance underfilling of the left heart and murmur of the hypertrophic cardiomyopathy with dynamic outflow tract obstruction. This is best done by placing the examiner's hand on the patient's abdomen. The patient is instructed to push back against the clinician's

hand when the hand presses on the belly. As the hand is pressing the abdomen, the murmur is auscultated to determine whether or not it is enhanced.

### Murmur of Hypertrophic Cardiomyopathy

A patient who has a murmur that sounds like aortic stenosis in the aortic region and mitral regurgitation at the apex may have hypertrophic cardiomyopathy (HCM). This patient will have a mixed murmur and typically has a PMI that is dynamic, active, forceful, and associated with an S<sub>4</sub> gallop. Maneuvers such as the Valsalva maneuver may enhance the murmur. Similarly, these patients, if they are the one-third of those with HCM who have outflow obstruction, may have a bifid aortic pulse. As their hearts decompensate, the dynamic nature of their pulses and in fact the murmur itself may change.

### Prosthetic Heart Valves

Increasingly surgeons are using bioprostheses. These are not associated with distinct sounds until the valves degenerate, at which time they may show progressive signs of stenosis or regurgitation. Mechanical valves (Starr Edwards, St. Jude, and Bjork Shilley) do create mechanical sounds when closed and opened. Therefore depending on the position in which they are located, there may be an ejection sound into an aortic or pulmonic region or an opening sound in the mitral or tricuspid position. In the mitral or tricuspid positions, the S<sub>2</sub> opening sound intervals can be used to judge the height of the atrial pressure. Each prosthetic valve, bioprosthetic or mechanical, will have a sewing ring. The sewing ring creates turbulence in the inflow or outflow area. Depending on the size of the prostheses (smaller are louder), there will be a systolic or diastolic flow murmur. This is most marked in the aortic position. Valves must be evaluated regularly to ensure that the closing and opening sounds remain crisp and clear. Evidence of excessive endothelial ingrowth into the mechanical prosthesis will result in diminished opening and closing sounds.

### Blood Pressure

Assessing the blood pressure is a critical part of every cardiac physical examination. Specific guidelines have been addressed by the American Heart Association and should be followed. The patient should be seated comfortably, and the arm should be at the level of the heart. The patient should be quiet and calm before the pressure is taken. The cuff must be appropriate to the size of the patient's arm. The pressure in the cuff is elevated to above systolic pressure and deflated slowly. Phase 1 of the Korotkoff sounds is a tapping in systole. This is usually differentiated as systolic pressure. Phase 2 of the sounds is a soft murmur of flow and phase 3 a louder murmur. Phase 4 represents a muffled deterioration of the murmur, and phase 5 is loss

of the sound altogether. The loss of the sound is usually termed *diastole*.

If the patient has difficult auscultation of the pressures because of low output or large arms, the arm can be raised

above the head for a few seconds while the cuff is inflated. Then the arm is lowered, and the cuff is deflated as earlier. Hand grip before auscultation may enhance the sounds in systole and diastole.

## Chapter Review

### Questions

1. A 68-year-old man with a long-standing history of hypertension and stable coronary disease complains of sudden severe acute chest pain radiating to his back. The emergency medical technicians measure blood pressure in both of his arms. The systolic pressure in his right arm is 98 mm Hg, and in his left arm it is 72 mm Hg. The most likely diagnosis is:
  - A. Acute myocardial infarction
  - B. Arterial thoracic outlet syndrome
  - C. Acute pulmonary embolism
  - D. Proximal dissection of his aorta
  - E. Acute pericarditis with cardiac tamponade
2. Which one of the following is the typical auscultatory finding in mitral valve prolapse?
  - A. An opening snap in diastole
  - B. A pericardial knock in diastolic
  - C. Mid systolic to late systolic click
  - D. A third heart sound (S<sub>3</sub>)
  - E. An early systolic click
3. Match the characteristic carotid pulsation with the cardiac disorder:
  - 3.1. Jerky, with full expansion followed by sudden collapse (Corrigan or water-hammer pulse)
  - 3.2. Bifid carotid pulse with normal or delayed rise
  - 3.3. Low amplitude and volume pulse with a delayed peak
  - 3.4. Bounding and prominent pulse
  - A. Hypertension
  - B. Aortic stenosis
  - C. Aortic valve regurgitation
  - D. Combined aortic stenosis and regurgitation
4. Match the characteristic JVP abnormality with the cardiac disorder:
  - 4.1. Steep x descent
  - 4.2. Absent A waves
  - 4.3. Prominent V waves
  - A. Atrial fibrillation
  - B. Cardiac tamponade
  - C. Tricuspid regurgitation

### Answers

1. D
2. C
- 3.1. C
- 3.2. D
- 3.3. B
- 3.4. A
- 4.1. B
- 4.2. A
- 4.3. C

## Acute Coronary Syndromes

ERIN A. BOHULA

**A**cute coronary syndromes (ACS) are the result of acute myocardial ischemia occurring in the presence of coronary artery disease (CAD). The spectrum of ACS presentations includes unstable angina (UA), non-ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI) (Table 80.1). UA is a clinical diagnosis that is made when a patient reports new anginal symptoms, crescendo angina, or angina at rest. Myocardial infarction (MI) is distinguished from UA by the presence of cardiac biomarker abnormalities, which reflect myocardial necrosis. A diagnosed MI may be either a STEMI or a NSTEMI, depending on the absence or presence of ST-segment elevation on the presenting electrocardiogram (EKG).

In aggregate, ACS presentations account for over 1 million annual hospital admissions in the United States. Of all diagnosed MIs, approximately two-thirds are NSTEMI events and the remaining are STEMI events. Despite recent declines in associated mortality, CAD still causes one out of every seven deaths in the United States. Notably, half of MI-related deaths occur within the first hour, primarily caused by ventricular dysrhythmias. Therefore the presentation of ACS challenges the clinician to rapidly integrate key aspects of the history, physical examination, and diagnostic tests to correctly diagnose and effectively manage this potentially life-threatening condition.

### Pathophysiology

The pathophysiology underlying virtually all ACS is rupture or erosion of a vulnerable coronary atherosclerotic plaque. Vulnerable plaques usually cause only a mild or moderate degree of stenosis, contain a soft atherogenic lipid core, and are covered by a thin cap that can easily rupture. Conversely, stable plaques tend to be larger, less lipid laden, and covered by a thick fibrous cap. Numerous factors contribute to plaque vulnerability, including inflammation and shear stress. When a vulnerable plaque ruptures, the inner lipid-laden core is exposed to the bloodstream and activates multiple pathways leading to the rapid formation of a superimposed platelet- and fibrin-rich thrombus. This thrombus interrupts coronary blood flow, causing regional myocardial ischemia and, eventually, infarction if severe enough and

not promptly treated with reperfusion therapies. Subtotal arterial occlusion typically manifests as UA or NSTEMI, termed *non-ST-elevation ACS* (NSTEMI-ACS), whereas total occlusion of a coronary artery often manifests as STEMI (see Table 80.1).

### Diagnosis

ACS is diagnosed by integrating key aspects of the history, examination, EKG, and cardiac biomarkers (Table 80.2). During the evaluation of a patient with possible ACS, alternative cardiovascular and noncardiovascular causes of chest discomfort should always be entertained. In particular, cardiovascular conditions that can mimic ACS by presenting with chest pain and possible EKG changes include aortic dissection (with or without coronary involvement), acute pericarditis, stress cardiomyopathy, myocarditis, and pulmonary embolism.

### Clinical Presentation

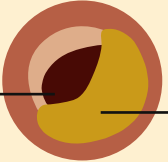

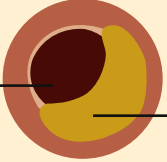

ACS can occur at any time of day and may be triggered by physiologic, physical, or emotional stress. Typical ACS symptoms include a substernal or left-sided chest discomfort, pain, or pressure that can radiate to the left arm, neck, or jaw. Accompanying symptoms may include dyspnea, nausea, vomiting, diaphoresis, lightheadedness, and palpitations. Women, older individuals, and patients with diabetes are more likely to present with atypical symptoms or experience silent MIs.

### Physical Examination

At baseline, CAD may be accompanied by signs of vascular disease in more accessible carotid or peripheral arterial beds with concomitant vascular bruits. At the time of an ACS, additional physical findings will vary depending on disease severity and associated complications. There can be an audible S<sub>4</sub> caused by impaired left ventricular (LV) compliance in the setting of myocardial ischemia. In an extensive MI, severe LV systolic dysfunction may be reflected by a palpable apical dyskinesia, soft S<sub>1</sub>, paradoxically split S<sub>2</sub>, and audible S<sub>3</sub> in addition to classic signs of heart failure (HF) (jugular venous distension, rales, and

**TABLE 80.1** Spectrum of Acute Coronary Syndromes

Definitions	Increasing Severity of Illness		
	Non–ST-Segment Elevation ACS		Myocardial Infarction
	Unstable Angina	NSTEMI	STEMI
Symptoms	New-onset angina (or equivalent); or angina worse in frequency, duration, or intensity; or angina at rest, usually <30 min		Angina (or equivalent) at rest, usually >30 min
EKG	ST depressions; or TW inversions or flattening; or normal-appearing EKG		ST elevation or equivalent
Biomarkers	Normal troponin	Elevated troponin	Very elevated troponin
Pathology	Subtotal coronary occlusion, more likely in the setting of multivessel disease with collaterals		Total coronary occlusion, more likely in the setting of single-vessel disease
			
Treatment	Immediate medical therapy ± cardiac catheterization before discharge		Immediate medical therapy and immediate reperfusion (fibrinolysis or PCI)

ACS, Acute coronary syndrome; EKG, electrocardiogram; NSTEMI, non–ST-segment elevation myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction.

**TABLE 80.2** Likelihood of ACS Based on Features of History, Examination, EKG, and Biomarkers

	High (Any of Subsequent)	Intermediate (Any of Subsequent)	Low (May Have Any or All of Subsequent)
History	Chest or left arm pain like prior angina, history of CAD	Chest or left arm pain, age >70 years, male, diabetes	Atypical symptoms
Examination	Hypotension, HF, transient MR	Evidence of extracardiac atherosclerosis (PAD or CVD)	Pain reproduced on palpation
EKG	New STD ( $\geq 0.5$ mm) or TWI ( $\geq 2$ mm)	Old Q waves, old ST or T wave abnormalities	TWF/TWI (in leads w/R waves) or normal
Cardiac biomarkers	Elevated Tn or CK-MB	Normal	Normal

ACS, Acute coronary syndrome; CAD, coronary artery disease; CK-MB, creatinine kinase MB; CVD, cerebrovascular disease; EKG, electrocardiogram; HF, heart failure; MR, mitral regurgitation; PAD, peripheral artery disease; Tn, troponin; TWF/TWI, T wave flattening or inversion.

edema). Frank cardiogenic shock can present with small volume pulses and a narrow pulse pressure in addition to classic signs of shock (cool extremities and end-organ hypoperfusion manifest as altered mental status and oliguria). Importantly, the degree of HF on examination portends a worse prognosis (Table 80.3).

Many ACS patients are hypertensive because of increased adrenergic stimulation. Conversely, hypotension

suggests the presence of peri-MI complications, in which case the examination should focus on detecting a murmur of mitral regurgitation or a ventricular septal defect (often accompanied by a palpable thrill). Severe hypotension may also be part of the specific but insensitive triad for right ventricular (RV) infarct, which includes elevated jugular venous pressure (JVP), clear lungs, and hypotension.

**TABLE 80.3 Killip Classification for ST-Segment Elevation Myocardial Infarction**

Killip Class	Examination	Mortality (30 Days)
1	No heart failure	6%
2	+S3 or basilar rales	17%
3	Pulmonary edema (rales >halfway up)	30%–40%
4	Cardiogenic shock (systolic blood pressure <90 mm Hg)	60%–80%

## Electrocardiogram

The critical diagnostic test is the 12-lead EKG, which allows the clinician to differentiate between NSTEMI-ACS and STEMI (or equivalent entities) and then to determine the most appropriate management (Fig. 80.1).

In NSTEMI-ACS, a number of EKG patterns can be seen: ST-segment depressions, T-wave inversions, nonspecific ST- and T-wave changes, and occasionally no changes at all (see Table 80.1). EKG changes that come and go in timing with chest discomfort are often called *dynamic* and are highly suggestive of ischemia. The regionality of EKG changes in NSTEMI-ACS may correspond to but are not specific for the location of a coronary lesion.

In STEMI, the classic defining criteria include acute ST-segment elevations of new ST elevation in two contiguous EKG leads:  $\geq 2$  mm (men) or  $\geq 1.5$  mm (women) in leads V2-V3 or  $\geq 1$  mm in other leads. These criteria are not only specific for the location of a coronary lesion and the area of myocardium at risk (Table 80.4), but they are also specific for the presence of an acute coronary occlusion in need of emergent reperfusion.

When there is clinical concern for a possible STEMI or STEMI-equivalent, careful evaluation of the standard 12-lead EKG may prompt nonstandard EKG acquisition. For example, the suggestion of ST-segment elevations in the inferior leads (II, III, aVF) should prompt the placement of a right-sided lead (R-V4), which can show findings more specific for an RV infarct. The suggestion of ST-segment elevations in the inferior or high lateral leads (I, aVL) or reciprocal ST-segment depressions isolated to the right-sided precordial leads (V1, V2) should prompt the placement of posterior leads (V7, V8, V9), which can reveal findings more specific for a posterior infarction. Because of its posterior location, the left circumflex artery is the one coronary territory that may suffer a total occlusion despite a “silent” or apparently normal EKG.

A new left bundle branch block (LBBB) is considered equivalent to a STEMI. The presence of an old LBBB typically interferes with the assessment of ST-segment changes. However, many would also consider an old LBBB with new ST deviations that are 1 mm concordant (in the same direction as the QRS) or 5 mm discordant (in the opposite direction from the QRS) as equivalent to STEMI.

Whereas ST-segment elevations typically represent injured myocardium, Q waves typically represent infarcted myocardium. Historically, the presence of pathologic Q waves in the distribution of a coronary territory on EKG was considered to reflect the presence of an old or recent transmural infarction. We now know that Q waves do not necessarily reflect the transmural nature of an infarct. However, the development of Q waves still suggests the presence of less prominent collaterals, a larger infarct, a lower ejection fraction (EF), and increased mortality.

## Cardiac Biomarkers

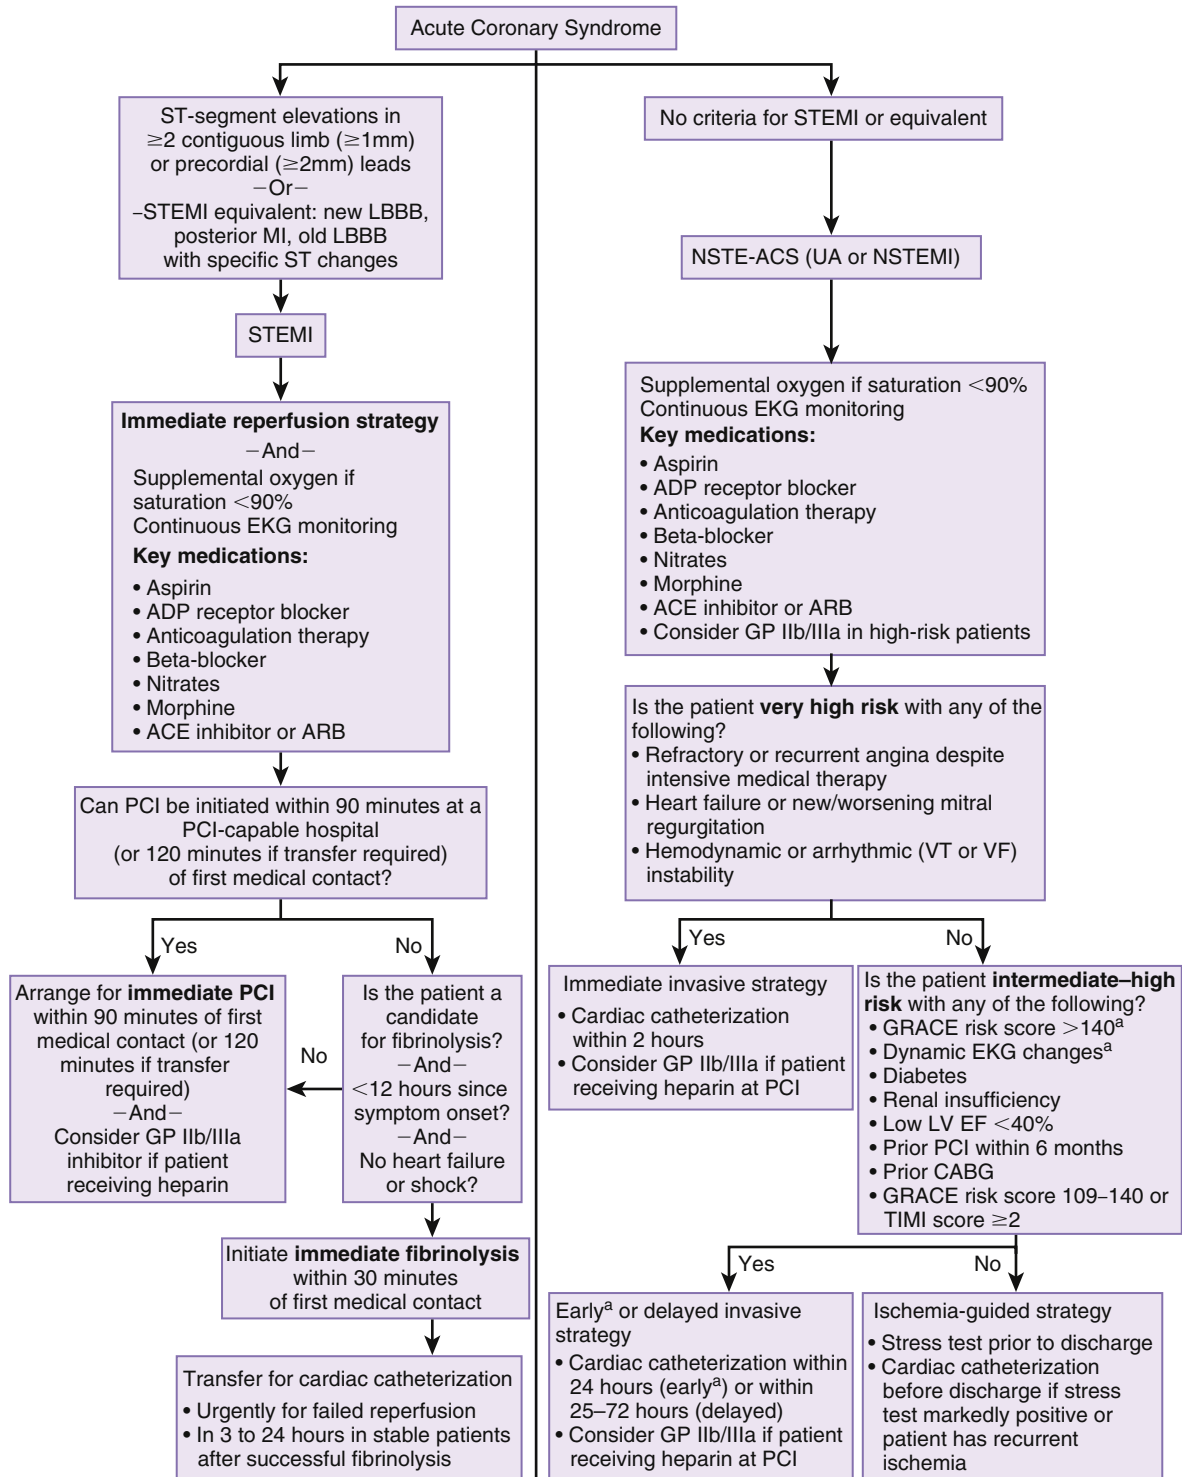

The diagnosis of MI can be made in the setting of a rise and/or fall in a cardiac biomarker with at least one value above the 99th percentile upper reference limit in combination with any of the following: ischemic symptoms, EKG evidence of ischemia or recent infarct, imaging evidence of new ischemia or infarction, and/or a new intracoronary thrombus seen by coronary angiography or autopsy (Fig. 80.2). Moreover, the specific timing and pattern of cardiac biomarker elevation following the onset of myocardial ischemia offer prognostic as well as diagnostic information (Fig. 80.3). Notably, the absolute peak as well as the combination of time to peak and duration of elevation (“area under the curve”) of cardiac-specific markers corresponds to the extent of myocardial injury, subsequent myocardial dysfunction, and overall 1-year mortality.

## Cardiac-Specific Markers

Detecting abnormally elevated cardiac-specific markers can facilitate early diagnosis of an acute MI and expedite management. Cardiac troponin I and T are proteins that originate from the cardiomyocyte apparatus and therefore are highly specific for cardiac injury when detected in the systemic circulation. Troponins start to rise within 3 hours of chest pain onset, peak within 24 to 48 hours, and return to baseline within 7 to 14 days (see Fig. 80.3). Notably, troponin levels can be elevated in the setting of renal dysfunction; thus interpretation must take this factor into account. However, in the appropriate clinical context, an elevated troponin in a patient with renal dysfunction remains a marker of poor prognosis.

Although elevations in total creatinine kinase (CK) correlate well with the extent of myocardial injury in ACS, the CK-MB isoenzyme is more specific to cardiac versus extracardiac muscle damage. CK-MB isoenzyme levels rise within 4 hours after acute injury, peak within 24 hours, and return to baseline within 48 to 72 hours (see Fig. 80.3). Because CK-MB levels normalize more quickly than troponins after an acute MI, serial CK-MB measures are more useful for the detection of post-MI ischemia and reinfarction, particularly following percutaneous coronary intervention (PCI).

Importantly, cardiac biomarkers may be negative very early in ACS (see Fig. 80.3). However, the advent of highly sensitive cardiac troponin assays has improved the diagnostic accuracy of the troponin, increasing the sensitivity of a single

<sup>a</sup>Early (within 24 hours) invasive strategy recommended in the setting of an elevated GRACE risk score or dynamic EKG changes. ACE, Angiotensin-converting enzyme; ADP, adenosine diphosphate; ARB, angiotensin receptor blocker; CABG, coronary artery bypass grafting; EKG, electrocardiogram; GP, glycoprotein; GRACE, Global Registry for Acute Coronary Event; LBBB, left bundle branch block; LV EF, left ventricular ejection fraction; MI, myocardial infarction; NSTEME-ACS, non-ST-elevation acute coronary syndrome; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; TIMI, thrombolysis in myocardial infarction; VF, ventricular fibrillation; VT, ventricular tachycardia.

**TABLE 80.4** Localization of ST-Segment Elevation Myocardial Infarction

Myocardial Region	EKG Leads With ST Elevations	Coronary Artery
Anteroseptal	V1–V4	Proximal LAD
Anterior	V3–V4	Mid-LAD
Apical	V5–V6	Distal LAD, LCX, or RCA
Lateral	I, aVL	LCX
Posterior	Posterior leads: V7–V9 (and ST depressions in V1–V2)	LCX
Inferior	II, III, aVF	RCA (~85%), LCX (~15%)
RV	V1–V2, R–V4	Proximal RCA

*EKG*, Electrocardiogram; *LAD*, left anterior descending; *LCX*, left circumflex; *RCA*, right coronary artery; *RV*, right ventricle.

**Criteria for acute myocardial infarction**

The term *acute myocardial infarction* (MI) should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischemia. Under these conditions any one of the following criteria meets the diagnosis for MI:

- Detection of a rise and/or fall of cardiac biomarker value (preferably cardiac troponin [cTn]) with at least one value above the 99<sup>th</sup> percentile upper reference limit (URL) and with at least one of the following:
  - ◆ Symptoms of ischemia
  - ◆ New or presumed new significant ST-segment–T wave (ST–T) changes or new left bundle branch block (LBBB)
  - ◆ Development of pathologic Q waves in the EKG
  - ◆ Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
  - ◆ Identification of an intracoronary thrombus by angiography or autopsy
- Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemia EKG changes or new LBBB, but death occurred before cardiac biomarkers were obtained or before cardiac biomarker values would be increased.
- Percutaneous coronary intervention (PCI)-related MI is arbitrarily defined by elevation of cTn values (>5 x 99<sup>th</sup> percentile URL) in patients with normal baseline values (≤99<sup>th</sup> percentile URL) or a rise of cTn values >20% if the baseline values are elevated and are stable or falling. In addition, either (i) symptoms suggestive of myocardial ischemia, or (ii) new ischemia EKG changes, or (iii) angiographic findings consistent with a procedural complication, or (iv) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality is required.
- Stent thrombosis associated with MI when detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall of cardiac biomarker values with at least one value above the 99<sup>th</sup> percentile URL.
- Coronary artery bypass grafting–related MI is arbitrarily defined by elevation of cardiac biomarker values (>10 x 99<sup>th</sup> percentile URL) in patients with normal baseline cTn values (≤99<sup>th</sup> percentile URL). In addition, either (i) new pathologic Q waves or new LBBB, or (ii) angiographic documented new graft or new native coronary artery occlusion, or (iii) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

**Criteria for prior myocardial infarction**

Any one of the following criteria meets the diagnosis for prior MI:

- Pathologic Q waves with or without symptoms in the absence of nonischemic causes
- Imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract, in the absence of a nonischemic cause
- Pathologic findings of a prior MI

• **Fig. 80.2** Diagnosis of myocardial infarction. *EKG*, Electrocardiogram.

sample at presentation from 75% to 90%. Moreover, serial use of highly sensitive assays increases the sensitivity at presentation to as high as 98%. Thus troponin is now considered the preferred biomarker for diagnosing ACS (see Fig. 80.2).

Conversely, positive biomarkers may not always represent a typical ACS process. A number of non-ACS cardiac

conditions can occasionally lead to myonecrosis and mildly elevated cardiac biomarkers: non-ACS coronary obstruction (e.g., spasm from Prinzmetal angina or cocaine, embolism, dissection, vasculitis); fixed atherosclerotic coronary disease with increased demand or decreased supply (e.g., tachycardia, hypovolemia, anemia, HF, aortic stenosis, or

• **Fig. 80.3** Appearance, peak, and duration of cardiac biomarker elevations after myocardial infarction. CK-MB, Creatinine kinase MB.

sepsis); and other causes of myonecrosis (e.g., myocarditis, pulmonary embolism, cardiomyopathy, cardiac trauma, or subarachnoid hemorrhage).

## Treatment

Early and appropriate risk stratification is essential for managing ACS. The critical decision point is the EKG; if ST-segment elevation (or its equivalent) is present, the patient should be treated with immediate reperfusion in addition to guideline-recommended medical therapies; if there is no ST-segment elevation (or equivalent), the patient should receive the same guideline-recommended medical therapies and then further risk stratification to decide if coronary angiography should be pursued within the next 72 hours (see Fig. 80.1).

## Basic Management

Any patient with suspected ACS should receive bed rest and continuous EKG monitoring to screen for ischemia and rhythm changes. All patients diagnosed with a probable or definite ACS should be treated in a coronary care or step-down unit, depending on the severity of the ACS. Supplemental oxygen is recommended if the oxygen saturation is <90%. In addition, a number of specific American College of Cardiology/American Heart Association recommended medications should be promptly administered (see Fig. 80.1). The general goal of these therapies is (1) to counteract platelet and thrombin activity in the involved coronary artery and (2) to improve the myocardial oxygen supply-demand mismatch caused by disrupted coronary blood flow.

Antiplatelet and antithrombin therapies are the foundation of medical treatment in ACS and should be administered at the time of initial evaluation.

- Aspirin will immediately and covalently modify cyclooxygenase-1 by acetylation, resulting in near-totally blocked thromboxane  $A_2$  production by platelets, which halts thromboxane  $A_2$ -mediated platelet aggregation. Because aspirin has utility across the entire spectrum of ACS, it should be given immediately to all suspected ACS patients.
- Adenosine diphosphate (ADP) receptor blockers inhibit the P2Y<sub>12</sub> platelet ADP receptor, thereby decreasing platelet activation and aggregation, and are indicated for all patients diagnosed with ACS. ADP receptor blockers include clopidogrel (currently the most widely used) and the third-generation agents prasugrel, ticagrelor, and cangrelor. Clopidogrel, a prodrug, is typically given with a loading dose (except for patients age >75 years receiving fibrinolysis, in whom a loading dose should be avoided) and takes 4 to 6 hours to reach steady-state platelet inhibition. Because clopidogrel is an irreversible platelet inhibitor, it is routinely held for 5 days before coronary artery bypass grafting surgery. Prasugrel is also a prodrug but is more quickly converted to its active metabolite. It has shown efficacy in the setting of patients with planned PCI and so is typically not given until the coronary anatomy has been defined and PCI is planned. In contrast, ticagrelor has a completely different chemical structure, does not require metabolic activation, and is a reversible ADP receptor blocker. Ticagrelor was found to be superior to clopidogrel for prevention of major cardiovascular events in the setting of ACS. Cangrelor, administered intravenously, is a particularly fast-acting reversible ADP receptor blocker and has been shown to reduce ischemic events following PCI for STEMI or NSTEMI-ACS.
- Anticoagulant therapy should also be given to all ACS patients. Several rapidly acting options exist including unfractionated heparin (UFH), the low-molecular-weight heparin enoxaparin, the highly selective Xa-inhibitor fondaparinux, and the direct thrombin

inhibitor bivalirudin. Long-term oral anticoagulant therapy may also be indicated for concurrent LV thrombus, atrial fibrillation, or deep venous thrombosis.

- Glycoprotein (GP) IIb/IIIa inhibitors block the final common pathway of platelet aggregation and thereby complement the antiplatelet actions of aspirin and ADP receptor blockade. There are currently three types of GP IIb/IIIa inhibitors in use: abciximab (Fab fragment of a monoclonal antibody directed at the IIb/IIIa receptor), eptifibatid (a synthetic peptide), and tirofiban (a synthetic nonpeptide molecule). GP IIb/IIIa agents are reserved for higher-risk patients with MI, particularly in the setting of heparin use during PCI.

Several antiischemic medications are available to help improve myocardial oxygen supply-demand mismatch:

- Beta-blockers reduce heart rate, blood pressure, and contractility, which effectively decrease myocardial oxygen demand while also augmenting supply. In addition to relieving pain, beta-blockers also reduce infarct size and prevent serious arrhythmias. Therefore beta-blockers should be started for suspected ACS unless contraindicated (see Fig. 80.1). The dosing goal of beta-blockers is to control resting heart rate and blood pressure while relieving ischemic signs and symptoms. Nondihydropyridine calcium channel blockers (diltiazem or verapamil) may be considered as an addition or a substitute if beta-blocker therapy is inadequate or contraindicated.
- Nitrates are vasodilators that relax coronary arteries and reduce cardiac afterload and preload, which lowers ventricular wall tension and oxygen demand. In addition, they improve blood flow to the subendocardium and through collateral vessels. Therefore nitrates should be used to treat chest discomfort and symptoms of HF unless contraindicated (see Fig. 80.1).
- Morphine is an analgesic with vasodilator properties and is recommended for refractory chest discomfort or in the presence of HF unless contraindicated (see Fig. 80.1). Anxiolytics may be used in addition to morphine to decrease anxiety in the acute setting.

In addition to the aforementioned therapies, certain additional medications can serve to optimize conditions affecting the vasculature and myocardium in the setting of an ACS. These medications effectively improve longer-term outcomes and can begin to offer benefit when started early, even within the first 24 hours:

- Angiotensin-converting enzyme (ACE) inhibitors block renin-angiotensin-aldosterone activity and, in doing so, reduce afterload and also prevent infarct expansion and remodeling. Therefore ACE inhibitors should be given to all ACS patients with HF, LV dysfunction, or hypertension and considered in all patients without contraindications (see Fig. 80.1). In this respect, angiotensin receptor blockers (ARBs) are likely equivalent and can be used as a substitute in cases of allergy to ACE inhibitors.
- Aldosterone blockers are also recommended for patients without significant renal dysfunction or hyperkalemia and who are already on therapeutic doses of an ACE

inhibitor or ARB, have an EF  $\leq$ 40%, and have either symptomatic HF or diabetes.

- Specific lipid-lowering therapies reduce recurrent events for all MI patients. Statins improve outcomes through lipid-lowering and possibly via antiinflammatory mechanisms. A high-dose statin should be started within the first 24 hours typically regardless of the patient's baseline lipid profile. A non-statin lipid-lowering therapy, ezetimibe, also reduces recurrent events when added to statin therapy following ACS.

Medications to avoid in ACS include dihydropyridine calcium channel blockers (e.g., nifedipine) and empirical antiarrhythmics, which can increase mortality in the peri-MI setting.

## Management of ST-Segment Elevation Myocardial Infarction

Rapid recognition of a STEMI is critical. The faster that normal flow can be restored to an occluded artery, the more myocardial necrosis can be prevented and the more likely that at-risk myocardium will be salvaged, LV function preserved, and MI-related morbidity and mortality decreased. On diagnosing STEMI, therefore reperfusion therapy should be performed immediately with concurrent administration of key adjunctive medical therapies (see Fig. 80.1).

### Emergent Reperfusion

The most important initial decision point in managing STEMI pertains to which method of emergent reperfusion to pursue. At a PCI-capable hospital, PCI should be performed within 90 minutes of the patient's first medical contact. PCI is also preferred if rapid transfer to a PCI-capable hospital will allow PCI to be performed within the time-sensitive goal of 120 minutes of first medical contact (see Fig. 80.1). If PCI cannot be initiated within 120 minutes, and <12 hours have passed since the onset of ischemic symptoms, then fibrinolysis should be administered within 30 minutes of first medical contact unless contraindicated (Box 80.1). In the time frame of 12 to 24 hours since symptom onset, PCI is still reasonable for treating ongoing signs of ischemia. PCI should be considered irrespective of time from symptom onset in the setting of HF or cardiogenic shock. The benefit of fibrinolysis given >12 hours after symptom onset is less clear, but it is reasonable if there are ongoing ischemic symptoms and/or persistent ST-segment elevations without PCI availability.

### Fibrinolysis

The fibrinolytic agents currently used to treat STEMI include streptokinase and the fibrin-specific agents alteplase, reteplase, and tenecteplase. Fibrin-specific agents are associated with lower mortality rates than streptokinase but also with a slightly higher risk of intracerebral hemorrhage. Concurrent antiplatelet and antithrombin therapies are required along with fibrinolysis to prevent reinfarction (see Fig. 80.1).

### • BOX 80.1 Contraindications to Fibrinolytic Therapy

#### Absolute Contraindications

Any prior ICH  
 Intracranial neoplasm or AVM  
 Ischemic CVA within last 3 months (except ischemic stroke in the last 4.5 hours)  
 Suspected aortic dissection  
 Active internal bleed (except menses)  
 Significant close-head or facial trauma in last 3 months  
 Intracranial or intraspinal surgery in last 2 months  
 Severe uncontrolled hypertension (refractory to therapy)

#### Relative Contraindications

BP >180/110 mm Hg or history of chronic severe hypertension  
 Any prior ischemic CVA, dementia, or other intracranial lesion  
 Recent internal bleed within 2–4 weeks  
 Major trauma or surgery in last 3 weeks  
 Traumatic or prolonged CPR  
 Noncompressible vascular punctures  
 Pregnancy  
 Active peptic ulcer disease  
 Oral anticoagulant therapy

*AVM*, Arteriovenous malformation; *BP*, blood pressure; *CVA*, cerebrovascular accident; *ICH*, intracerebral hemorrhage.

Fibrinolysis offers a 50% to 85% success rate at opening the occluded artery within 90 minutes and is associated with a 20% mortality reduction in patients with STEMI or new LBBB. In fact, fibrinolysis given in a timely fashion before hospital arrival is associated with an additional 17% mortality reduction. The magnitude of benefit is inversely related to the time-to-treatment, where the greatest mortality reduction is seen when fibrinolytics are given within 1 to 3 hours of symptom onset. As more time passes, the mortality benefit progressively falls. Thus fibrinolytics are recommended up to 12 hours after symptom onset; with less convincing benefit 12 to 24 hours from symptom onset.

Fibrinolytics must be avoided in patients with absolute contraindications and given only with extreme caution in patients with relative contraindications (see [Box 80.1](#)). Notably, fibrinolysis poses an overall 5% to 6% risk of major bleed and an approximate 1% risk of intracranial hemorrhage. Patients at the highest risk for bleeding complications are older, lower in body weight, female, black, hypertensive, diabetic, with a history of stroke, and receiving excess heparinization or concurrent warfarin. Although age >75 years is not a contraindication to fibrinolysis, PCI is often favored in these patients.

Approximately 20% to 30% of patients receiving a fibrinolytic fail to reperfuse and subsequently have a high mortality rate. These patients should be transferred urgently to a PCI-capable facility for rescue PCI. Hemodynamically stable patients with clinical evidence of successful reperfusion should be transferred for coronary angiography no sooner than 3 hours postfibrinolysis but ideally within 24 hours (see [Fig. 80.1](#)).

### Percutaneous Coronary Intervention

In the setting of STEMI, the goal of PCI is to quickly determine the location of the acute thrombus by cardiac catheterization and then to mechanically recannulate the occluded coronary artery. Because PCI offers greater efficacy and safety than fibrinolysis when performed by skilled operators at high-volume centers, PCI is recommended when both are available. Even transferring a patient to a primary PCI hospital may also be superior if it can be done to achieve PCI initiation within 120 minutes of first medical contact.

The major advantages of primary PCI over fibrinolysis are related to the >90% success rate at opening an occluded artery while, at the same time, conferring a lower bleeding risk. Compared with fibrinolysis, primary PCI for STEMI is associated with a 27% reduction in mortality, 65% reduction in reinfarction, 54% reduction in stroke, and 95% reduction in intracerebral hemorrhage.

Primary PCI for treating STEMI has even greater relative efficacy over fibrinolysis in the highest-risk patients presenting with acute HF, cardiogenic shock, or severe arrhythmias. For patients with peri-MI cardiogenic shock, the window for benefit for revascularization with PCI is more prolonged due to the progressive, ischemic spiral associated with shock. As such, revascularization with PCI should be pursued as soon as possible and should not be withheld due to a prolonged delay from symptom onset.

PCI is also appropriate for patients with absolute or relative contraindications to fibrinolysis (see [Box 80.1](#)). However, the major limitations of PCI include the need for appropriate facilities, skilled/experienced personnel, and the timely availability of resources, all of which are more variable in practice than in clinical trials.

Of note, the optimal degree of revascularization with PCI in patients with STEMI and multivessel disease is unclear. Complete revascularization, including culprit and nonculprit obstructive lesions, can be considered in the setting of cardiogenic shock. However, the 2013 AHA/ACC STEMI guidelines do not recommend revascularization of nonculprit lesions in patients in the absence of cardiogenic shock based predominantly on observational data that demonstrated increased mortality in patients who underwent multivessel PCI compared with culprit-only PCI. Interestingly, several recent small randomized studies have suggested a potential benefit for complete revascularization of both culprit and nonculprit, obstructive lesions during the index hospitalization for STEMI. Additional data from larger, randomized control trials are necessary to determine the optimal strategy for revascularization in these patients.

### Immediate Medical Therapies for ST-Segment Elevation Myocardial Infarction

#### Antiplatelet Agents

Aspirin remains the key antiplatelet therapy in STEMI, adding a 23% mortality reduction to the benefits of fibrinolysis. When given along with aspirin plus fibrinolysis, clopidogrel improves rates of infarct artery patency and even further decreases cardiovascular events and mortality without

increasing the risk of major bleed. Concurrent administration of prasugrel or ticagrelor with a fibrinolytic has not been studied prospectively and is therefore not recommended. For patients undergoing PCI, prasugrel or ticagrelor may be favored over clopidogrel for reducing subsequent ischemic events; however, prasugrel should be avoided in patients with prior stroke or transient ischemic attack. Cangrelor is now approved for use during PCI in patients who have not received a P2Y<sub>12</sub> inhibitor before PCI.

### Anticoagulants

Anticoagulation with UFH promotes vessel patency in STEMI when given in support of fibrinolytics. Compared with UFH, the low-molecular-weight heparin, enoxaparin, decreases risk of death or MI by 17%. Fondaparinux (a specific factor Xa inhibitor) is more effective than placebo in STEMI and appeared comparable with UFH. For STEMI patients receiving fibrinolysis, UFH, enoxaparin, or fondaparinux is therefore appropriate. For patients receiving primary PCI, UFH or enoxaparin is a reasonable choice and may be combined with a GP 2b/3a inhibitor in the setting of a large thrombus burden or inadequate P2Y<sub>12</sub> receptor antagonist loading. Alternatively, monotherapy with bivalirudin (a direct thrombin inhibitor) can be considered. Although the data are mixed, a metaanalysis found that compared with heparin-based regimens, bivalirudin decreases the risk of bleeding but may increase the risk of MI and stent thrombosis. Fondaparinux should be avoided in PCI patients given the increased risk of catheter thrombosis.

### Antiischemics

Beta-blockers given early are associated with a decrease in reinfarction by 22% and life-threatening arrhythmias by 15%. When appropriately administered, beta-blockers are also likely to reduce all-cause death. Beta-blockers should only be given orally, as opposed to intravenously, unless used to treat concurrent hypertension. Beta-blockers should not be given to patients with HF because they can precipitate cardiogenic shock. Beta-blockers should also be avoided in patients with heart block or active asthma or reactive airways disease. Nitrates are effective at relieving ischemic symptoms and treating hypertension or HF by reducing preload and afterload. Nitrates may offer a small (<5%) mortality reduction in STEMI. Morphine offers no mortality benefit but can help to relieve refractory ischemic symptoms.

### Additional Therapies

Therapeutic hypothermia improves neurologically intact survival for comatose patients presenting with STEMI and documented out-of-hospital ventricular arrest, including those patients being treated with PCI. Adding to the benefits of aspirin and beta-blockers in STEMI, ACE inhibitors reduce mortality by 7% in the short term and 26% in the long term. The greatest benefit of ACE inhibitors is seen in patients with anterior MI, EF <40%, signs of HF, or a wall motion abnormality on imaging; ARBs appear roughly equivalent in this setting. Aldosterone antagonists

are recommended for patients on therapeutic doses of an ACE inhibitor or ARB, with an EF ≤40%, and either symptomatic HF or diabetes based on improved survival. High-intensity statin therapy begins to offer benefit shortly after an acute MI and so should be started even before a lipid profile is obtained. Ezetimibe can be added to statin therapy during hospitalization to achieve further lipid lowering and a reduction in recurrent cardiovascular events.

## Management of Non-ST-Segment Elevation Acute Coronary Syndromes

NSTEMI-ACS presentations reflect an imbalance between myocardial oxygen supply and demand, typically as a result of a nonocclusive thrombus that has developed over a disrupted atherosclerotic plaque (see [Table 80.1](#)). NSTEMI-ACS can also result from dynamic coronary obstruction, conditions that involve increased oxygen demand in the setting of a fixed supply, or some combination thereof. Similar to STEMI, medical therapies for NSTEMI-ACS are aimed at counteracting thrombosis, improving supply–demand mismatch, and optimizing vascular and myocardial outcomes. However, because the coronary thrombus is usually nonocclusive, immediate reperfusion is not required often (see [Fig. 80.1](#)).

Because NSTEMI-ACS presentations encompass a wide range of disease severities with outcomes that vary accordingly, risk stratification is essential for appropriately tailoring therapy. Patients with NSTEMI-ACS who have a clinically high risk for adverse events are more likely than lower-risk patients to benefit from more aggressive interventions, such as early cardiac catheterization. Conversely, more aggressive interventions may cause more harm than good in lower-risk patients.

The Thrombolysis in Myocardial Infarction (TIMI) and the Global Registry for Acute Coronary Event (GRACE) scoring systems are validated methods for identifying high-risk versus low-risk individuals. The TIMI risk score, in particular, has gained popularity for its ease of use at the bedside and its ability to identify patients more likely to benefit from early invasive therapy or GP IIb/IIIa therapy ([Box 80.2](#)). In addition to a high GRACE or TIMI risk score, additional clinical features that identify high-risk patients with NSTEMI-ACS include refractory or recurrent angina, EF <40%, hemodynamic or arrhythmic instability, pulmonary edema or other signs of HF, diabetes, renal insufficiency, elevated cardiac biomarkers, or dynamic EKG changes (see [Fig. 80.1](#)).

### Immediate Medical Therapies for Non-ST-Segment Elevation Acute Coronary Syndromes

#### Antiplatelets

As in STEMI, aspirin is the key antiplatelet agent in NSTEMI-ACS and provides a >50% reduction in death or reinfarction with the benefit starting within 1 day of treatment. The addition of clopidogrel to aspirin provides a further 20% reduction in cardiovascular death, MI, or stroke, with a reduction in ischemic events emerging within hours following treatment.

• **BOX 80.2** TIMI Risk Score for NSTEMI-ACS, With Factors Listed According to the Mnemonic “CARDIAC”

**Assign 1 Point for Each of the Following Factors, if Present**

- C Coronary artery disease, previously documented by angiogram as  $\geq 50\%$  stenosis
- A Age  $\geq 65$  years
- R Risk factors,  $\geq 3$  of the following: family history of CAD, hypertension, dyslipidemia, diabetes, smoking
- D Deviation of the ST segments of  $\geq 0.5$  mm
- I Ischemic pain occurring  $\geq 2$  times within the last 24 hours
- A Aspirin taken within the last 7 days
- C Cardiac biomarker elevation: troponin or CK-MB

**Sum the Points (Out of a Possible 7 Total) to Determine Risk**

The higher the total TIMI risk score, the higher the risk of combined outcome of death/MI/revascularization by 14 days: score 0–1, outcome risk 5%; score 2–3, risk 8%–13%; score 4–5, risk 20%–26%; score 6–7, risk 41%. Higher-risk patients derive greater benefit from LMWH, GP IIb/IIIa, and early invasive strategy.

CAD, Coronary artery disease; CK-MB, creatinine kinase MB; GP, glycoprotein; LMWH, low-molecular-weight heparin; NSTEMI-ACS, non-ST-elevation acute coronary syndrome; TIMI, thrombolysis in myocardial infarction.

For patients going on to PCI, there is an approximate 30% reduction in post-PCI ischemic events when clopidogrel is given before PCI rather than at the time of PCI. Therefore upstream therapy with both aspirin and clopidogrel is advocated. Alternatively, in the setting of PCI, prasugrel reduces the risk of recurrent major adverse cardiovascular events compared with clopidogrel while conferring an increased risk of both nonsurgical and surgical bleeding. Similarly, in ACS patients treated with or without PCI, ticagrelor has been shown to lower the risk for recurrent major adverse cardiovascular events compared with clopidogrel, including cardiovascular mortality, whereas it slightly increases the risk of nonsurgical but not surgical bleeding. Finally, cangrelor was shown to reduce the risk of periprocedural MI, stent thrombosis, and repeat revascularization without a significant increase in severe bleeding when compared with clopidogrel. Cangrelor is now approved for use during PCI in patients who have not been treated with a P2Y<sub>12</sub> inhibitor.

GP 2b/3a inhibitors offer additional antiplatelet activity. The greatest benefit is seen in high-risk patients with positive troponins, a TIMI risk score  $\geq 4$ , and who are going for PCI. The timing of initiation of GP 2b/3a inhibitors remains controversial, with upstream therapy tending to reduce ischemic events at the cost of significantly higher bleeding.

**Anticoagulants**

Therapy with UFH, in addition to aspirin, appears to reduce death or MI by approximately one-third compared with

aspirin alone. Use of the low-molecular-weight heparin, enoxaparin, as compared with UFH, further reduces ischemic events. Therefore either UFH or enoxaparin is appropriate anticoagulant therapy in NSTEMI-ACS. Fondaparinux may be even more effective than enoxaparin at reducing mortality and is preferred in patients with an increased bleeding risk. Given its associated risk of catheter thrombosis, however, fondaparinux should be reserved for patients treated conservatively; otherwise, it should be supplemented with UFH when used around the time of PCI. In cases of high bleeding risk or heparin allergy, bivalirudin monotherapy can be used instead of combined heparin and GP 2b/3a therapy. Regardless of the chosen anticoagulant regimen, concomitant antiplatelet therapy, in the form of both aspirin and an ADP receptor blocker, should be given in a timely fashion.

**Antiischemics**

Beta-blockers are proven to prevent reinfarction and decrease mortality following any type of MI. In a threatening or evolving MI, beta-blockers even slow progression to MI by 13%. Therefore all NSTEMI-ACS patients should receive beta-blocker therapy unless contraindicated (see Fig. 80.1). A nondihydropyridine calcium-channel blocker may help to alleviate ischemic symptoms if beta-blocker therapy is inadequate or contraindicated. Although nitrates have no proven mortality benefit, they effectively improve signs and symptoms of ischemia and therefore should be given promptly when indicated. As with STEMI, morphine offers no known mortality benefit in NSTEMI-ACS but is also effective at relieving ischemic symptoms that are refractory to beta-blockers and nitrates. It is important to note that patients with refractory symptoms are best treated with urgent coronary angiography.

**Additional Therapies**

All NSTEMI-ACS patients with hypertension, diabetes, clinical HF, or low EF should receive an ACE inhibitor whenever possible. If not tolerated because of cough, the ACE inhibitor may be replaced by an ARB. Similar to STEMI, aldosterone blockade is recommended in patients on therapeutic doses of an ACE inhibitor and beta-blocker, with a low EF and diabetes or HF.

Although statins are best known for a marked approximate 30% long-term mortality reduction in CAD patients, starting intensive statin therapy early in the course of a hospitalization for ACS adds even more benefit. Initiating early therapy improves long-term treatment rates, and high-dose compared with moderate-dose therapy offers a 16% further reduction in cardiovascular events or coronary death. The benefits of early statin therapy may be seen as early as 6 weeks following NSTEMI-ACS. Therefore every patient should be on a high-dose statin within 24 to 96 hours of admission. Ezetimibe, an inhibitor of cholesterol absorption, further reduces recurrent cardiovascular events by 6% when added to statin therapy in patients stabilized after ACS.

**Cardiac Catheterization**

A risk-based provision of cardiac catheterization and revascularization is recommended for management of NSTEMI-ACS

(see Fig. 80.1). Risk stratification tools, such as the TIMI and GRACE risk scores, are used to identify patients most likely to benefit from an invasive coronary strategy as well as those where a conservative or ischemia-driven approach is more prudent.

In the invasive strategy, diagnostic coronary angiogram is pursued in an individual with suspected NSTEMI-ACS with the intent to perform coronary revascularization if the anatomy is amenable. The timing of the invasive approach includes immediate (within 2 hours) for unstable patients, early (within 24 hours) for stabilized but high-risk individuals, and delayed (within 24–72 hours) for those with intermediate risk (see Fig. 80.1). Unstable patients include those with hemodynamic compromise, sustained VT or VF, or refractory angina despite intensive medical therapy. In stabilized, high-risk patients, an early invasive strategy substantially reduces risk of recurrent MI or ischemia and modestly reduces mortality when compared with the conservative strategy. The highest-risk stabilized patients, defined by an elevated GRACE risk score of >140, dynamic EKG or biomarkers changes, or recurrent ischemia or angina, derive the greatest benefit from an early invasive strategy involving PCI within 24 hours of admission. Intermediate-risk patients, defined by an intermediate TIMI or GRACE risk score, diabetes, renal insufficiency, or LV dysfunction, can be considered for a delayed invasive approach within 24 to 72 hours.

The ischemia-guided or conservative strategy is recommended for low-risk patients (e.g., low-risk, troponin-negative women). Medical therapy should be provided and intensified, as needed, and a low-level treadmill or pharmacologic stress test is recommended before discharge. Coronary angiography is then limited to patients who ultimately fail medical therapy as evidenced by recurrent angina or who demonstrate objective evidence of recurrent ischemia (dynamic EKG changes or significant ischemia on noninvasive testing).

## Complications

Severe complications following MI are now much less frequent because of the success of modern reperfusion and adjunctive therapies. Nevertheless, they can still occur in the peri-MI period and particularly in patients who present late following a nonreperfused MI. The most severe post-MI complications (including shock, mechanical complications, and malignant dysrhythmias) are more often seen with STEMI than NSTEMI-ACS.

### Cardiogenic Shock

Although in-hospital mortality rates from cardiogenic shock complicating MI have decreased from 70% to 80% in the 1970s to approximately 40% to 60% currently, cardiogenic shock remains the major cause of death among patients hospitalized with acute MI. Most cases of peri-MI cardiogenic shock are caused by extensive LV dysfunction, which is frequently attributed to a large anterior infarction.

Alternatively, shock can be a result of severe RV infarction, which occurs in up to 40% of patients with an inferior STEMI. Cardiogenic shock may also be due to mechanical complications of anterior or inferior infarcts.

Identifying the cause of cardiogenic shock following MI is critical for determining the most appropriate management. To this end, bedside echocardiogram and right heart catheterization can be useful diagnostic tools (Table 80.5).

### Mechanical Complications

Mechanical complications result from gross disruption of myocardial tissue and typically occur 1 to 10 days following an acute MI, at which time the infarcted myocardium is still inflamed and friable. Mechanical complications most often occur in patients who present late with a large infarct in the absence of significant collateralization. The most definitive treatment for mechanical complications is emergent surgical repair (see Table 80.5).

An acute papillary muscle rupture can occur within 2 to 10 days post-MI, usually following an inferior MI caused by the single-vessel blood supply (posterior descending artery) to the posteromedial papillary muscle. Papillary muscle rupture causes acute mitral regurgitation (MR) and presents with sudden onset dyspnea, hypoxia, HF, and hypotension. The MR may not be audible on examination as a result of rapid equalization of the left atrial (LA) and LV pressures, but the diagnosis can be confirmed by echocardiogram or suggested by V waves in the pulmonary capillary wedge tracing on right heart catheterization. Patients with acute MR may be temporized briefly with an intraaortic balloon pump (IABP) or other mechanical circulatory support; however, definitive treatment with surgical repair is emergently indicated.

Ventricular septal rupture causing an acute ventricular septal defect (VSD) can occur 1 to 20 days following either an anterior or inferior MI. An acute VSD usually presents with sudden-onset dyspnea and hypotension in addition to a pansystolic murmur and palpable systolic thrill. The diagnosis is confirmed by echocardiogram and/or right heart catheterization (see Table 80.5). If associated with an inferior MI, acute VSDs have a poorer prognosis because of the typically serpiginous nature of the rupture. Similar to acute MR, patients may be temporized with mechanical support; however, definitive therapy with surgical repair, or possibly catheter-based closure, should be pursued urgently.

A ventricular free wall rupture can occur 2 to 14 days following an anterior or inferior STEMI. Elderly women are particularly at risk for free wall rupture, which can present as pseudoaneurysm, tamponade, sudden electromechanical dissociation, or death. Tamponade physiology may require immediate percutaneous pericardiocentesis before emergent surgery.

### Dysrhythmias

Fortunately, widespread beta-blocker use has reduced the frequency of life-threatening peri-MI ventricular dysrhythmias. Premature ventricular contractions (PVCs)

**TABLE 80.5** Diagnosing and Treating Cardiogenic Shock Following Myocardial Infarction

	Bedside Echo	Right Heart Catheterization				
		RA Pressure	Wedge Pressure	Cardiac Output	Other Possible Findings	Treatment
LV infarct/failure	Poor LV function	High	Very high	Very low	Loss of R voltage across anterior leads (on EKG)	Inotropes ± vasopressors, IABP or VAD, emergent reperfusion
RV infarct/failure	Dilated RV, poor RV function	Very high	Low	Very low	ST elevation in RV4–RV6 leads (on EKG)	Volume resuscitation (goal RA pressure 10–14 mm Hg) ± dobutamine, pulmonary vasodilators, emergent reperfusion
Papillary muscle rupture → MR	Severe MR	High	Very high	Very low	V waves in PCWP tracing (on RHC)	Diuretics, vasodilators, IABP/VAD, emergent surgery
Ventricular septal rupture	Septal defect	High	Very high	High	Step up of O <sub>2</sub> sat from RA to PA	Diuretics, vasodilators, inotropes, IABP/VAD, emergent surgery
Free wall rupture → tamponade	Effusion and tamponade	Very high	Very high	Very low	Equalization of end-diastolic pressures (on RHC)	Fluid resuscitation ± inotropes, ± pericardiocentesis, emergent surgery
Pulmonary embolus	Dilated RV, poor RV function	Very high	Low	Low	PA diastolic pressure in excess of wedge	Anticoagulation, emergent fibrinolysis or thrombectomy

*EKG*, Electrocardiogram; *IABP*, intraaortic balloon pump; *LV*, left ventricle; *MR*, mitral regurgitation; *PA*, pulmonary artery; *PCWP*, pulmonary capillary web pressure; *RA*, right atrium; *RHC*, right heart catheter; *VAD*, ventricular assist device.

are common in the first 24 to 72 hours and are usually asymptomatic and benign. Nonsustained ventricular tachycardia (defined as  $\geq 3$  sequential PVCs lasting for <30 seconds) can be managed by treating any persistent ischemia, normalizing electrolytes, and uptitrating beta-blocker therapy. Sustained and hemodynamically stable ventricular tachycardia (VT) can be managed with beta-blockade plus a trial of antiarrhythmics before consideration of defibrillation. Hemodynamically unstable VT or ventricular fibrillation (VF) should be treated with immediate defibrillation according to advanced cardiac life support protocols.

Ventricular fibrillation predominantly occurs within the first 48 hours and is associated with an immediate mortality of 20%. These patients have often sustained a larger infarct with a lower EF and a higher incidence of HF. Periinfarct VF always requires immediate defibrillation, along with beta-blockade plus antiarrhythmic therapy with amiodarone or lidocaine while efforts are prioritized toward urgent reperfusion. Any hemodynamically unstable ventricular dysrhythmias (VT or VF) that are refractory to antiarrhythmic therapies should be considered for VAD insertion in addition to urgent reperfusion. Furthermore, any late-occurring ventricular dysrhythmias should prompt a full evaluation for recurrent ischemia.

In general, malignant ventricular arrhythmias are more likely to occur post-MI among individuals with low EF, chronic HF, or nonsustained ventricular arrhythmias. In the absence of an indication for internal cardiac defibrillator (ICD) placement before discharge, evaluation for

future ICD placement is recommended for individuals who have a persistently low EF documented at least 40 days following the MI event. A wearable defibrillator can be considered for those with a low EF and symptomatic HF in the short term following MI before permanent ICD placement.

Bradyarrhythmias are usually seen <24 to 48 hours following MI. At the time of an acute MI, symptomatic or advanced atrioventricular block can be treated with temporary pacing as attempts at reperfusion are made. Transcutaneous temporary pacing is arguably safer in the setting of fibrinolytic therapy, but transvenous temporary pacing is more effective in patients who have sustained large infarcts and may eventually require permanent pacing.

Sinus bradycardia or second-degree Mobitz I block (Wenckebach) can be seen in patients with inferior MI. These conditions typically resolve within 2 to 3 days and respond to atropine if associated with hypotension or ischemia. New Mobitz II block and third-degree (complete) heart block are usually associated with a large MI (anterior or inferior) and require temporary pacing. New bifascicular block or alternating right bundle branch block and LBBB also require temporary pacing because of the risk of progressing to complete heart block. Although it is relatively uncommon for patients presenting with MI to eventually need a permanent pacemaker, indications include unresolved severe sinus node dysfunction and second-degree Mobitz II block with BBB and third-degree block.

## Other Complications

Pericarditis can follow any type of MI by 2 to 14 days and can present with chest discomfort, pericardial rub, and diffuse ST depressions and PR depressions on EKG. A more severe autoimmune pericarditis, also referred to as Dressler syndrome, with fever can manifest several weeks later. Post-MI pericarditis responds well to nonsteroidal antiinflammatory agents, which can include high-dose aspirin. Anticoagulation should be avoided, if possible, to prevent intrapericardial bleed.

An LV aneurysm is a noncontractile outpouching of thinned myocardium that can form in up to 5% of patients originally presenting with STEMI. Aneurysm formation typically occurs at least several days to weeks following a large transmural MI that is usually anterior in location. An anterior LV aneurysm can manifest with persistent anterior ST-segment elevations on EKG. Anticoagulation can be considered for patients with an LV aneurysm or apical dyskinesia to decrease the risk of mural thrombosis and systemic embolism. Anticoagulation is recommended for patients with a documented LV mural thrombus, although it has not yet been shown to improve survival.

## Secondary Prevention

Care following any type of MI should include risk factor modification, long-term secondary preventative therapies, and cardiac rehabilitation. Risk factor modification includes:

- Smoking cessation
- Blood pressure: recent randomized control trial data support systolic blood pressure goals of <130 mm Hg (and possibly <120 mm Hg) in patients with cardiovascular disease
- Lipid control: goal low-density lipoprotein of at least <100 mg/dL, but preferably <55 to 70 mg/dL
- Exercise  $\geq 30$  minutes daily
- Weight optimization: goal body mass index 18.5 to 24.9 and goal waist circumference <40 inches for men and <35 inches for women

## Chapter Review

### Questions

1. A severe RV infarct can typically present with which of the following features?
  - A. Normal JVP, clear lungs, hypotension, ST elevation in lead II
  - B. Elevated JVP, clear lungs, hypotension, ST elevation in lead III
  - C. Elevated JVP, clear lungs, hypertension, ST elevation in lead III
  - D. Depressed JVP, clear lungs, hypotension, ST elevation in aVF
  - E. Depressed JVP, rales halfway up the back, hypotension, ST elevation in II, III, and aVF
2. A 75-year-old woman with a history of long-standing hypertension, high cholesterol, diabetes, and former tobacco use arrives in the emergency department. She

Long-term secondary preventative therapies should include:

- Aspirin (at least 81 mg daily is recommended; even following PCI, long-term doses above 100 mg daily are likely not needed in the setting of concurrent ADP receptor blocker therapy)
- ADP receptor blocker therapy, ideally for at least 12 to 30 months (recommended uninterrupted duration of therapy depending on the type of treatment received for acute MI)
- Beta-blocker therapy
- ACE inhibitor (or ARB) therapy for all patients with LV dysfunction, hypertension, diabetes, or chronic kidney disease
- Aldosterone blockers for all patients with LV function and HF or diabetes
- Lipid-lowering therapies, including statins, ezetimibe, or PCSK9 inhibitors

The addition of very low-dose anticoagulant therapy with the oral Xa inhibitor, rivaroxaban, to dual antiplatelet therapy with aspirin and clopidogrel has been shown to decrease mortality, but it has not been approved for this indication in the United States. All patients with CAD should receive an annual influenza vaccine. In addition, all CAD patients age >65 years should receive a pneumovaccine.

A program of exercise-based cardiac rehabilitation is recommended for all patients with CAD and may be particularly beneficial for those who have just had an MI. In conjunction with proven medical therapies for secondary prevention, cardiac rehabilitation may offer added benefit with regard to quality of life, exercise tolerance, and even mortality reduction.

## Acknowledgments

The author and editors gratefully acknowledge the contributions of the previous edition authors, Drs. Susan Cheng and Marc S. Sabatine.

appears diaphoretic and is complaining of nausea. Her initial EKG shows 1.5-mm ST-segment elevations in leads III and aVF. The diagnosis is most likely:

- A. Peptic ulcer disease
  - B. Appendicitis
  - C. Acute MI most likely caused by thrombotic occlusion of the right coronary artery branch
  - D. None of the above
3. Which of the following factors is not associated with an added risk for adverse outcomes in a patient diagnosed with NSTEMI-ACS?
    - A. Presenting at age 70 years
    - B. Having a history of hypertension, high cholesterol, and diabetes
    - C. Having taken an aspirin every day for the prior 3 months

- D. Having a prior history of pneumonia
  - E. Having ST-segment depressions of 0.5 mm in leads V5 and V6
4. Which of the following factors would disqualify a patient with STEMI from being eligible for fibrinolytic therapy at a PCI-capable hospital?
- A. Presenting within 2 hours of symptom onset
  - B. Presenting within 10 hours of symptom onset
  - C. Lack of resources to perform a PCI within 90 minutes of first medical contact
  - D. History of a 1-cm intracranial arteriovenous malformation diagnosed 9 months ago
  - E. Active menstruation
5. A 72-year-old woman presents with dyspnea, a blood pressure of 95/50 mm Hg, ST-segment elevations in V2 through V5, and bilateral pulmonary edema on chest x-ray. She becomes more hypotensive as well as progressively obtunded and requires intubation. Arrangements

for emergent PCI are being made. A bedside echocardiogram shows a severely depressed EF, an extensive anterior wall motion abnormality, and mild MR. Which of the following medicines should be avoided in this patient?

- A. Aspirin
- B. Beta-blocker
- C. Unfractionated heparin
- D. GP 2b/3a inhibitor
- E. High-dose statin

## Valvular Heart Disease

CHRISTIAN T. RUFF AND PATRICK T. O'GARA

Valvular heart disease is frequently encountered in clinical practice. The prevalence of moderate-to-severe valvular heart disease in the United States is estimated to be 2.5% and increases significantly with age for both men and women. Whereas rheumatic disease remains a public health issue in many developing countries, degenerative diseases such as those associated with myxomatous replacement and calcification predominate in industrialized countries. The physiologic importance of valvular heart disease relates to its effects on cardiopulmonary performance. Symptom onset equates with a distinct change in natural history. The development of atrial fibrillation (AF), ventricular remodeling, hypertrophy, and/or pump dysfunction impacts long-term survival. Diagnosis is most commonly triggered by the appreciation of a heart murmur, following which a decision is made regarding the need for echocardiography for further assessment. Many heart murmurs are benign and need not prompt additional testing. Institution of medical therapy to ameliorate symptoms or prevent complications, such as the use of anticoagulation, should be coupled with an appraisal of the indications for surgical or transcatheter intervention. An integrated understanding of natural history based on the severity of the valve lesion within the context of individual patient comorbidities is the foundation for appropriate clinical decision-making. We review here the major valve lesions; treatment and prevention of infective endocarditis (IE) are covered elsewhere.

### Mitral Stenosis

#### Etiology and Pathology

Two-thirds of all patients with mitral stenosis (MS) are women. MS is predominantly rheumatic in origin and rarely congenital. Often, there is coexistent mitral regurgitation (MR) and/or aortic valve disease. The incidence of MS has declined in developed nations because of a reduction in the incidence of streptococcal-mediated acute rheumatic fever, but it remains a major problem in developing nations. Less common causes include severe mitral annular calcification with leaflet involvement, a large left atrial (LA) myxoma, and congenital deformity of the valve apparatus.

The pathology of rheumatic MS involves thickening and scarring of the leaflets with fibrous tissue replacement and calcification. Fusion of the commissures and involvement of the subvalvular apparatus with fusion and foreshortening of the chordae tendineae result in a rigid, narrowed, funnel-shaped valve with a “fish-mouth” appearance. Thrombi may form on the calcified valve itself but most often develop within the LA appendage or directly on chronically inflamed mural endocardium.

#### Pathophysiology

In normal adults, the cross-sectional area of the mitral valve (MV) is 4 to 6 cm<sup>2</sup>. Significant obstruction with alteration of hemodynamic function begins to occur when the orifice is reduced to 2 cm<sup>2</sup> (mild MS). Severe MS results when the MV opening is reduced to less than 1.5 cm<sup>2</sup>. When MS becomes significant, LA pressure rises to maintain normal cardiac output. Chronically, this increase in LA pressure will lead to elevated pulmonary venous and arterial pressures, with a reduction in pulmonary compliance. Pulmonary artery hypertension results in right ventricular enlargement, secondary tricuspid regurgitation (TR), and pulmonic regurgitation (PR), as well as right-sided heart failure.

#### Symptoms

The latent period between acute rheumatic carditis and the development of symptoms is variable but generally about two decades. The initial symptoms are predominantly exertional dyspnea and fatigue, reflecting elevated LA/pulmonary artery (PA) edge pressures and reduced cardiac output. Before the development of mitral valvotomy (see later), death usually occurred within 2 to 5 years from onset of symptoms. Symptoms are precipitated when a stressor causes LA pressures to rise acutely. Examples of such triggers include exercise, infection, anemia, rapid AF or other tachycardia, pregnancy, and thyrotoxicosis. As MS progresses, lesser degrees of stress can precipitate symptoms. Symptoms and signs of left-sided heart failure (e.g., orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema) can occur. Atrial arrhythmias, particularly AF, occur with increasing

frequency as MS severity worsens. Pulmonary infections (bronchitis and pneumonia) are common, especially in the winter months. Systemic and pulmonary emboli (frequently from the enlarged atrial appendages of patients in AF) are an important cause of morbidity and mortality. Hemoptysis may occur with pulmonary infarction, pulmonary edema, pneumonia, or rupture of an engorged bronchial vein into the airway. With bronchial venous rupture, the sputum is bright red and not blood tinged. Bleeding of this nature is very rare and usually subsides spontaneously.

### Physical Examination

Inspection may be completely normal, but in some patients with severe MS, a malar flush with pink/purplish telangiectasias may be observed. Patients in AF will have an irregular pulse. If severe pulmonary hypertension is present and the patient is in sinus rhythm, prominent *A* waves can be seen in the jugular venous waveform caused by vigorous right atrial systole. Large *V* waves indicate TR. Palpation may reveal a parasternal lift or tap caused by an enlarged or pressure-overloaded right ventricle (RV). Stigmata of right-sided heart failure (hepatomegaly, ascites, pleural effusion, peripheral edema) are observed with chronic, severe MS that has led to PA hypertension and RV decompensation. A loud and slightly delayed first heart sound (*S*<sub>1</sub>) is heard in the early stages of the disease. Its intensity diminishes as the valve becomes more calcified and rigid. The intensity of the pulmonic component (*P*<sub>2</sub>) of the second heart sound (*S*<sub>2</sub>) increases as PA pressures rise. The opening snap (*OS*) is heard best when listening over the apex in the left lateral decubitus position in expiration and is followed by a low-pitched, rumbling, diastolic murmur. The time interval between *S*<sub>2</sub> and the *OS* is inversely related to the height of the LA pressure. The *OS* fades as the valve becomes less pliable with time. Presystolic accentuation of the diastolic rumble can be appreciated in some patients in sinus rhythm but is not present once AF intervenes.

### Laboratory Evaluation

The electrocardiogram (EKG) may show AF, LA enlargement, or signs of RV hypertrophy (RVH). On chest x-ray (CXR), there may be straightening of the left-heart border and prominence of the pulmonary arteries. Kerley B lines are present when marked elevations in LA pressure result in chronic interstitial pulmonary edema. Transthoracic echocardiography (TTE) is the most sensitive and specific noninvasive imaging test for the diagnosis and assessment of MS. The evaluation should provide information regarding the morphologic appearance of the MV apparatus, peak and mean pressure gradients, MV area, presence of MR or other valvular pathology, estimated PA systolic pressure, and ventricular function. The findings can be used to determine suitability for percutaneous mitral balloon valvotomy (PMBV); left- and right-heart catheterization is useful when there is a discrepancy between the clinical and TTE

findings. Transesophageal echocardiography (TEE) is necessary to exclude LA thrombi before undertaking PMBV.

### Treatment

Prophylaxis for prevention of IE is no longer recommended in the absence of a history of previous IE. Prophylaxis for secondary prevention of rheumatic fever should be provided according to current guidelines. Symptomatic patients benefit from oral diuretics and sodium restriction. If AF is present, beta-blockers, nondihydropyridine calcium antagonists, and digitalis glycosides help provide rate control. Anticoagulation with warfarin is indicated if AF is present and/or in any patient with a prior embolic event or known LA thrombus. Non-vitamin K antagonist oral anticoagulants are not currently indicated for patients with moderate-to-severe rheumatic MS.

Mitral valvotomy can be performed surgically or percutaneously with a balloon and is indicated in symptomatic patients with isolated severe MS (valve area less than 1.5 cm<sup>2</sup> or 1.0 cm<sup>2</sup>/m<sup>2</sup> body surface area). PMBV may be considered in symptomatic patients with mild or moderate MS (valve area greater than 1.5 cm<sup>2</sup>) and a pulmonary capillary wedge pressure >25 mm Hg with exercise, when no other cause for symptoms can be identified. Ideal patients for PMBV have relatively mobile, thin leaflets without extensive calcification, subvalvular thickening, or significant MR, as assessed by TTE. An echo score derived from an integrated assessment of leaflet thickening, calcification, and mobility, as well as extent of subvalvular disease, provides a method to identify which patients would predictably benefit from a transcatheter approach. A score of ≤8 is considered favorable, and long-term results in appropriately selected patients are comparable with those achieved with surgery but with less morbidity and lower periprocedural mortality. A surgical approach (repair or replacement) is necessary in patients with significant MR, persistent LA thrombus, and those with an MV that has undergone prior transcatheter or operative manipulation (Table 81.1).

## Mitral Regurgitation

### Etiology and Pathology

MR is caused by a myriad of conditions that may affect the leaflets, annulus, chordae tendineae, papillary muscles, or subjacent left ventricular (LV) myocardium. Primary MR refers to disease affecting the leaflets and/or chordae (prolapse, flail, endocarditis, rheumatic disease, radiation, congenital cleft), whereas secondary or functional MR refers to disease affecting the ventricle and/or annulus (ischemic cardiomyopathy, idiopathic dilated cardiomyopathy, hypertrophic obstructive cardiomyopathy, AF). In secondary MR, the valve itself is really an innocent bystander, and long-term prognosis is more intimately related to underlying LV function.

**TABLE 81.1** Management of Mitral Stenosis**Medical Management**

Rheumatic fever prophylaxis for appropriate patients

Rate or rhythm control and anticoagulation for atrial fibrillation

Diuretics and sodium restriction when indicated by dyspnea and heart failure

**Percutaneous Mitral Balloon Valvotomy (PMBV)**

Favorable valve morphology		Symptoms + MVA $\leq 1.5$ cm <sup>2</sup>
		or
Absence of left atrial thrombus	+	Asymptomatic + MVA $\leq 1.5$ cm <sup>2</sup> + new onset AF
		or
		Asymptomatic + very severe MS (MVA $< 1$ cm <sup>2</sup> )
		or
Absence of moderate/severe MR		Symptoms not attributable to another cause + MVA $> 1.5$ cm <sup>2</sup> + PCW pressure $> 25$ mm Hg with exercise

**Mitral Valve Surgery (Repair or Replacement)**

Not a candidate for PMBV	+	Symptoms + MVA $\leq 1.5$ cm <sup>2</sup>
--------------------------	---	---

AF, Atrial fibrillation; MS, mitral stenosis; MR, mitral regurgitation; MVA, mitral valve area; PCW, pulmonary capillary wedge; PMBV, percutaneous mitral balloon valvotomy.

**Pathophysiology**

It is important to recognize the pathophysiologic differences between acute and chronic MR. In acute severe MR, a significant volume load is delivered into an unprepared and relatively noncompliant LA, resulting in a significant rise in LA pressure and symptoms and signs of pulmonary edema. In chronic severe MR, the LA enlarges gradually, and its compliance characteristics are maintained. LA pressure does not rise precipitously, and the volume overload may be well tolerated for many years. Eventually, however, the LV dilates, and its contractile performance declines, leading to hemodynamic derangements and symptoms of heart failure. The natural history of the disease may be punctuated by AF or some other insult (chordal rupture, myocardial infarction [MI], IE, etc.) with more abrupt clinical deterioration (acute on chronic MR).

**Symptoms**

Acute severe MR may develop in the setting of an acute MI, IE, or blunt chest wall trauma. Symptoms are related

chiefly to the resultant pulmonary edema and include severe dyspnea, air hunger, restlessness, diaphoresis, and apprehension. Early symptoms with chronic severe MR include fatigue and decreased exercise tolerance because of the progressive reduction in forward cardiac output. Eventually, symptoms of pulmonary congestion, orthopnea, and exertional dyspnea will develop.

**Physical Examination**

With acute severe MR, the LV apical impulse is hyperdynamic but neither displaced nor enlarged. A left parasternal pulsation transmitted from systolic LA expansion may be felt. The systolic murmur is of relatively short duration, decrescendo in its configuration, and of grade 3 or less intensity. It is best heard at the apex or toward the left lower sternal border. These characteristics derive from the rapid rise in LA pressure and the continued decline in the pressure gradient between the LV and LA during the first half of systole. The murmur may not be audible in a ventilated patient with a large chest. In chronic severe MR, the LV impulse may be enlarged and displaced laterally. A loud S2 suggests pulmonary hypertension. The murmur may be holosystolic in timing and plateau in configuration. Radiation of the murmur reflects the direction of the MR jet. With central MR, the murmur typically radiates into the axilla. In patients with posterior leaflet prolapse or flail, the jet is directed anteriorly, and thus the murmur radiates to the base, where it may masquerade as aortic stenosis (AS). Anterior leaflet prolapse or flail is associated with a posteriorly directed jet and a murmur that can be heard in the axilla or back. There is great individual variability. Mitral valve prolapse (MVP) may be accompanied by a nonejection click, heard after the onset of the carotid upstroke. With severe MR, a short diastolic filling complex may be heard, comprising a third sound followed by a low-pitched murmur, and is attributable to enhanced, rapid LV filling. Bedside maneuvers are often used to help identify a systolic murmur as mitral in origin. With hand grip and an increase in LV afterload, the MR murmur becomes louder. The click and murmur of MVP move closer to S1 with rapid standing from a squatting position, as LV preload is abruptly decreased. With squatting, the click and murmur move away from S1, signifying the later onset of leaflet prolapse with increased LV preload. The midsystolic murmur associated with hypertrophic obstructive cardiomyopathy behaves in a similar fashion.

**Laboratory Evaluation**

EKG signs of LA enlargement should be sought in the presence of sinus rhythm. AF occurs commonly in patients with chronic severe MR and often marks the onset of symptoms. Increased LV voltage owing to eccentric hypertrophy is also often observed in patients with chronic severe MR. The CXR may show evidence of LA or LV enlargement,

depending on the clinical context and chronicity of the MR. With acute severe MR, there is often dense alveolar pulmonary edema despite a normal heart size. On rare occasion, the edema may be asymmetric and follow the course of the regurgitant jet into one or the other upper lobe pulmonary veins (right > left). Pulmonary venous redistribution and Kerley B lines are indicative of chronically elevated left-sided filling pressures. TTE is indicated to define the mechanism and severity of the MR, assess chamber sizes and ventricular function, and estimate PA pressures. The findings often dictate the timing of surgery. Serial TTE studies are an important component of longitudinal follow-up. TEE may be needed for greater clarification of the anatomic and physiologic findings in some patients. Three-dimensional TEE is usually reserved for intraoperative assessment and surgical planning. Cardiac MRI can be used to provide an accurate and semiquantitative assessment of MR severity in patients with suboptimal echocardiographic studies. Left-heart and right-heart catheterization is pursued when there is a discrepancy between the clinical and noninvasive findings. Routine coronary angiography before anticipated surgery can be performed invasively or using CT techniques. The clinical context might also dictate the need for invasive angiography, as for example, with post-MI acute MR or chronic, ischemic MR.

## Treatment

Surgery is required for treatment of acute severe MR (Box 81.1). The type of operation is dictated by the anatomic findings and the presence or absence of coronary artery disease (CAD). Repair is preferred over replacement whenever possible in patients with primary MR given its more favorable effect on LV function, lesser need for anticoagulation, and greater preservation of native valve tissue. Temporizing medical measures include diuretics for pulmonary congestion, sodium nitroprusside for rapid preload and afterload reduction, inotropic therapy as required, and intraaortic balloon counterpulsation if needed. Management of chronic primary MR is focused on early identification of the indications for elective surgery in appropriate candidates, including onset of symptoms, LV ejection fraction (EF)  $\leq 30\%$ , and/or LV end-systolic dimension  $\geq 40$  mm. Surgery is also reasonable in asymptomatic patients with PA hypertension or recent-onset AF. Some authorities advocate surgery for patients with severe MR who have none of these other indications provided there is a high likelihood of successful and durable repair at low-operative risk in experienced hands. Transcatheter repair of primary MR is restricted to patients with New York Heart Association class III/IV symptoms who are not considered candidates for surgery. Vasodilators are not indicated in the absence of systemic hypertension or LV systolic dysfunction. Rhythm management is similar to that for patients with MS; anticoagulation is provided once AF intervenes. Treatment of angina for patients with ischemic MR follows standard principles.

### • BOX 81.1 Primary Mitral Regurgitation: Indications for Surgery

- Symptomatic patients with severe MR and EF  $>30\%$
- Asymptomatic patients with severe MR and LV dysfunction (EF  $<60\%$  and/or LV end-systolic dimension  $\geq 40$  mm)
- Asymptomatic patients with severe MR and recent onset AF or PA HTN
- Asymptomatic patients with severe MR, normal LV function, no AF, no PA HTN if successful repair can be done with low operative morbidity and mortality by experienced surgeon
- MV repair preferable to MV replacement when anatomically feasible

AF, Atrial fibrillation; EF, ejection fraction; LV, left ventricular; MR, mitral regurgitation; MV, mitral valve; PA HTN, pulmonary arterial hypertension.

Patients with severe secondary MR are offered surgery (either repair or replacement depending on the aggregate findings) only after medical therapy has failed. Surgery may ameliorate heart failure symptoms but has not been shown to extend survival compared with optimal medical therapy. Surgery for moderate degrees of secondary MR is controversial.

## Mitral Valve Prolapse

### Etiology and Pathology

MVP occurs in 1% to 2% of the general population with a female predominance and has a variable clinical course. The etiology is most often related to myxomatous replacement of mitral leaflet tissue. MVP occurs in patients with Marfan syndrome and similar connective tissue diseases but most often develops spontaneously. Two types of myxomatous change are described: fibroelastic deficiency (classic MVP) and Barlow disease, which refers to an extreme form of leaflet redundancy and billowing. Myxomatous MV disease is by far the most common cause of MR for which surgery is required.

### Pathophysiology

Prolapse is defined by the superior displacement of one or both MV leaflets above the annular plane at end systole. Lack of leaflet coaptation leads to MR, the severity of which can worsen with chordal rupture, flail, and/or annular dilatation. The MR is usually eccentric and directed opposite to the involved leaflet. With bileaflet prolapse, the MR can be central or eccentric. Changes in LA and LV size and function follow along the same course as expected for MR of other etiology.

### Symptoms

The clinical course is frequently benign. Patients may experience premature ventricular or atrial contractions and paroxysmal supraventricular (including paroxysmal

atrial fibrillation) and ventricular tachycardia, precipitating palpitations, lightheadedness, or syncope. Sudden death is very rare. Patients may report chest pain, although the mechanism is unclear. A variety of other disorders have been associated with MVP, including migraine, stroke, transient ischemic attacks, hypercoagulability, and panic, although a cause-and-effect relationship has not been consistently established. Many patients have hypermobile joints, thoracic spine disease, or inguinal hernias. IE can be the presenting illness.

### Physical Examination

Classically, auscultation reveals a mid-to-late systolic click murmur complex best heard at the lower left sternal border or apex. The changes in the timing of the click and murmur with standing and squatting as previously described are useful adjuncts to correct bedside diagnosis.

### Laboratory Evaluation

The EKG is usually unremarkable but may show biphasic or inverted T waves in the inferior and apical leads. The diagnosis is confirmed with TTE, which also allows characterization of MR severity, ventricular function, and suitability for valve repair if indicated. TEE can provide superior visualization if needed for clinical decision making.

### Treatment

Most patients do not require any specific therapy. Treatment of symptomatic arrhythmias may be required, and often beta-blockers will be of use. Indications for MV repair are as discussed previously. Posterior leaflet repair is technically easier and more durable than anterior or bileaflet repair. The latter often requires construction of neochordae and/or chordal transposition. Posterior leaflet repair should be feasible in >95% of patients with this anatomy.

## Aortic Stenosis

### Etiology and Pathology

Bicuspid aortic valve and its congenital variants (e.g., unicuspid valve) are now recognized as the most common causes of AS requiring valve replacement surgery. Bicuspid disease is often familial and may be accompanied by an aortopathy characterized by root or ascending aortic aneurysm disease in up to 30% of patients. Coarctation occurs less frequently. Age-related calcific degeneration of a trileaflet valve is the second most common cause of AS. Rheumatic disease is rarely encountered in developed countries. Degenerative valve disease and atherosclerosis share several common risk factors, histopathologic characteristics, and pathogenetic traits. In older adults with AS, the prevalence of significant CAD exceeds 50%.

### Pathophysiology

The obstruction to LV outflow produces a systolic pressure gradient between the LV and the aorta. Concentric LV hypertrophy develops gradually in response to the pressure overload to normalize wall stress. Initially, cardiac output is preserved, and LV chamber dimensions are preserved. Diastolic performance is altered by the hypertrophy and interstitial fibrosis; LV diastolic pressure is increased. Ultimately, with unrelieved obstruction of sufficient magnitude, LV pump failure occurs with dilation of the cavity and reduction in cardiac output, a phenomenon known as afterload mismatch. Severe AS is defined by a valve area of  $<1 \text{ cm}^2$ . In the presence of normal LV systolic function, severe AS is also characterized by a peak transvalvular jet velocity of  $\geq 4 \text{ m/s}$  and mean valve gradient of  $\geq 40 \text{ mm Hg}$ .

### Symptoms/Natural History

Symptoms are rarely present until the valve obstruction is severe because of the ability of the hypertrophied LV to maintain a normal stroke volume. Although the rate of progression of AS varies among individual patients, longitudinal echocardiographic studies have suggested an average increase in mean gradient of  $7 \text{ mm Hg}$  per year and decrease in valve area of  $0.1 \text{ cm}^2$  per year. Both the peak jet velocity and the severity of valve calcification are predictive of event-free survival. The cardinal symptoms of AS are exertional dyspnea, angina, and syncope. Although these symptoms are usually not apparent in patients with degenerative, trileaflet AS until the sixth to eighth decade, an insidious history of decreasing exercise tolerance and fatigue is often elicited, as may also be the case with younger patients with bicuspid disease. Symptoms or signs of more advanced left- or right-heart failure are ominous.

The natural history of untreated severe AS has been well documented. The average time to death from the onset of angina, syncope, and dyspnea are 5 years, 3 years, and 2 years, respectively. Heart failure and ventricular arrhythmias are the most common causes of death. Sudden death as the manifestation of severe AS in adult patients is very rare.

### Physical Examination

The carotid or brachial artery pulse is characteristically reduced in amplitude and rises slowly to its peak (*pulsus parvus et tardus*), although arterial wall stiffening may mask this finding in the elderly. LV hypertrophy can be detected by a forceful, sustained apical impulse. A systolic thrill present at the base of the heart that tracks along the carotid arteries suggests significant stenosis. As AS progresses, LV systole is prolonged, moving the closure of the aortic valve (A2) closer to that of the pulmonic valve (P2). Eventually, A2 becomes inaudible and S2 single. Paradoxical splitting of S2 may also occur. An S4 is invariably

present in sinus rhythm secondary to LV hypertrophy. An S3 signifies elevated LV end-diastolic pressures in a dilated ventricle. The murmur of AS is typically a loud (at least grade III or IV) diamond-shaped ejection murmur that begins after S1 and is heard best at the base of the heart in the right second intercostal space with radiation to the carotid arteries. Note that in patients with severe stenosis and LV failure, the murmur may be soft and brief caused by reduced transvalvular flow rates. A systolic ejection click is audible in many young patients with bicuspid disease. A diastolic murmur of aortic regurgitation (AR) signifies mixed disease.

### Laboratory Evaluation

The EKG commonly shows LV hypertrophy with associated repolarization abnormalities (LV strain pattern) although there is no association between EKG findings and severity of obstruction. The CXR may be unremarkable. Calcium in the region of the aortic valve should be assessed on the lateral film. Dilatation of the ascending aorta may signify aneurysm. Signs of aortic coarctation should be sought in young patients with bicuspid disease. TTE is essential in the diagnosis and management of AS. Leaflet number, morphology, calcification, and excursion are noted. Measurement of the transaortic valve velocity with continuous wave Doppler can be used to estimate AS severity. Severe AS is defined by a valve area  $<1 \text{ cm}^2$  whereas moderate AS is defined by a valve area of 1 to  $1.5 \text{ cm}^2$  and mild AS by a valve area  $1.5$  to  $2 \text{ cm}^2$ . LV size and function are important in clinical management, as is the presence or absence of concomitant ascending aorta dilatation. Dobutamine stress echocardiography is useful for evaluation of patients with AS and severe LV systolic dysfunction. Left-heart catheterization and coronary angiography are routinely performed in older adult patients with severe AS referred for surgery or in patients with AS and symptoms of myocardial ischemia.

### Treatment

The medical treatment is quite limited, and AS should be thought of as a surgical disease (Box 81.2). Patients with severe AS should be advised to avoid strenuous physical activity and dehydration.

When heart failure is present, sodium restriction and the cautious administration of diuretics are indicated, but care must be taken to avoid volume depletion, which can cause a dangerous and potentially fatal decline in cardiac output. The critical management decision is the timing of surgical referral for aortic valve replacement (AVR). Surgery is indicated in symptomatic patients with severe AS (valve area  $1 \text{ cm}^2$  or  $0.6 \text{ cm}^2/\text{m}^2$ ). In asymptomatic patients with severe AS, surgery is indicated if LV dysfunction (defined by an EF of less than 0.5) is present. The operative risk is considerably higher, and long-term

## • BOX 81.2 Management of Aortic Stenosis

### Clinical Indicators of Severe Aortic Stenosis

#### Cardinal Symptoms

- Exertional dyspnea
- Angina
- Syncope

#### Physical Examination

- Carotid pulse weak with slow rise (*pulsus parvus et tardus*)
- Late-peaking diamond-shaped systolic murmur with single S<sub>2</sub>

#### Transthoracic Echocardiography

- Valve area  $<1 \text{ cm}^2$
- Mean gradient  $>40 \text{ mm Hg}$
- Jet velocity  $>4 \text{ m/s}$

### Indications for Aortic Valve Replacement

- Symptoms + severe AS
- Severe AS + undergoing CABG, surgery on aorta, or replacement of another valve
- Severe AS + LV dysfunction (EF  $<50\%$ )
- Moderate AS + other cardiac surgery (such as CABG)

AS, Aortic stenosis; CABG, coronary artery bypass grafting; EF, ejection fraction; LV, left ventricular.

survival is diminished in patients with significant LV systolic dysfunction, so it is imperative to intervene before this advanced stage. Aortocoronary bypass grafting is performed with AVR in patients with coexisting CAD. AVR can be considered for treatment of moderate AS (valve area  $1$ – $1.5 \text{ cm}^2$ ) when surgery is performed for another indication (such as coronary artery bypass grafting [CABG]).

Transcatheter AVR (TAVR) can be undertaken in appropriately selected patients at prohibitive, high, or intermediate surgical risk, as defined by the Society for Thoracic Surgeons predicated risk of mortality score in combination with a multidisciplinary team assessment of anatomic and medical comorbidities, including frailty. Although TAVR has proven transformative, the associated risks of procedural stroke, pacemaker therapy, and long-term paravalvular AR must be acknowledged. Valve durability through at least 5 years of follow-up is acceptable, but early reports have surfaced of valve degeneration at the 7-year mark. The decision between surgical versus TAVR for treatment of severe symptomatic AS is best made by the heart team as informed by patient values and preferences.

Percutaneous aortic balloon valvuloplasty is commonly performed in children and young adults with congenital AS and pliable valve leaflets without significant AR. It is not nearly as successful in adults because of high procedural morbidity and excessive rates of restenosis but may have a role as a temporary bridge to AVR in patients with significant comorbid conditions or shock. It is performed routinely as a part of the TAVR procedure.

## Aortic Regurgitation

### Etiology and Pathology

AR is caused by primary aortic valve and/or root disease. Valvular AR may be caused by congenital bicuspid disease, myxomatous disease with prolapse, IE, or rheumatic disease. Aortic root disease leads to AR because of annular enlargement or deformation with subsequent impairment of leaflet coaptation. Causes of aortic root disease include hypertension, cystic medial degeneration (as seen with Marfan syndrome), inflammatory aortitis (ankylosing spondylitis, Reiter syndrome), and acute aortic dissection. Syphilitic aortitis is rarely seen in the current era.

### Pathophysiology

In acute severe AR, the unprepared LV operates on the steep portion of its diastolic pressure-volume relationship. LV diastolic pressure rises rapidly, and pulmonary edema ensues. Forward LV stroke volume is compromised, and the heart rate increases to maintain cardiac output. The rate of rise of LV pressure dictates that the diastolic murmur is of short duration and relatively low intensity. With chronic AR, the LV undergoes compensatory dilatation and eccentric hypertrophy, which allow the preservation of a normal, effective, forward stroke volume, EF, and systolic performance. Chronic AR is a state of excess preload and afterload. Eventually, afterload mismatch or preload exhaustion will occur to the extent that LV function will decline and symptoms develop.

### Symptoms

Patients with acute severe AR present with profound dyspnea, weakness, and signs of shock. Other symptoms or signs may provide clues as to the etiology of the AR, such as severe chest pain in patients with aortic dissection or fever and embolic phenomena in patients with IE. Patients with chronic AR may remain asymptomatic for years. Palpitations are common and usually attribute to isolated premature beats. Eventually, uncorrected chronic severe AR will lead to dyspnea as a manifestation of LV dysfunction. Anginal chest pain may occur in the absence of epicardial vessel atherosclerosis caused by inadequate coronary driving pressure in the face of excess demand. Angina, orthopnea, and paroxysmal nocturnal dyspnea are all indicative of important LV compromise for which urgent intervention is warranted.

### Physical Examination

The examination findings in acute severe AR are often subtle and can be easily missed. They include a soft S1 (because of premature close of the MV); a short, soft, diastolic murmur; and the absence of signs of severe diastolic

runoff. The systolic blood pressure is not elevated, and the diastolic blood pressure does not reach the low levels seen with chronic AR. Therefore the pulse pressure in acute AR may not be appreciably widened. The eponymous findings in chronic AR have been the subject of many textbooks on cardiology. Classic findings include systolic hypertension, low diastolic pressure, a wide pulse pressure, and a rapid rise and fall of the arterial upstroke (Corrigan or water-hammer pulse). Lower extremity blood pressure is typically >10 mm Hg above the upper extremity blood pressure (Smith sign), and the magnitude of this difference may reflect the qualitative severity of the AR. Korotkoff sounds may be heard throughout deflation of the blood pressure cuff (pistol shots), light pressure over the tips of the fingernails may cause systolic and diastolic blushing of the nail capillaries near their base (Quincke pulsation), or a diastolic bruit may be heard over the femoral artery as the pressure with which the diaphragm of the stethoscope is applied is gradually lessened (Duroziez sign). The carotid upstrokes may rarely be bisferiens (bifid). The second peak occurs before aortic valve closure. Palpation reveals a heaving, laterally displaced LV. The diastolic murmur of AR is typically high pitched and decrescendo, heard best along the left sternal border, especially when the patient is in the sitting position, leaning forward, at end-expiration. When the murmur is louder to the right of the sternum, aortic root disease should be suspected, as would also be the case with palpation of a pulsatile ascending aorta in the upper right parasternal area. The Austin Flint murmur in mid-diastole to late diastole is better heard near the apex. It is created by an eccentric jet of AR striking the anterior MV leaflet. It can be distinguished from the diastolic murmur of MS on the basis of its response to vasodilators (decrease in intensity) and by the absence of other trappings of MS, such as an OS or AF. A systolic ejection click would suggest bicuspid valve disease. The examination should account for signs of underlying diseases such as Marfan syndrome (general appearance), IE (embolic phenomena, fever), or ankylosing spondylitis (bamboo spine).

### Laboratory Evaluation

In chronic AR, there is EKG evidence of LV hypertrophy and repolarization abnormalities. The CXR shows cardiomegaly with LV enlargement. The aorta may be ectatic or aneurysmal, although such changes may be difficult to discern. TTE is indicated to evaluate the mechanism of AR, quantitate its severity, assess LV size and systolic function, and examine the anatomy of the root and ascending aorta. With severe AR, the central jet assessed by color flow Doppler imaging exceeds 65% of the LV outflow tract, the regurgitant volume is  $\geq 60$  mL per beat, the regurgitant fraction is  $\geq 50\%$ , and there is diastolic flow reversal in the proximal descending thoracic aorta. If the aorta cannot be adequately visualized with TTE, then CT angiography, magnetic resonance angiography, or TEE should be performed, whenever

there is suspicion of aortic pathology. Cardiac MRI can also provide excellent quantitation of AR severity. Cardiac catheterization with contrast aortography can provide supplemental information in difficult cases but is now mainly used to assess coronary anatomy preoperatively.

## Treatment

Acute, severe AR is poorly tolerated, and appropriate patients should be evaluated for emergency surgery, the nature of which depends on the cause of the AR (Box 81.3). Medical treatment of chronic AR should focus on blood pressure control to below 140/90 mm Hg, which can be difficult to achieve. The routine use of vasodilators to extend the compensated phase of asymptomatic AR is no longer recommended. Indications for AVR in the chronic setting include onset of symptoms or the development of LV systolic dysfunction, defined by a resting EF that falls below the lower limit of normal for the noninvasive laboratory in which the patient is followed (usually 50%). Progressive or severe LV dilatation despite preserved systolic function, approaching an end-diastolic dimension of 65 mm or an end-systolic dimension of 50 mm or 25 mm/m<sup>2</sup>, is an additional consideration for surgery. Patients with root or ascending aortic disease with concomitant AR in the setting of bicuspid pathology are candidates for surgery once the maximal aortic dimension reaches or exceeds 5.5 cm. A lower size threshold is recommended in patients with a family history of aortic complications. In patients with severe AR for whom AVR is indicated based on symptoms or LV dysfunction, surgery on the root or ascending aorta is recommended when maximal size exceeds 4.5 cm. A valve-sparing root replacement procedure can sometimes be accomplished in appropriately selected patients. Valve replacement is required for patients with deformed or calcified leaflets or enlarged annuli.

## Tricuspid Stenosis

### Etiology and Pathology

Rheumatic heart disease is the most common cause of tricuspid stenosis (TS). In most patients, the valve pathology is mixed (TS/TR), and left-sided disease with MS is present.

#### • BOX 81.3 Severe Aortic Regurgitation: Indications for Surgery

- Symptoms
- Asymptomatic + LVEF <50%
- Asymptomatic with EF >50% and severe or progressive LV dilation (end-systolic dimension >50 mm or end-diastolic dimension >65 mm)
- Moderate or severe AR and root or ascending aortic aneurysm requiring surgery

AR, Aortic regurgitation; EF, ejection fraction; LV, left ventricular.

## Pathophysiology

TS results in a diastolic pressure gradient between the right atrium (RA) and RV that leads to systemic venous congestion. Cardiac output is compromised with relatively normal RV and PA pressures. The severity of concomitant MS is often underappreciated because the proximate valve lesion may mask the findings associated with the more distal valve lesion.

## Symptoms

Fatigue is frequent because of the low cardiac output. Systemic venous hypertension leads to peripheral edema, ascites, and hepatomegaly, which can cause significant discomfort.

## Physical Examination

TS results in jugular venous distension with giant *a* waves and a slow *y* descent. Palpation and percussion of the abdomen may reveal hepatic enlargement and splenomegaly. In cases of severe hepatic congestion, cirrhosis can result in jaundice, ascites, and anasarca. Auscultation may reveal an OS of the tricuspid valve with a diastolic murmur heard best along the lower left sternal border. The murmur of TS is augmented during inspiration, which helps distinguish it from the murmur of MS.

## Laboratory Evaluation

The EKG demonstrates RA enlargement or AF. The chest reveals a prominent RA. TTE is used to identify a thickened, rheumatic valve, measure the transvalvular gradient, and assess the severity of obstruction (tricuspid valve area) as well as the presence of any TR or left-sided disease. Severe TR is characterized by a valve area  $\leq 1$  cm<sup>2</sup> or pressure half-time of  $\geq 190$  ms.

## Treatment

Medical therapy with salt restriction and diuretics helps relieve the symptoms of venous congestion. Surgery is recommended in symptomatic patients with moderate to severe TS (valve area <2 cm<sup>2</sup>, mean transvalvular gradient >4 mm Hg). Valve repair/commissurotomy is preferable to replacement when feasible. Percutaneous balloon valvuloplasty can be performed in selected patients but is generally not favored because of the associated high rate of procedural TR.

## Tricuspid Regurgitation

### Etiology and Pathology

TR may be primary or secondary. Primary causes include prolapse, endocarditis, Ebstein anomaly, carcinoid, radiation therapy, blunt chest wall trauma, damage during right

ventricular endomyocardial biopsy, and erosion or perforation with intracardiac device leads. Secondary TR, which is much more common, is usually caused by dilatation of the tricuspid annulus from right ventricular enlargement in response to a variety of insults, including pulmonary hypertension.

### Pathophysiology

With TR, blood is ejected back into the RA during systole, resulting in the inscription of large *CV* waves in the jugular vein pulse. Progressively severe TR leads to the ventricularization of the RA wave form. The RV becomes more dilated and volume overloaded. Forward cardiac output is reduced, and atrial arrhythmias are common. Hepatic function may decline.

### Symptoms

Fatigue from low cardiac output is frequent. Right-sided heart failure symptoms such as hepatomegaly, ascites, and peripheral edema predominate.

### Physical Examination

Examination reveals elevation of the jugular venous pressure with prominent, systolic *CV* waves. Hepatomegaly (which may be pulsatile), ascites, and peripheral edema are common. Palpation of the heart reveals a parasternal RV lift. Auscultation is notable for a holosystolic murmur at the lower left sternal border that increases with inspiration (Carvallo sign).

### Laboratory Evaluation

The EKG may show signs of either RA enlargement or RVH. AF may be present. The CXR may demonstrate RA and RV enlargement. TTE is indicated to assess the mechanism of TR, quantify its severity, estimate PA pressures, examine RV size and function, and screen for the presence of left-sided heart disease.

### Treatment

The treatment of TR depends in large measure on whether it is primary or secondary. On rare occasion, severe primary TR will necessitate valve repair or replacement if symptoms are not easily controlled with low-dose diuretic therapy and there is a progressive decline in RV systolic function. On occasion, the severity of secondary TR will diminish with successful treatment of the

left-sided heart disease or pulmonary hypertension that caused it. In patients with mitral and tricuspid valve disease, assessment of TR severity before MV surgery, with measurement of tricuspid valve annulus size, is required to inform a decision regarding the need for concomitant tricuspid valve surgery. The threshold for tricuspid valve repair has decreased progressively over the past decade. Repair is recommended at the time of left-sided surgery when severe TR is present and even for only moderate degrees of TR when the tricuspid annular dimension exceeds 40 mm.

### Prosthetic Valves

The major differences between mechanical and bioprosthetic (tissue) heart valve substitutes relate to durability and thrombogenicity. Mechanical valves are more durable and last longer but necessitate the use of life-long anticoagulant therapy with a vitamin K antagonist (VKA) to prevent valve thrombosis and embolism. Bioprosthetic valves are less durable and prone to structural deterioration within 10 to 15 years of implantation but do not require anticoagulant therapy unless AF or other indications for anticoagulation are present. The choice of heart valve substitute varies on an individual basis as a function of age, the desirability of future pregnancy, medical adherence, and lifestyle. In recent years, the pendulum has swung considerably in favor of tissue valve substitutes, primarily because of the problems associated with long-term anticoagulation. A tissue valve is generally recommended for patients age >60 to 65 years. Younger patients who choose a tissue valve substitute to avoid anticoagulation must accept the need for reoperative surgery in the future. The advent of valve-in-valve transcatheter implantation has altered decision making in many instances.

Oral anticoagulation with a VKA is recommended life-long for all patients with a mechanical prosthesis and for the first 3 months after bioprosthetic MV regurgitation. It can also be considered for the first 3 months after implantation of an aortic bioprosthesis. Treatment with low-dose aspirin instead of a VKA is an accepted alternative after implantation of an aortic bioprosthesis. Oral factor IIa or Xa inhibitors are not currently approved as antithrombotic agents in patients with prosthetic heart valves.

Antibiotic prophylaxis is indicated for any patient with a heart valve substitute or prior valve repair with ring annuloplasty.

## Chapter Review

### Questions

1. An asymptomatic 67-year-old man is referred by his primary care physician for evaluation of a heart murmur. He has not seen a physician regularly since he retired 10 years ago. He takes no medications.

The heart rate is 82 beats per minute, and blood pressure is 147/85 mm Hg. Examination reveals an enlarged and laterally displaced LV impulse. A 3/6 holosystolic murmur is heard at the apex with radiation to the base. His jugular venous pressure is elevated. The rest of the examination is unremarkable. EKG shows normal sinus rhythm with evidence of LA enlargement. TTE reveals thickening of the mitral valve with partial flail of the posterior leaflet. There is an anteriorly directed jet of severe MR. The LA and LV are dilated (LV end-systolic dimension 4.7 cm). Estimated LV EF is 40%.

Which of the following treatment strategies would you recommend?

- A. Medical therapy with an angiotensin-converting enzyme inhibitor with repeat echocardiogram in 6 weeks
  - B. No medical therapy but watchful waiting with close clinical follow-up for symptoms
  - C. Referral for mitral valve replacement
  - D. Referral for mitral valve repair
  - E. Medical therapy with a diuretic and exercise echocardiography
2. An 18-year-old woman is referred to you for evaluation of a heart murmur first heard during a routine preparticipation college athletic physical examination. She has no significant medical history and takes no medications. She trains 6 days a week for field hockey, including long runs, sprints, and weight training. She reports being short of breath at the end of sprints but denies chest pain, dizziness, or syncope. There is no family history of premature cardiac disease or sudden cardiac death.

Her heart rate is 58 beats per minute, and her blood pressure is 100/65 mm Hg. Cardiac auscultation reveals an ejection click and a 2/6 crescendo-decrescendo systolic murmur at the second right interspace. EKG shows sinus bradycardia and normal LV voltage.

Which of the following is the most likely diagnosis?

- A. Bicuspid pulmonic stenosis
  - B. Hypertrophic obstructive cardiomyopathy
  - C. Bicuspid aortic stenosis
  - D. MVP
  - E. Membranous aortic stenosis
3. A 22-year-old woman who recently emigrated from South Africa is referred from the high-risk obstetrics clinic. She has a history of rheumatic fever as a child and has known MS. She is 24 weeks pregnant. She complains of palpitations and shortness of breath with activities of daily living. Her medications include metoprolol, furosemide, and digoxin.

Her heart rate is irregular at a rate of 110 to 120 beats per minute, and her blood pressure is 94/66 mm Hg. Her venous pressure is approximately 12 cm H<sub>2</sub>O. She has a parasternal lift. P2 is loud. There is an OS and a grade 3 middiastolic apical rumble with presystolic accentuation. She has 1+ bilateral lower extremity edema. Echocardiogram demonstrates severe MS with mitral valve area of 1 cm<sup>2</sup> and a low echo score. There is minimal MR. Estimated PA systolic pressure is 65 mm Hg.

Which of the following treatments would you recommend?

- A. Continued medical management until delivery
  - B. Surgical mitral commissurotomy
  - C. Mitral valve replacement with a bioprosthesis
  - D. Percutaneous mitral balloon valvotomy
  - E. Mitral valve replacement with a mechanical prosthesis
4. A 31-year-old man is brought to the emergency department after a head-on motor vehicle accident. He was intubated in the field. Triage vital signs include a heart rate of 115 beats per minute and blood pressure of 86/60 mm Hg. General examination is notable for pre-sternal bruising. Cardiac auscultation reveals a regular tachycardia with a summation gallop. Soft systolic and diastolic murmurs are heard along the upper left sternal border. EKG reveals sinus tachycardia. CT scan of the chest shows multiple rib fractures and pulmonary edema. There is no pericardial effusion. A “stat” TTE is ordered.

What is the most likely next step in the patient’s management?

- A. Placement of an intraaortic balloon for temporary hemodynamic support
  - B. Mitral valve surgery
  - C. Aortic valve replacement
  - D. Placement of an LV assist device
5. A 45-year-old man is referred to you from the orthopedics clinic for perioperative recommendations regarding anticoagulation in anticipation of elective anterior cruciate ligament repair. Two years ago, he underwent bileaflet mechanical aortic valve replacement for a bicuspid aortic valve. His medical workup is also significant for hyperlipidemia. His only medications are warfarin and simvastatin. He has had no thromboembolic complications and is in sinus rhythm.
- Which of the following strategies would you recommend?
- A. Warfarin can be discontinued. It is only indicated for the first 3 months following mechanical aortic valve replacement in patients at low risk for thromboembolism.
  - B. Warfarin should be stopped 72 hours before the procedure and restarted 24 hours after the procedure. During the interruption, he should be bridged with intravenous unfractionated heparin

- until his international normalized ratio (INR) returns to 2 to 3.
- C. Warfarin should be stopped 48 to 72 hours before the procedure and restarted 24 hours after the procedure. During the interruption, he should be bridged with aspirin 325 mg until his INR returns to 2 to 3.
- D. Warfarin should be stopped 48 to 72 hours before the procedure and restarted 24 hours after the procedure. During the interruption, he should be bridged with intravenous unfractionated heparin until his INR returns to 2.5 to 3.5.
- E. Warfarin should be stopped 48 to 72 hours before the procedure and restarted 24 hours after the procedure with a goal INR 2 to 3. No bridging is necessary.

## Heart Failure

GARRICK C. STEWART

**H**ear failure is a complex clinical syndrome occurring in patients with abnormal cardiac structure or function that impairs the ability of the heart to fill with or eject blood. Patients with heart failure develop a constellation of symptoms (dyspnea and fatigue) and signs (edema and rales) that lead to frequent hospitalizations, poor quality of life, and a reduced life expectancy. Heart failure has also been defined as the failure of the heart to pump enough blood to meet the metabolic demands of the body or the ability to do so only at elevated filling pressures. Congestive heart failure is the end-stage syndrome for many cardiac diseases. *Cardiomyopathy* refers to any condition in which there is a structural abnormality of the myocardium itself.

The overall prevalence of heart failure in adults in developed countries is 2% and rises sharply with age. After age 40 years, the lifetime risk of developing heart failure for both men and women is one in five. Over 5 million Americans are living with heart failure, and it is a contributing factor in over 250,000 deaths each year. Heart failure accounts for over \$35 billion in annual health care costs in the United States and remains the leading hospital discharge diagnosis in patients age >65 years. Nearly half of all patients with heart failure have a preserved ejection fraction (EF) (>40%–50%). As such, heart failure is now broadly categorized as heart failure with depressed EF (systolic failure) or heart failure with preserved EF (diastolic failure). Other common heart failure descriptors emphasize the physiology and tempo of clinical disease. This nomenclature includes left- or right-sided or biventricular, systolic or diastolic, forward or backward, high-output or low-output, and acute or chronic failure. Specific diagnostic schemes have been proposed for heart failure, such as the modified Framingham criteria (Table 82.1).

The most popular classification scheme for heart failure severity is the New York Heart Association (NYHA) functional class (Box 82.1). Functional class is assigned based on current symptom limitation, with changing functional classes over time. There is a strong relationship between NYHA class and mortality. Another classification scheme is the American Heart Association (AHA)/American College of Cardiology (ACC) stages of heart failure (Box 82.2). These stages emphasize the progressive nature of heart failure, from antecedent risk factors to the development of

structural heart disease and the evolution of symptoms that may become refractory to medical therapies.

### Etiology and Precipitants of Heart Failure

The underlying and precipitating causes of heart failure must be identified when caring for patients. Risk factors for heart failure development include hypertension, coronary artery disease, valvular disease (particularly aortic stenosis and mitral regurgitation), left ventricular (LV) hypertrophy, age, and diabetes. Studies estimate that coronary artery disease accounts for approximately two-thirds of heart failure in both men and women. Meanwhile 75% of patients with heart failure have a history of hypertension, many of whom have concurrent coronary disease. The cornerstone of heart failure prevention in the community is appropriate coronary risk factor reduction, blood pressure (BP) control, along with the prevention of diabetes and the metabolic syndrome.

**TABLE 82.1** Diagnosis of Heart Failure: Modified Framingham Criteria

Major	Minor
Elevated jugular venous pressure	Dyspnea on exertion
Pulmonary rales	Bilateral leg edema
Paroxysmal nocturnal dyspnea	Nocturnal cough
Orthopnea	Hepatomegaly
Third heart sound (S3 gallop)	Pleural effusion
Cardiomegaly on chest radiography	Tachycardia (>120 beats per minute)
Pulmonary edema on chest radiography	Weight loss >4.5 kg in 5 days
Weight loss >4.5 kg in 5 days in response to diuretic therapy for presumed heart failure	

Diagnosis requires 2 major or 1 major and 2 minor criteria to be present and not attributed to another condition.

### • BOX 82.2 American Heart Association/American College of Cardiology Stages of Heart Failure

- Stage A: At risk for heart failure but without structural heart disease or symptoms of heart failure
- Stage B: Structural heart disease but without signs or symptoms of heart failure
- Stage C: Structural heart disease with prior or current symptoms of heart failure
- Stage D: Refractory heart failure requiring specialized intervention (e.g., mechanical circulatory assist devices, intravenous inotropes, or vasodilators)

From Hunt SA, Abraham WT, Chin MH, et al. 2009 focused update incorporated into the ACC/AHA 2005 Guidelines for the Diagnosis and Management of Heart Failure in Adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines: developed in collaboration with the International Society for Heart and Lung Transplantation. *Circulation*. 2009;119(14):e391–479.

The progression of heart failure with reduced EF is mediated by cardiac remodeling and chamber enlargement accompanied by an obligatory reduction in EF, leading to a dilated cardiomyopathy. The causes of a dilated cardiomyopathy are listed in [Box 82.3](#). Potentially reversible etiologies of systolic heart failure and cardiomyopathy include myocarditis, peripartum-induced, stress-induced, tachycardia-induced, and drug-induced cardiomyopathies. The most common cause of right heart failure is left heart failure.

Heart failure is a chronic progressive disease with relapsing and remitting symptoms. Periods of relative compensation can be punctuated by exacerbations marked by signs of congestion such as dyspnea or edema, often referred to as acute decompensated heart failure. Precipitants for heart failure exacerbation are myriad and can be attributed to patient behaviors such as dietary indiscretion (increased salt or excess fluid intake), medication noncompliance (diuretics), disturbances in cardiac function (new atrial fibrillation or acute valvular dysfunction), or concurrent medical illness (pneumonia) ([Box 82.4](#)).

### • BOX 82.4 Precipitants of Heart Failure Exacerbation

- Inadequate patient education
- Excess salt and fluid intake
- Concurrent medical illness (e.g., pneumonia, renal failure, thyroid disease)
- Cardiac arrhythmias (atrial fibrillation/flutter, ventricular tachycardia)
- Uncontrolled hypertension
- Medication noncompliance
- Acute myocardial ischemia
- Worsening valvular heart disease
- Anemia

## Presenting Features and Evaluation of Heart Failure

### Symptoms

Heart failure has several characteristic symptoms that vary markedly among patients. The most common symptom of heart failure is shortness of breath (dyspnea), usually on exertion, related to either elevated intracardiac filling pressures transmitted to stretch receptors in the lungs or inadequate cardiac output to meet the demands of the body during exercise. Orthopnea, dyspnea when lying down, is characteristic of left-sided heart failure and is often quantified as the number of pillows used at night. Paroxysmal nocturnal dyspnea may also be present with left heart failure with patients awakening at night and needing to sit on the edge of the bed or go to the window for fresh air. Occasionally, heart failure patients may prefer to lie in the right lateral decubitus position, a condition known as trepopnea.

Fatigue and exercise intolerance are also cardinal symptoms of heart failure. Fatigue may be present with activity and can even persist for hours or days after strenuous exertion. Symptoms of anorexia, early satiety, and abdominal discomfort, particularly in the right upper quadrant, are common in more advanced heart failure and reflect right-sided congestion. Other symptoms of heart failure include insomnia, cough, and depression. A careful history must be taken to screen for sleep apnea (snoring, daytime somnolence), an important and underappreciated comorbid condition in many heart failure patients.

It must be emphasized that there is often discordance between the severity of symptoms at presentation and the objective degree of structural heart disease.

### Signs

The physical examination provides important information about the nature of cardiac dysfunction, degree of volume overload, adequacy of cardiac output, and presence of concurrent circulatory abnormalities such as pulmonary hypertension. Clues to the nature of cardiac dysfunction can be found by looking for signs of systemic illness affecting the heart (e.g., hyperthyroidism) and by auscultating for cardiac murmurs that reflect underlying structural heart disease (e.g., the systolic murmur of aortic stenosis).

Gallop rhythms are best appreciated with the stethoscope bell placed at the cardiac apex, often with the patient in the left lateral decubitus position. An S3 gallop may be heard just after the second heart sound (S2). This third heart sound results from limitation of blood flow into the ventricle during early diastole, as in dilated cardiomyopathy or significant mitral regurgitation. The presence of an S3 is highly specific for a reduced EF and elevated left-sided filling pressure and has important prognostic significance. Patients with an S3 and asymptomatic LV dysfunction are more likely to develop heart failure. Those with existing heart failure with an S3 gallop are more likely to be hospitalized for heart failure and have a higher mortality. Alternatively,

an S4 gallop may be heard just before S1 and reflects a stiff ventricle responding to the atrial systolic contraction and thus is absent in atrial fibrillation. S4 gallops are common in conditions leading to a noncompliant ventricle and diastolic heart failure, such as chronic hypertensive heart disease, aortic stenosis, or hypertrophic cardiomyopathy (HCM).

Ventricular enlargement can be appreciated by palpation of the precordium. Signs of LV enlargement include an enlarged point of maximal impulse displaced toward the midaxillary line, a sustained apical impulse, and even a palpable S3 gallop in severe heart failure. A holosystolic murmur of mitral regurgitation is often present in the setting of LV enlargement caused by annular dilatation and apical displacement of the mitral leaflet tips resulting in incomplete coaptation. Pulsus alternans, an evenly spaced alternation of strong and weak peripheral pulses, can be present in severe LV systolic heart failure. Signs of reduced cardiac output include depressed mental status, cool and clammy extremities, pallor, oliguria, distant heart sounds, resting tachycardia, narrow pulse pressure, and hypotension.

Signs of volume overload in heart failure include pulmonary congestion, elevated jugular venous pressure (JVP), and peripheral edema. Pulmonary congestion reflects evidence of left-sided heart failure. Pulmonary rales are often most prominent at the lung bases in heart failure and reflect an elevated pulmonary capillary wedge pressure leading to increased transudation of fluid from the blood pool to the interstitium and alveoli. Rales are more commonly heard in acute decompensated heart failure. Rales may be absent in chronic heart failure despite elevated filling pressures because of increased lymphatic drainage and venous capacitance within the lungs. Pleural effusions (hydrothorax) can be present, often only in the right hemithorax, and are best appreciated by finding dullness to percussion and decreased breath sounds at the bases. Severe chronic heart failure may produce cardiac cachexia. Periodic breathing (Cheyne-Stokes respiration) may also be present in advanced heart failure and is marked by oscillations between rapid breathing and near apnea.

Signs of right-sided heart failure include peripheral edema, increased abdominal girth from ascites, congestive hepatomegaly and splenomegaly, and an elevated JVP. The JVP reflects the filling pressure of the right atrium and is an important window into the heart. Serial assessment of the JVP may be singularly the most important physical finding in following patients with heart failure. The JVP is measured in centimeters from the right atrium, which by convention is located 5 cm below the manubriosternal angle. It is best appreciated using the internal jugular vein on the right side of the neck with the patient sitting at 45 degrees with legs horizontal. An abnormally elevated JVP is >10 cm. Manual compression of the right upper quadrant for >30 seconds can lead to a sustained elevation of JVP in states of volume overload, a sign known as hepatojugular reflux. The JVP normally goes down during inspiration because of negative intrathoracic pressure. However, an absence of a decrease or an increase in JVP during inspiration is known as the Kussmaul sign and

reflects impaired right ventricular filling. The Kussmaul sign may be present in constrictive pericarditis, restrictive cardiomyopathy, and right ventricular infarction.

Secondary pulmonary hypertension is common in chronic left-sided heart failure and may significantly impair exercise tolerance. Physical signs of pulmonary hypertension include a loud P2, evidence of a murmur of pulmonic valve insufficiency (a high-pitched blowing, decrescendo diastolic murmur at the left second or third intercostal space, also known as a Graham-Steel murmur), and a palpable pulmonary tap at the left second intercostal space. Right-sided murmurs and sounds often increase with inspiration (Carvallo sign) because of increased venous return to the right ventricle, resulting in prolonged ejection time.

### Laboratory Evaluation

The evaluation of a patient with new or suspected heart failure can be informed by several laboratory tests. Testing should include a complete blood count to assess for anemia, which can precipitate heart failure. A basic metabolic panel should be checked for renal function before initiation of diuretics or medications acting on the renal-angiotensin-aldosterone system. Renal insufficiency is common in heart failure and is often referred to as the cardiorenal syndrome, which may limit the ability to remove excess volume via the kidneys with diuretic therapy. Elevated liver function tests may reflect passive hepatic congestion or low cardiac output. Fasting glucose should be checked for the presence of underlying diabetes. When a dilated cardiomyopathy is present, its etiology may be discovered by assaying thyroid-stimulating hormone (thyrotoxicosis or hypothyroidism), iron studies (hereditary hemochromatosis), antinuclear antibodies (lupus), or HIV serology.

In states of elevated filling pressures, cardiac myocytes secrete a hormone called *B-type natriuretic peptide* (BNP). Plasma concentrations are elevated in patients with both asymptomatic and symptomatic LV dysfunction. BNP has been shown to be useful in distinguishing between heart failure from either systolic or diastolic dysfunction and pulmonary causes of dyspnea in the emergency room. Cutoff points for BNP have varied. In the emergency department setting, BNP >100 pg/mL was highly sensitive for the diagnosis of heart failure, whereas a level >400 pg/mL improved specificity at the price of reduced sensitivity. A newer test for the N-terminal fragment of the BNP hormone (NT-proBNP) has been developed. NT-proBNP is elevated out of proportion to BNP in LV dysfunction. However, several factors confound the routine use of BNP and NT-proBNP, including the fact that levels are lower in obese individuals and higher with those in kidney failure. The utility of measuring natriuretic peptide levels in the diagnosis and monitoring of heart failure patients continues to evolve. Several other biomarkers have been used to assess prognosis in heart failure. For example, a mildly elevated cardiac troponin after admission for acute decompensated heart failure is a marker

of increased in-hospital mortality, but it is of little help in guiding heart failure therapy.

### Predictors of Prognosis

Many predictors of prognosis in heart failure have been reported in the literature. These include NYHA classification, etiology, EF, low serum sodium, comorbidities, concurrent coronary risk factors, a wide QRS duration, high circulating neurohormonal levels (e.g., norepinephrine), rhythm disturbances, frequency of hospitalization for decompensated heart failure, and an inability to tolerate heart failure pharmacotherapies. Many of these factors have been integrated into risk calculators such as the Seattle Heart Failure Model, which can inform conversations with patients about their estimated prognosis and the potential impact of medical and device therapy. Once heart failure has become clinically overt, physiologic parameters that assess the true impact on cardiac function are also important prognostic determinants. These would include resting heart rate, systolic BP, cardiac output, and both pulmonary artery and pulmonary capillary wedge pressure. Formal cardiopulmonary testing to determine maximum oxygen uptake provides a quantitative assessment of functional capacity and important prognostic information about mortality in chronic heart failure. This is the best single prognostic determinant when advanced therapies, such as cardiac transplantation or ventricular assist device therapy, are being considered.

### Imaging and Hemodynamic Assessment

Chest radiography in suspected heart failure may reveal cardiomegaly, interstitial pulmonary edema, or pleural effusions. All patients with suspected heart failure should undergo routine electrocardiography to evaluate for the presence of arrhythmias, conduction disease, prior infarction, and chamber enlargement. Transthoracic echocardiography should be used in conjunction with the physical examination to determine the nature of underlying structural heart disease and to determine if LV systolic function is preserved or reduced. The end-systolic and end-diastolic dimensions can be easily calculated and provide additional prognostic information. An end-diastolic diameter >7 cm portends a particularly dire prognosis. MRI can provide high-resolution images to assess cardiac structure, function, and perfusion. Gadolinium contrast can be used with cardiac MR to assist in the diagnosis of cardiac fibrosis, infiltrative diseases, and myocardial edema suggestive of active inflammation. Gadolinium use is contraindicated in patients with moderate-to-severe kidney disease. Patients with heart failure and concurrent risk factors or a history of coronary artery disease should undergo an evaluation for ischemia, either with coronary angiography or a myocardial perfusion study.

Invasive hemodynamic assessment can be used to measure filling pressures and calculate cardiac output. Right heart and pulmonary artery catheterization is performed using a

Swan-Ganz catheter. The catheter is balloon tipped and can be “wedged” into a branch of the pulmonary artery, creating a static column of blood to the left atrium and ventricle. The resulting pulmonary catheter wedge pressure provides a good estimate of LV preload in the absence of significant pulmonary vascular disease, mitral stenosis, or tachycardia. A pulmonary artery catheter is important for distinguishing between cardiogenic pulmonary edema related to left heart failure (elevated wedge pressure >18 mm Hg) or acute respiratory distress syndrome (normal wedge). Patients whose pulmonary wedge pressure cannot be lowered below 25 mm Hg with aggressive medical therapies carry a poor prognosis. Routine use of pulmonary artery catheters to guide heart failure therapy has diminished after clinical trials failed to show a mortality benefit, while exposing the risk of infection, pulmonary infarction, and arrhythmia.

### Heart Failure With Reduced Systolic Function Pathophysiology

Heart failure often arises when acute adaptive mechanisms meant to compensate for some functional or structural cardiac abnormality become maladaptive. For example, in acute heart failure, salt and water retention increases preload, vasoconstriction maintains perfusion to the vital organs, sympathetic stimulation augments cardiac output, hypertrophy unloads individual muscle fibers, and increased collagen production may reduce chamber dilatation. Over time these same mechanisms can impair cardiac performances. Salt and water retention produces pulmonary congestion and anasarca, vasoconstriction exacerbates pump dysfunction, sympathetic activation leads to increased mechanoenergetic inefficiency and ventricular remodeling, hypertrophy leads to deterioration and death of cardiac myocytes, and increased collagen production impairs cardiac relaxation. Over time, these maladaptive mechanisms alter energy metabolism, change in sarcomeric protein expression, resulting in abnormal excitation-contraction coupling, and leading to interstitial fibrosis and myocyte apoptosis. Activation of neurohormones, the renin-angiotensin-aldosterone system, the adrenergic nervous system, cytokines, and vasoactive peptides mediate and reinforces progressive remodeling and cardiac dysfunction. Fortunately, these same molecular pathways have been fruitful targets for the development of drug therapies for chronic heart failure.

### Acute Decompensated Heart Failure

Treatment of acute decompensated heart failure involves stabilizing hemodynamics and ensuring tissue perfusion. All patients should be positioned upright, receive supplemental oxygen, and be ventilated adequately, often with the aid of noninvasive positive-pressure ventilation or endotracheal mechanical ventilation. Acute pulmonary edema may also be treated with vasodilators such as nitrates (which venodilate acutely), morphine, and furosemide (which produces

net fluid loss through diuresis.) Intravenous vasodilators such as nitroglycerin or sodium nitroprusside may be initiated along with intravenous loop diuretics either in bolus form or as a continuous drip. Beta-blockade is relatively contraindicated in patients with acute decompensated heart failure. Temporary use of intravenous inotropes (dobutamine or milrinone) or mechanical circulatory support may be required to augment cardiac output.

## Pharmacologic Treatment of Systolic Heart Failure

### Diuretics

Pharmacologic therapy for chronic systolic heart failure has the goal of improving symptoms and prolonging survival. Medical therapies may be divided into those that both improve mortality and reduce symptoms and those that only confer symptomatic benefit (Table 82.2). The most commonly used medications to relieve congestive symptoms are loop diuretics, which promote net sodium and water loss by blocking sodium reuptake in the loop of Henle. Loop diuretics (furosemide, torsemide, bumetanide, ethacrynic acid) are available in both intravenous formulations for in-hospital use during acute exacerbations and oral forms for maintenance therapy. Despite their widespread use for symptomatic relief, loop diuretics have never been shown to confer a mortality benefit in chronic heart failure. In acute decompensated heart failure, parenteral diuretic administration is equally effective in relieving signs and symptoms of congestion when given in bolus form or as a continuous intravenous infusion.

Diuretic resistance may develop with chronic loop diuretic use. Resistance may be caused by increased salt intake, modulation of sodium channels in the loop of Henle and distal convoluted tubule, and upregulation of the renin-angiotensin-aldosterone system. Thiazide diuretics such as chlorothiazide or metolazone may be added 30 to 60 minutes before loop diuretics for a synergistic response because they block sodium absorption in the distal nephron. Use of

**TABLE 82.2 Pharmacologic Therapy for Chronic Systolic Heart Failure**

Improved Mortality	Symptomatic Improvement Only
Beta-blockers	Loop diuretics
ACE inhibitors	Digoxin
ARBs	Nitrates
ARNIs	Ivabridine
Aldosterone antagonists (spironolactone, eplerenone)	
Hydralazine/Isordil combination (African-American patients only)	
<small>ACE, Angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; ARNIs, angiotensin receptor–neprilysin inhibitors.</small>	

loop diuretics may also result in potassium loss, requiring the administration of a potassium-sparing diuretic such as spironolactone or eplerenone.

### **Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Angiotensin Receptor–Nepriylsin Inhibitors**

Angiotensin-converting enzyme (ACE) inhibitors were the first class of medicines to reduce mortality in chronic heart failure and prevent development of heart failure after myocardial infarction. They are the mainstay of therapy in both asymptomatic and symptomatic LV dysfunction and should be used in all patients with LV dysfunction unless contraindicated or not tolerated. ACE inhibitors are balanced arterial and venous vasodilators and block the deleterious remodeling effects of the renin-angiotensin system, which is upregulated in heart failure. ACE inhibitors exhibit a class effect and should be titrated to a target dose with close monitoring of renal function because they often result in a drop in glomerular filtration rate in heart failure patients. Caution should be used in patients with baseline renal dysfunction or hyperkalemia, in whom ACE inhibitors may be contraindicated. A common side effect of ACE inhibitors is a dry cough, thought to be from an increase in circulating bradykinins.

Angiotensin receptor blockers (ARBs) provide an alternative to heart failure patients intolerant to ACE inhibitors because of cough. ARBs block angiotensin II receptors, which may be upregulated in patients with chronic ACE inhibition, and their concurrent use may prevent “ACE escape” by blocking downstream effects of angiotensin II. However, ARBs have a similar incidence of hyperkalemia, renal insufficiency, and hypotension. The evidence that ARBs should be added to patients already on ACE inhibition is less compelling.

An ARB combined with an inhibitor of neprilysin, or angiotensin receptor–neprilysin inhibitor (ARNI), has become a potent new therapy for symptomatic patients with systolic heart failure. Neprilysin is an enzyme that degrades natriuretic peptides, bradykinin, and adrenomedullin. In a randomized trial of the first approved ARNI, valsartan/sacubitril, there was a significantly reduced combined endpoint of cardiovascular death or hospitalization for heart failure by 20% with an ARNI compared with enalapril, an ACE inhibitor. Head-to-head comparisons between an ARNI and ARB do not exist. As with other renin-angiotensin inhibitors, potential side effects of ARNI include hypotension, renal insufficiency, and angioedema. ARNI should not be administered concurrently with ACE inhibitors or within 36 hours of the last dose of an ACE inhibitor.

### **Beta-Adrenergic Blockers**

Activation of the sympathetic nervous system in heart failure was first described in the 1960s, and circulating catecholamine levels correlate with disease severity and mortality. Early paradigms of heart failure focused on

the acute compensatory nature of sympathetic activation with a reduced EF. The deleterious effects of chronic sympathoadrenergic activity were later proven after oral beta-blocking convincingly reduced mortality in patients with heart failure and a reduced EF. Long-term administration of beta-blockers prevents remodeling, attenuates fibrosis and hypertrophy, reduces arrhythmias, and improves functional status. Specific beta-blockers shown to confer a mortality benefit in heart failure include carvedilol, extended-release metoprolol, and bisoprolol, but their relative efficacy has not been clearly determined. The most cardioselective beta-blocker with efficacy in systolic heart failure is bisoprolol, which is preferred for patients’ asthma, reactive airways disease, or chronic obstructive pulmonary disease. Beta-blockers should be used in all patients with stable, euvolemic heart failure and low EF and even in patients with asymptomatic LV dysfunction. There are additive benefits to beta-blockers and ACE inhibitors and ARBs, although which drug to initiate first has been uncertain. In general, beta-blockers should not be initiated in the decompensated state when there is evidence for fluid accumulation. Beta-blockers are usually started at a low dose while the patient is in the hospital and titrated over several weeks after discharge. Patients should be monitored for signs of fatigue, bradycardia, and fluid retention, which may prompt adjustment of loop diuretic dosing.

### **Aldosterone Antagonists**

Spironolactone, an aldosterone receptor antagonist, is indicated for patients with NYHA class III/IV systolic heart failure (EF <35%) who are already on an ACE inhibitor and beta-blocker. Spironolactone further inhibits the renin-angiotensin-aldosterone axis and attenuates remodeling and fibrosis in chronic heart failure. Eplerenone, a more selective aldosterone antagonist, has been shown to improve mortality in patients with postinfarction heart failure and more recently in class II patients with EF ≤35%. Close monitoring of serum potassium and renal function must be undertaken after initiation of aldosterone antagonism. Great caution must be used with these agents in patients with renal dysfunction because of the risk of potentially fatal hyperkalemia. Low-dose aldosterone antagonists can be considered in such instances. Painful gynecomastia and galactorrhea may be seen in male patients on spironolactone, but these side effects are rare with eplerenone.

### **Digoxin**

Although the use of digitalis-based glycosides from the foxglove plant has been a mainstay of treating congestive heart failure since the 18th century, these agents were only recently subjected to the rigor of clinical trials. Digoxin has been shown to reduce heart failure hospitalizations and improve symptoms, but it does not improve mortality in chronic heart failure. Digoxin works by augmenting intracellular calcium levels and bolstering contractility while

also reducing vagal input to the atrioventricular node. This combination of effects makes it an excellent drug for those heart failure patients with atrial fibrillation and a reduced EF. Digoxin use should be avoided in renal insufficiency. In heart failure, digoxin is generally given at a low dose, with serum levels maintained  $<1$  ng/mL. Signs of digoxin toxicity include nausea, abdominal discomfort, yellow halo around lights, and heart block. Withdrawal of digoxin is often associated with worsening heart failure symptoms.

### Ivabridine

Elevated heart rate has been shown consistently to be associated with increased mortality in systolic heart failure. This increase in heart rate may be a reflection of a reduced stroke volume or sympathetic activation. Ivabridine is a new therapeutic agent that selectively inhibits the  $I_f$  current in the sinoatrial node and reduces heart rate. In patients with symptomatic systolic heart failure in sinus rhythm with resting heart rate  $>70$  beats per minute, there was a reduction in hospitalizations for heart failure. Given the well-proven mortality benefits of beta-blockers, it is important to initiate and titrate beta-blockers to target doses before assessing heart rate for consideration of ivabridine.

### Other Treatments

Venodilators such as long-acting nitrates may reduce congestive symptoms in some heart failure patients and may reduce chronic ischemia by lowering preload. Hydralazine and nitrates were the first vasodilators shown to improve heart failure survival, and they remain an effective alternative for patients who cannot be given an ACE inhibitor or ARB because of drug intolerance or renal insufficiency. This combination is also reasonable to consider in patients already taking an ACE inhibitor and beta-blocker with persistent symptoms. In self-identified African-American patients, a fixed-dose combination of hydralazine and isosorbide dinitrate has been shown to confer a mortality benefit.

Electrolyte monitoring and supplementation constitute an important part of ongoing drug therapy for heart failure. For example, potassium depletion is common with diuretic use, whereas hyperkalemia may be seen with ACE inhibitors, ARBs, aldosterone antagonists, and in renal insufficiency. In general, oral potassium supplements may be required to keep serum potassium levels between 4 and 5 mEq/L. Loss of both magnesium and calcium is also common with chronic diuretic use.

Many nonpharmacologic measures are central to chronic heart failure therapy. Patient education regarding diet, medications, and fluid management is critical to prevent recurrent hospital admission and improve functional status. Patients with recurrent heart failure exacerbations should be told to have a salt-restricted diet ( $<2$  g daily) and should adhere to an overall fluid restriction (often  $<2$  L per day, or  $<64$  oz). Daily weights should be measured each morning after voiding. If weight increases 2 pounds in a day or 5 pounds in 1 week, adjustment of diuretic dosing is indicated. Last,

heart failure patients may benefit from an exercise program and cardiac rehabilitation, along with remote monitoring of their weight and vital signs.

There is no consensus that the presence of heart failure alone should be an indication for anticoagulation with warfarin therapy. A recent clinical trial in systolic heart failure patients in sinus rhythm suggested that the combined risk of embolic stroke, hemorrhagic stroke, or death was no different between aspirin and warfarin. However, there is no question that such therapy is indicated in patients with heart failure and atrial fibrillation or with comorbidities of transient cerebral ischemia, pulmonary embolism, venous thrombosis, recent anterior myocardial infarction (MI), or documented ventricular or atrial thrombosis.

Finally, for more advanced systolic dysfunction, intravenous inotropes or vasodilators may be initiated. Inotropes such as dobutamine (a beta-receptor agonist), dopamine (an alpha- and beta-agonist), or milrinone (a phosphodiesterase-3 inhibitor) increase myocardial contractility, stroke volume, and heart rate and modestly reduce afterload by vasodilatation, thereby augmenting cardiac output. Unfortunately, even as it improves perfusion, inotropic therapy can lead to malignant tachyarrhythmias and cardiac ischemia and may increase mortality with either continuous or intermittent infusions, even as they improve symptom profile. Pure vasodilators such as nitroprusside or nesiritide may also be used to reduce afterload and unload the failing ventricle. However, nitroprusside use is limited to a few days because of thiocyanate toxicity. Use of intravenous nesiritide, a recombinant form of BNP, may be associated with hypotension and has not been shown to alter the risk of death or rehospitalization when used in acute heart failure.

### Adverse Effects of Medical Therapies

There are important mishaps in medical therapy that deserve emphasis. Nonsteroidal antiinflammatory agents should be avoided if possible because they will promote excess sodium retention. L-type calcium channel blocking agents (e.g., verapamil, diltiazem) have negative inotropic effects and should not be given in systolic heart failure. Oral drug absorption can be poor if there is bowel edema caused by right heart failure or low cardiac output with reduced mesenteric blood flow. Overly vigorous diuresis can lead to intravascular volume depletion, prerenal azotemia, and orthostatic intolerance. Recurrent heart failure may reflect inadequate afterload reduction, too much beta-blockade, or inadequate diuresis; more often, it reflects inadequate patient education or noncompliance with and misunderstanding of complex medical regimens.

### Device-Based Therapies

Heart failure patients with a reduced EF are six to nine times more likely to suffer sudden cardiac death than the general population. The mechanism of sudden cardiac

death is ventricular tachycardia/fibrillation related to electrical instability of the myopathic heart. Implantable cardioverter defibrillators (ICDs) for the primary prevention of sudden death reduce overall mortality in symptomatic (NYHA class II–III) heart failure patients with a reduced EF (<35%). ICDs also have a proven mortality benefit in patients after MI with an EF <30%. To be considered an ICD candidate, patients should be >40 days after MI or >3 months after percutaneous coronary intervention or coronary artery bypass graft. ICDs are also superior to medical therapy such as amiodarone for primary prevention of sudden cardiac death. All symptomatic heart failure patients should be optimized on medical therapy (particularly beta-blockers and ACE inhibitors) for at least 3 months before ICD placement because reverse remodeling may obviate the need for an ICD.

Many heart failure patients with a low EF often also have intraventricular conduction delay, as manifest by a widened QRS complex (>120 ms) on the surface electrocardiogram (EKG) caused by either a bundle branch block or nonspecific intraventricular conduction delay. This conduction delay creates mechanical dyssynchrony in ventricular contraction and can contribute to remodeling, mitral regurgitation, and fluid congestion. Symptomatic heart failure patients with reduced EF and conduction delay may benefit from cardiac resynchronization therapy (CRT), also known as biventricular pacing. Pacemaker leads are placed in the right ventricle apex and the lateral free wall of the left ventricle via the coronary sinus to “resynchronize” contraction of both ventricles. This may lead to reverse remodeling, decreased mitral regurgitation, and reduced mortality in select patients. Not every heart failure patient will respond to CRT. Those most likely to benefit from CRT include patients in sinus rhythm, with moderate heart failure symptoms, left bundle branch block, and/or a QRS duration >150 ms. CRT is not indicated for asymptomatic patients with reduced EF in the absence of other indications for pacing. Many patients eligible for ICD placement also meet criteria for resynchronization and are offered both therapies with a single device, known as a CRT-D (CRT-defibrillator).

Severe refractory chronic heart failure or acute cardiogenic shock may require temporary or durable mechanical circulatory support. Traditionally this has taken the form of a temporary intraaortic balloon counterpulsation pump. Although effective in reducing afterload and augmenting coronary perfusion, balloon pumps have a short lifespan (days to a few weeks), may lead to vascular compromise, including limb ischemia and renal failure, and can cause consumptive thrombocytopenia.

Recent technologic advances have led to a rapid evolution of ventricular assist devices. Devices have been developed for temporary support in acute heart failure and life long therapy for end-stage cardiomyopathy. Mechanical circulatory support may be used as a bridge to cardiac transplantation, a bridge to cardiac recovery in acute heart failure, or as permanent destination therapy for patients ineligible for

transplant. Durable LV assist devices (LVADs) are now in widespread use. LVADs generate nonpulsatile, continuous blood flow from a rotary blood pump that removes blood from the left ventricle and provides flow into the ascending aorta. Most pumps are implanted in patients with end-stage heart failure who are dependent on intravenous inotropes. In this stage D population, LVADs have been shown to substantially improve survival, quality of life, and functioning. Improving outcomes have encouraged expanded use in select patients with NYHA class IV symptoms who are not yet on inotropes. Common complications of LVAD therapy include stroke, infection, gastrointestinal bleeding, and mechanical pump malfunction caused by thrombosis. The significant mismatch between donor heart availability and the expanding epidemic of advanced heart failure makes mechanical circulatory support a crucial, rapidly evolving therapy to extend life and improve symptoms in end-stage heart failure patients.

### Heart Failure With Preserved Systolic Function

Heart failure with preserved EF (>40%), sometimes referred to as diastolic heart failure, is a disorder of impaired cardiac filling (diastole). Diastolic dysfunction is not synonymous with diastolic heart failure. Isolated diastolic dysfunction may occur in the absence of heart failure symptoms. Diastolic dysfunction can be seen in the elderly, particularly women, in patients with a history of hypertension, or concurrently in patients with systolic dysfunction. Patients with diastolic dysfunction often have an S4 gallop on examination and no evidence of ventricular dilatation. Diastolic function can be assessed noninvasively using echocardiography.

Nearly half of all heart failure patients have preserved systolic function. Etiologies of heart failure with preserved systolic function include chronic hypertension, HCM, aortic stenosis with normal EF, ischemic heart disease, and restrictive cardiomyopathy. Women are more likely to be affected by diastolic heart failure than men. Diastolic heart failure from coronary ischemia is caused by increased myocardial stiffness produced from either a reduced supply related to epicardial coronary disease or an increased myocardial oxygen demand. Concentric LV hypertrophy after years of hypertension may also contribute to diastolic heart failure because the stiff chamber cannot relax normally, and its thickened walls can predispose to subendocardial ischemia. The presence of heart failure with severe aortic stenosis is an indication for aortic valve replacement. A common precipitant of heart failure in patients with diastolic dysfunction is atrial fibrillation. Atrial fibrillation is poorly tolerated because of the loss of the atrial kick, which is important for filling a stiff ventricle, and poor rate control with reduced diastolic filling time.

The evidence base for treating heart failure with preserved EF is regrettably small, in part because diastolic heart failure has only recently been considered a distinct entity and because of varying definitions of heart failure

with preserved EF. No single pharmacologic agent has yet been shown to confer a mortality benefit in a randomized trial. In general, diuretics are used to prevent volume overload. Spironolactone may reduce the frequency of heart failure hospitalization in heart failure with preserved EF, but vigilant laboratory monitoring for renal dysfunction and hyperkalemia is mandatory. Hypertension should be controlled, often with ACE inhibitors, ARBs, or dihydropyridine calcium channel blockers. Heart rate control is maintained, often with a beta-blocker, to allow for adequate time for ventricular filling. When possible, patients should be maintained in sinus rhythm given the intolerance to atrial fibrillation.

### High-Output Heart Failure

Whereas most heart failure is characterized by a reduced cardiac output and elevated systemic vascular resistance, high-output failure is defined by a markedly elevated cardiac output and a low systemic resistance. This leads to ineffective blood volume and pressure, neurohormonal activation, and volume overload. There are several common etiologies of high-output heart failure, most notably systemic arteriovenous fistulas, thyrotoxicosis, and thiamine deficiency (Box 82.5).

The physical examination in high-output heart failure reveals inappropriate tachycardia and a venous hum over the jugular veins. Arterial examination is notable for signs of increased stroke volume, including a wide pulse pressure, bounding pulse with quick upstroke, and “pistol shot” sound heard over the femoral arteries. The extremities are often warm with evidence of vasodilatation. This must be carefully distinguished from aortic regurgitation, which is also characterized by increased stroke volume but also produces a diastolic murmur. Cardiac examination may reveal an enlarged point of maximal impulse caused by cardiomegaly and a third heart sound from volume loading of the left ventricle.

The syndrome of high-output failure is markedly different from the temporary physiologic increases in cardiac output seen with excitement, exercise, fever, and pregnancy. Although high-output states may be the sole cause of heart failure, the need to augment cardiac output

transiently may trigger a heart failure exacerbation in patients with poor cardiac reserve from conditions such as valvular heart disease or underlying cardiomyopathy. The cornerstones of treatment for high-output heart failure are the identification and reversal of the underlying cause of the high-output state.

### Specific Cardiac Disorders Presenting With Heart Failure

#### Myocarditis

Myocarditis represents a constellation of different cardiac diseases, each marked by inflammation and myocyte damage, usually triggered by an infection or autoimmune response. Inflammation may be focal or diffuse and involve any or all the cardiac chambers. The gold standard for diagnosis is endomyocardial biopsy, although cardiac MRI with gadolinium enhancement is increasingly being used to identify cases. In the developed world, viral infections such as coxsackievirus, adenovirus, and parvovirus B19 have been identified as the most common pathogens. However, a host of infectious agents can trigger myocarditis. For example, Chagas myocarditis from a parasitic infection with *Trypanosoma cruzi* is by far the most common cause of cardiomyopathy in Central and South American countries. A treatable and common form of myocarditis in the northeastern United States is Lyme carditis from *Borrelia burgdorferi* infection. This form of myocarditis has a predilection for the conduction system and often leads to heart block requiring a temporary pacemaker, although conduction disturbance often resolves with a course of intravenous antibiotics.

The spectrum of myocarditis can range from subclinical disease to fulminant myocarditis, in which cardiovascular collapse and death can occur shortly after a viral syndrome. Myocarditis, particularly postviral or lymphocytic myocarditis, may present as heart failure or a dilated cardiomyopathy. Often a viral prodrome may be recalled, although the development of cardiac dysfunction can lag considerably from the initial infectious insult. Myocarditis may also present with chest pain, often mimicking myocardial infarction with ST segment changes or troponin release, sudden cardiac death, or arrhythmias. In addition to volume overload, physical findings include a gallop rhythm signaling ventricular dysfunction, and a friction rub is suggestive of myopericarditis. The most dreaded form of myocarditis is idiopathic giant cell myocarditis, which can lead to profound heart failure and often requires urgent consideration of mechanical support or cardiac transplantation. Treatment for myocarditis typically involves supportive care, monitoring for arrhythmias, avoidance of exercise, and pharmacologic therapy for heart failure. Targeted immune modulating therapies have shown mixed results in speeding resolution of myocarditis and preventing development of dilated cardiomyopathy, with immunosuppression generally reserved for giant cell myocarditis. There is no consensus as to the most appropriate immunosuppressive agent.

#### • BOX 82.5 Causes of High-Output Heart Failure

Systemic arteriovenous fistulas (congenital or acquired)  
 Hyperthyroidism  
 Chronic anemia  
 Beriberi (vitamin B-1 or thiamine deficiency)  
 Dermatologic disorders (e.g., psoriasis)  
 Acromegaly  
 Paget disease of the bone  
 Cirrhosis  
 Renal disease (volume expansion)  
 Hyperkinetic heart syndrome

### Hypertrophic Cardiomyopathy

HCM is a familial disorder inherited in an autosomal dominant fashion and is associated with both heart failure and sudden cardiac death. HCM produces significant LV hypertrophy (>15 mm) in the absence of conditions that increase afterload, such as aortic stenosis or long-standing hypertension. HCM arises because of mutations in genes encoding proteins of the cardiac sarcomere and has an estimated prevalence of 1 in 500. First-degree relatives of confirmed HCM patients should be screened for the disease using physical examination, EKG, and echocardiography. Genetic testing is available but should always be accompanied by careful genetic counseling.

Asymmetric septal hypertrophy can lead to obstruction of outflow from the left ventricle during systole as a result of dynamic narrowing of the outflow tract beneath the aortic valve and systolic anterior motion of the mitral valve. This condition is often referred to as hypertrophic obstructive cardiomyopathy or its previous name, idiopathic hypertrophic subaortic stenosis. Great care must be taken on physical examination to distinguish between HCM with dynamic outflow obstruction and valvular aortic stenosis (Table 82.3). HCM with outflow obstruction has several characteristic physical findings. These include a bifid carotid pulse, double apical impulse, and a systolic ejection murmur that increases with both Valsalva maneuver and standing. These two maneuvers decrease LV preload, thereby decreasing the diameter of the LV outflow tract and leading to a louder murmur.

Severe outflow obstruction with HCM can result in angina, syncope, and sudden death. HCM can also lead to diastolic heart failure even without frank obstruction. Anything prompting a drop in preload must be avoided in HCM with obstruction, including the use of vasodilators and dehydration. Pharmacologic treatment for symptomatic HCM with LV outflow obstruction includes beta-blockers, diltiazem, verapamil, or disopyramide, a class 1A antiarrhythmic drug with negative inotropic effects. Patients with HCM who remain symptomatic despite optimization of medical therapy are candidates for septal reduction therapy using either surgical septal myectomy or alcohol septal ablation. Risk factors for sudden death in HCM include a history of unexplained syncope, a family history of sudden death, nonsustained ventricular tachycardia on ambulatory EKG monitoring, and extreme hypertrophy (>30-mm

wall thickness). Presence of one or more of these risk factors should prompt consideration of ICD therapy for primary prevention of sudden death.

### Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a rare but devastating cause of heart failure affecting mothers in the last month of pregnancy and up to 5 months postpartum. This diagnosis should not be made in women with preexisting cardiac disease or another cause of cardiac dysfunction. The incidence of peripartum cardiomyopathy is 1:2500 to 1:4000 births in the United States. Peripartum cardiomyopathy is characterized by an absence of other underlying cardiac disorder, symptoms of heart failure, and reduced systolic function on echocardiography. A number of risk factors for the development of peripartum cardiomyopathy have been identified, including older maternal age, multiparity, and African descent. The precise etiology of peripartum cardiomyopathy remains unknown, although compelling emerging data suggest that abnormal cleavage of the lactation hormone prolactin and/or cardiac angiogenic imbalance may lead to the disease.

Overall, treatment is similar to that of heart failure with low EF, including stabilizing hemodynamics and symptom relief. However, medications must be carefully scrutinized for compatibility with pregnancy and lactation. For example, ACE inhibitors and ARBs are contraindicated in pregnancy and must never be given antepartum because of the risk of fetal renal failure, oligohydramnios, premature labor, and pulmonary hypoplasia. Hydralazine is the vasodilator of choice in this setting given its good safety profile. The overall 2-year mortality rate is 10%, but most women have complete recovery of their EF and carry a good prognosis. In women with peripartum cardiomyopathy who do not have normalization of their systolic function, a subsequent pregnancy is particularly high risk and should be avoided. A multidisciplinary team including a high-risk obstetrician, obstetric anesthesiologist, cardiologist, and neonatologist should be assembled to guide the pregnant patient with peripartum cardiomyopathy through parturition.

### Stress Cardiomyopathy

Reversible severe ventricular dysfunction has been reported after sudden episodes of emotional distress, neurologic

**TABLE 82.3 Distinguishing Hypertrophic Obstructive Cardiomyopathy From Valvular Aortic Stenosis on Physical Examination**

	Hypertrophic Cardiomyopathy	Aortic Stenosis
Valsalva maneuver	Increased murmur	Decreased murmur
Standing	Increased murmur	Decreased murmur or no change
Passive leg elevation	Decreased murmur	Increased murmur or no change
Carotid pulsation	Brisk, often bifid	Parvus et tardus (weak and delayed)

injury, or trauma. This so-called stress cardiomyopathy has a predilection for creating wall motion abnormalities in the LV apex and is also known as apical ballooning syndrome or takotsubo cardiomyopathy, after the shape of a traditional Japanese octopus pot. Chest pain and dyspnea are typical presenting features along with widespread T-wave inversions. Women are more likely to be affected than men. Cardiac catheterization is typically required to rule out coronary ischemia before assigning the diagnosis of stress cardiomyopathy. Marked improvement in EF is seen within a few days to 3 weeks of presentation. Plasma catecholamines are significantly elevated in this condition and may result in transient ventricular stunning. Traditional heart failure therapy is initiated, although patients may require a brief period of mechanical circulatory support until their myocardial function recovers. Overall prognosis after stress cardiomyopathy is usually good, although it may recur in vulnerable patients.

### Cardiac Amyloidosis

Amyloidosis is a systemic disorder characterized by deposition of protein fibrils in the extracellular matrix. Amyloid protein can be produced as a result of a plasma cell dyscrasia, such as primary amyloid (AL, or light chain amyloid), mutations in the transthyretin gene (familial amyloid), or senile amyloid from wild-type transthyretin deposits. Amyloid protein infiltrating the myocardium produces a noncompliant rubbery heart with frequent intracardiac thrombi and characteristic Congo red staining with green birefringence under polarized light on biopsy. Amyloid cardiomyopathy is defined by myocardial dysfunction or conduction disease, with a clinical course that is largely determined by the nature and extent of protein deposition. Cardiac involvement with AL amyloid has a rapid clinical progression, whereas familial or senile amyloid is typically associated with milder symptoms and a more indolent course.

The clinical presentation of amyloid heart disease is often dominated by signs of right heart failure, postural hypotension, and syncope, along with cardioembolic events such as stroke. The most common electrocardiographic finding is markedly low voltages in the limb leads. Echocardiography shows diastolic dysfunction, wall thickening, an increased echogenicity related to protein deposition, and the evolution of a restrictive cardiomyopathy. Cardiac magnetic resonance is more sensitive than echocardiography for diagnosis and often reveals transmural or subendocardial late gadolinium enhancement in amyloid. The presence of heavy proteinuria, hepatomegaly, orthostatic hypotension, and neuropathy along with heart failure provides diagnostic clues for systemic amyloidosis. Tissue diagnosis may be made from endomyocardial or fat pad biopsy. Treatment of cardiac amyloidosis is largely supportive. In general ACE inhibitors, calcium channel blockers, and digoxin should be avoided given their binding to amyloid protein and predilection for the development of hypotension. With the thrombotic risk,

anticoagulation must be considered, particularly if atrial fibrillation is present.

### Restrictive Cardiomyopathy Versus Constrictive Pericarditis

Restrictive cardiomyopathy is a disorder that produces a nondilated, rigid ventricle with normal wall thickness and preserved systolic function but severely impaired ventricular filling (diastole). Constrictive pericarditis results from scarring and loss of elasticity of pericardial sac, leading to impaired filling of all four cardiac chambers. Both diseases may present with heart failure and a preserved EF. They must be carefully distinguished from each other because their treatment and prognosis are quite different.

A history of acute pericarditis, chest radiation, cardiac surgery, trauma, or a systemic disease affecting the pericardium (e.g., malignancy or tuberculosis) makes constrictive pericarditis more likely. A history of infiltrative disease (amyloidosis, hemochromatosis, or sarcoidosis) favors restrictive cardiomyopathy. Both conditions may have an elevated JVP with a prominent descent during diastole, and both may produce the Kussmaul sign. A pericardial knock can sometimes be heard in constrictive pericarditis. Both conditions generate low voltage on electrocardiography. Chest imaging with either CT or MRI reveals a thickened pericardium in constrictive pericarditis.

In restrictive cardiomyopathy, pericardial compliance is normal, and respiratory changes are transmitted to all chambers of the heart. However, in constriction, because the pericardium shields the cardiac chambers but not the pulmonary vasculature from respirophasic pressure changes, venous filling of the right heart exceeds that of the left heart, and the interventricular septum bows to the left. Also, because all four chambers of the heart are within the constricted pericardium, there is equalization of end-diastolic pressure in all chambers on cardiac catheterization. Treatment of constrictive pericarditis involves excision of the pericardium (pericardiectomy). Treatment of restrictive cardiomyopathy is similar to that of other causes of diastolic heart failure, and its prognosis is poor, particularly in advanced cases when systolic function also becomes depressed.

### Cor Pulmonale

Cor pulmonale is a condition of dilatation and hypertrophy of the right ventricle leading to refractory right heart failure produced by chronic, severe pulmonary hypertension caused by diseases affecting the lung or its vasculature. Commonly patients will have a history of significant lung disease, such as severe emphysema, pulmonary fibrosis, and chronic hypoxemia, or may have a history of recurrent pulmonary thromboembolism. Presenting symptoms of cor pulmonale include fatigue, lethargy, angina in the absence of epicardial coronary disease, as well as right upper quadrant discomfort from hepatic congestion. Physical findings include peripheral edema, an elevated JVP, loud pulmonic component of the second heart sound (P2) from pulmonary hypertension, a right-sided S4 gallop from right ventricular hypertrophy,

and plethora related to polycythemia. The EKG reveals signs of chronic right ventricular overload, including right atrial enlargement (P pulmonale), right axis deviation, R > S wave amplitude in V1, and incomplete right bundle branch block. Supplemental oxygen is the treatment of choice for cor pulmonale if chronic hypoxemia is the cause because it may reduce right heart failure symptoms along with polycythemia. Other treatments include diuretics, pulmonary vasodilators, digoxin, and even phlebotomy if the hematocrit

is >55% to prevent hyperviscosity. In chronic obstructive pulmonary disease, the development of pulmonary hypertension and cor pulmonale portends a poor prognosis.

## Chapter Review

### Questions

1. A 42-year-old man without prior medical history presents with progressive fatigue and dyspnea on exertion over several months. He notes difficulty putting on his shoes because of ankle edema. Family history is notable for a brother who underwent heart transplantation at age 35 years. On examination, he is overweight with BP 122/90 mm Hg and heart rate 70 beats per minute, and respirations are 20 breaths per minute with saturation 96% on room air. Jugular veins are distended to 14 cm water, lungs have bibasilar rales, and heart sounds are regular, with a II/VI holosystolic murmur, a third heart sound, and an enlarged point of maximal impulse. Chest radiography shows cardiomegaly with prominent pulmonary interstitial markings with apical redistribution. EKG shows sinus rhythm with LV hypertrophy. Echocardiography reveals an estimated EF of 25% with ventricular dilatation and moderate mitral regurgitation. Which of the following pharmacologic agents has been shown to improve survival in this condition?
  - A. Furosemide
  - B. Digoxin
  - C. Milrinone
  - D. Carvedilol
  - E. Ivabridine
2. Which of the following is true about BNP?
  - A. Levels decrease with age.
  - B. Levels decrease with treatment (e.g., carvedilol, spironolactone).
  - C. Levels increase with obesity.
  - D. Levels decrease with renal failure.
  - E. Levels are higher in heart failure with preserved EF.
3. A 51-year-old woman with a history of nonischemic dilated cardiomyopathy and EF 25% presents to your office after recent hospitalization for heart failure. She is short of breath walking three blocks. Current medications

include enalapril 10 mg twice daily (bid), metoprolol succinate 100 mg daily, furosemide 80 mg bid, and potassium chloride 10 mEq bid. Her BP is 120/78 mm Hg, JVP 10 cm water, and heartbeat is regular without an audible gallop. Her creatinine is 0.8 mg/dL and her potassium 4 mEq/L. Which would be the next best treatment to implement to reduce her risk of cardiovascular mortality and heart failure hospitalization?

- A. Valsartan 40 mg daily
  - B. Aspirin 81 mg daily
  - C. Simvastatin 10 mg nightly
  - D. Eplerenone 12.5 mg daily
  - E. Amlodipine 5 mg daily
4. Match the ACC/AHA stages of heart failure with the appropriate characteristics of the stage:
    - 4.1 Stage A
    - 4.2 Stage B
    - 4.3 Stage C
    - 4.4 Stage D
    - A. Structural heart disease with prior or current symptoms
    - B. Structural heart disease but without signs or symptoms of heart failure
    - C. Refractory heart failure requiring specialized interventions
    - D. At high risk for heart failure but no structural heart disease
