The pericardium is a two-layered sac that surrounds the heart. It is composed of an outer stiff fibrous coat (the *parietal pericardium*) and a thin inner membrane that is adherent to the external surface of the heart (the *visceral pericardium*). The visceral pericardium reflects at the level of the great vessel origins to form the inner lining of the parietal layer. The space between these two layers normally contains 15 to 50 mL of serous pericardial fluid, which permits the heart to contract in a minimum-friction environment. The major diseases of the pericardium are acute pericarditis, cardiac tamponade, and constrictive pericarditis.

### Acute Pericarditis

#### Etiology

Although many conditions can lead to acute pericardial inflammation (Box 83.1), ~90% of cases are postviral or of unknown (idiopathic) origin. Because most instances of idiopathic pericarditis are likely caused by undetected viral infection, the two are considered equivalent illnesses. The most commonly implicated viruses are coxsackie and echovirus strains. Less frequently cytomegalovirus (CMV), Epstein-Barr virus, adenovirus, parvovirus B19, and HIV are causal. The presence of such infections could be confirmed by polymerase chain reaction (PCR) amplification of DNA obtained from pericardial fluid, but that is uncommonly undertaken because management decisions would not typically be affected.

Tuberculosis (TB) is only rarely encountered as a cause of pericarditis in industrialized countries today. However, it remains an important etiology in immunocompromised patients and in less developed regions of the world. In Africa, TB is the most common etiology of pericardial disease in patients with HIV.

Pyogenic bacterial pericardial infections (e.g., staphylococci, pneumococci, streptococci) are also rare but may arise from spread of pneumonia, rupture of a perivalvular abscess, or hematogenous seeding.

Pericarditis may arise after several forms of cardiac injuries. Pericarditis after myocardial infarction (MI) presents in two forms. The early type occurs 1 to 3

days after a transmural MI and arises from extension of myocardial inflammation to the adjacent pericardium. With the advent of acute revascularization therapies for ST segment elevation MI, this form of pericarditis has become rare. The delayed form of post-MI pericarditis, termed *Dressler syndrome*, arises in some patients weeks or months following an acute MI and is thought to be of autoimmune origin, resulting from exposure to antigens released from necrotic myocardial cells. It too has become uncommon in the modern era. A similar syndrome, postpericardiotomy pericarditis, may arise weeks following cardiac surgical procedures. Pericarditis can also be precipitated by thoracic trauma or from vascular perforation as a complication of invasive procedures, including pacemaker lead placement.

Uremic pericarditis occurs in 6% to 10% of patients with chronic renal failure, and its development correlates with blood urea nitrogen levels. Pericarditis also occasionally develops by an unknown mechanism in patients already on chronic dialysis therapy.

Neoplastic pericarditis and effusions result most often from metastatic spread or local invasion by carcinoma of the lung, breast, or lymphoma. Gastrointestinal carcinomas and melanoma are less common causes. Primary pericardial tumors are very rare.

Radiation-induced pericarditis arises from prior therapeutic mediastinal irradiation. Its incidence correlates with the cumulative radiation dose and volume of cardiac exposure. Such injury may cause acute symptomatic pericarditis soon after the radiation is delivered, or instead it may result in fibrosis that first manifests as constrictive pericarditis many years later.

Pericardial involvement is common in collagen vascular diseases, presumably on an autoimmune basis. Up to 25% of patients with rheumatoid arthritis, 40% of those with systemic lupus erythematosus, and 10% of individuals with progressive systemic sclerosis experience clinical manifestations of acute pericarditis in the course of their systemic disease.

Drug-induced pericarditis has been reported with many pharmaceutical agents, either by inducing a lupus-like syndrome (e.g., hydralazine, procainamide, isoniazid, phenytoin, methyl dopa) or on an idiosyncratic basis

(e.g., minoxidil, anthracycline derivatives, cyclophosphamide, sulfa drugs).

## Clinical Features

Common symptoms of acute pericarditis include low-grade fever and chest pain. The discomfort is typically of sudden onset, intense, and located in the retrosternal and left precordial regions; it may radiate to the neck and left trapezius ridge. It can be differentiated from the discomfort of myocardial ischemia by its sharp, pleuritic, and positional character. It tends to be worse when lying supine and improves with sitting and leaning forward. Chest pain may not occur at all when inflammation develops slowly, such as in some patients with pericarditis arising from TB, rheumatoid arthritis, neoplastic disease, radiation therapy, or uremia.

The predominant physical finding in acute pericarditis is a scratchy pericardial friction rub. It is of high frequency and heard best at end expiration with the diaphragm of the stethoscope applied to the lower left sternal border as the patient leans forward. In its full form, it consists of three components that correspond to phases of cardiac movement: ventricular contraction, ventricular relaxation, and

atrial contraction. The rub can be transient, or only one or two components may be heard.

The electrocardiogram (EKG) in acute pericarditis (Fig. 83.1) is abnormal in >90% of patients and passes through four stages:

Stage 1: Diffuse, concave upward ST elevation in most leads, with the exception of aVR, often accompanied by PR segment deviation opposite to the direction of the P wave (i.e., PR depression in lead II and PR elevation in lead aVR)

Stage 2: (Several days later): ST segments return to baseline  
 Stage 3: Generalized T-wave inversion develops

Stage 4: (Weeks or months later): ST segment and T waves have returned to baseline; no Q-wave development  
 Individuals with the common EKG variant known as *early repolarization* display baseline ST elevations that can mimic stage 1 pericarditis. However, distinct from those with early repolarization, the height of the ST segment in acute pericarditis tends to be >25% of the height of the T wave.

Most patients with acute pericarditis have no or only a small pericardial effusion, and chest radiography is frequently normal. However, if a large effusion (>250 mL) has accumulated, the cardiac silhouette becomes symmetrically enlarged. Echocardiography is a much more sensitive technique for the detection of pericardial effusion because it can identify a collection of as little as 15 mL (Fig. 83.2). A small effusion is identified as an echo-free space posterior to the left ventricle (LV). Larger effusions wrap around laterally and, if more than approximately 250 mL have accumulated, anterior to the heart as well.

The diagnosis of acute pericarditis can be considered firm when  $\geq 2$  of the features described in the preceding paragraphs are present (i.e., pleuritic positional chest pain, pericardial friction rub, typical EKG abnormalities, and more than a trivial pericardial effusion).

In addition, blood studies in patients with acute pericarditis typically reveal systemic inflammation (leukocytosis, elevated erythrocyte sedimentation rate, and C-reactive

• Fig. 83.1 Twelve-lead electrocardiogram of stage I pericarditis. Diffuse ST segment elevation is present.

• **Fig. 83.2** Two-dimensional echocardiogram. Parasternal long-axis view, demonstrating a posterior pericardial effusion (PE). LA, Left atrium; LV, left ventricle.

protein) and often minor elevation of cardiac-specific troponins. The latter reflects inflammation extending to the neighboring myocardium but does not predict an adverse outcome.

Additional testing may be useful when specific etiologies of pericarditis are suspected, such as purified protein derivative (PPD) skin testing or interferon gamma release assay for tuberculosis, serologic testing (e.g., antinuclear antibodies) for collagen vascular diseases, mammography or CT for screening of breast and lung cancers, respectively. Even when a pericardial effusion is present, pericardiocentesis is not recommended in uncomplicated cases because the diagnostic yield is low and rarely affects management. It should be reserved for patients with large effusions or those with evidence of cardiac chamber compression (see later).

## Management

Idiopathic or postviral pericarditis is a self-limited condition that tends to improve spontaneously within 1 to 3 weeks. Pharmacologic therapy hastens improvement and the immediate goals are to reduce pericardial inflammation to relieve symptoms. Nonsteroidal antiinflammatory drugs (NSAIDs) are first-line therapy (e.g., ibuprofen 600–800 mg 3 times daily or aspirin 650 mg/d). A useful adjunct is colchicine (0.5 mg twice daily, or 0.5 mg once daily if weight  $\leq 70$  kg, for 3 months), which has been shown in prospective randomized trials to reduce the rate of recurrent pericarditis and to shorten the course of initial symptoms.

Other potentially beneficial therapies include a brief course of narcotic analgesics for severe pain or, as last resort for refractory symptoms, a limited regimen of corticosteroids. Although the discomfort of pericarditis responds promptly to steroids, patients who receive them are more prone to relapses. The 2015 European Society of Cardiology pericardial guidelines recommend steroid therapy only

for patients with symptoms truly refractory to NSAID plus colchicine therapy or for patients with pericarditis caused by an underlying connective tissue or autoimmune disorder. One recent trial showed that a relatively low dose of prednisone (0.25–0.5 mg/kg/d for 2 weeks followed by a slow taper) is effective and associated with fewer relapses than higher dosages. Hospitalization is recommended for patients with high fever, a large pericardial effusion, hemodynamic compromise, chronic immunosuppression or anticoagulation, or when an etiology other than idiopathic/postviral is suspected.

Aspirin is the preferred antiinflammatory agent for patients with pericarditis early after MI because other NSAIDs may impair healing of infarcted tissue. Patients with delayed post-MI pericarditis (Dressler syndrome) or postpericardiotomy pericarditis characteristically respond promptly to standard NSAID regimens, which can be used with less reservation at that later phase. Tuberculous pericarditis requires prolonged, multidrug, antituberculous therapy. Purulent pericarditis mandates aggressive antibiotic therapy and often catheter drainage of the pericardium. Pericarditis caused by uremia is treated with initiation or intensification of dialysis. Forms of pericarditis associated with collagen vascular diseases respond to therapy directed against the underlying disorder, often including NSAID or glucocorticoid therapy. Drug-associated pericarditis responds to cessation of the offending agent. Neoplastic pericarditis is indicative of advanced-stage cancer, and therapy is usually palliative; if tamponade is present, drainage of pericardial fluid can be temporarily lifesaving (see later).

Recurrent pericarditis develops in up to 30% of patients after an initial episode. Recurrences are less frequent in patients who receive colchicine as part of the original treatment program. Recurrent pericarditis often responds to a renewed course of NSAID and colchicine therapy (which should be continued for  $\geq 6$  months); refractory cases may require glucocorticoids, usually with a very slow taper to prevent additional occurrences. In addition, reports of small numbers of patients have suggested benefit of immunosuppressive agents (e.g., azathioprine or methotrexate), intravenous immunoglobulin, and the interleukin-1 $\beta$  receptor antagonist anakinra in suppressing refractory symptoms of pericarditis. For unrelenting and highly symptomatic recurrences of pericarditis, surgical complete pericardiectomy may be considered.

Two serious complications may follow acute pericarditis: cardiac tamponade and chronic constrictive pericarditis.

## Cardiac Tamponade

Cardiac tamponade is characterized by the accumulation of pericardial fluid under sufficient pressure to compress and impair filling of the cardiac chambers. As a result, cardiac output declines substantially, which can lead to hypotensive shock and death.

• **Fig. 83.3** Electrocardiogram rhythm strip demonstrating electrical alternans. The depth of the QRS complex alternates from beat to beat as the heart swings within a large pericardial effusion, causing the mean electrical axis to shift back and forth.

## Etiology

Any cause of acute pericarditis can lead to tamponade physiology, but the most common etiologies are neoplastic, idiopathic, and uremic pericarditis. Tamponade can also result from acute hemorrhage into the pericardial sac, for example, following chest trauma, as a complication of a proximal aortic dissection, bleeding after cardiac surgery, or myocardial perforation during percutaneous cardiac procedures.

## Pathophysiology

Because the pericardium is a relatively stiff structure, the sudden introduction of even a small volume of fluid into the pericardial space (as with acute hemorrhage) can lead to life-threatening cardiac chamber compression. However, when effusions accumulate more gradually, the parietal pericardium may physically stretch over time and accommodate larger volumes (>1 L) before hemodynamic compromise occurs.

In tamponade, the surrounding tense effusion limits ventricular filling and causes the diastolic pressure of each cardiac chamber to become elevated and equal to the high pericardial pressure. The right side of the heart is more susceptible to external compression than the left side because of its normally lower pressures. Therefore impaired right-sided chamber filling is one of the earliest signs of tamponade. Because the compressed chambers cannot accommodate normal venous return, systemic venous pressures rise. Limitation of early diastolic ventricular filling across the tricuspid valve is responsible for blunting of the normal  $y$  descent in the right atrial and systemic venous pressure tracings. Concurrently, the reduced diastolic ventricular filling decreases stroke volume and forward cardiac output.

The high pericardial pressure in tamponade exaggerates the relationship of normal ventricular interdependence: the volume of one ventricle can expand only when the size of the other decreases by the same amount. This principle applies to respiratory variations in ventricular filling. In normal individuals, inspiration expands the right ventricle, shifts the interventricular septum toward the left, and thus slightly reduces LV filling and output over the next several beats. This results in a normal small inspiratory decline in systolic blood pressure (BP). In cardiac tamponade, the situation is amplified because the ventricles share a common, reduced space. Therefore there is greater inspiratory reduction of LV output and BP, and this is thought to be

responsible for pulsus paradoxus (an inspiratory decrease in systolic BP >10 mm Hg) in this condition.

## Clinical Features

Cardiac tamponade should be suspected when a patient with pericarditis or chest trauma develops signs and symptoms of systemic vascular congestion and decreased cardiac output. The patient may describe shortness of breath and chest discomfort; tachypnea and tachycardia are common. Other key physical findings are (1) hypotension with pulsus paradoxus; (2) jugular venous distension (with absence of the  $y$  descent); and (3) muffled heart sounds and inability to palpate the point of maximum cardiac impulse because of the surrounding effusion. Of note, pulsus paradoxus may not appear when coexisting conditions impede respiratory alterations in LV filling, including LV dysfunction, aortic regurgitation, and atrial septal defects. Conversely, pulsus paradoxus may appear in situations other than tamponade that cause large alterations in intrathoracic pressure, including acute and chronic pulmonary disease, and in some patients with constrictive pericarditis (see later).

The EKG typically demonstrates sinus tachycardia as well as low limb-lead voltage if a large effusion has accumulated. Electrical alternans (alternating height of the QRS complex in sequential beats; Fig. 83.3) is uncommon but highly suggestive of a large effusion because it results from shifting of the mean electrical axis as the heart swings from side to side within the large pericardial volume.

Echocardiography is the most useful noninvasive technique to evaluate for tamponade physiology. It can identify the presence, volume, and location of pericardial effusion and assess its hemodynamic significance. Sensitive and specific signs of tamponade include early diastolic collapse of the right ventricle (more specific) and cyclical compression of the right atrium (more sensitive). It is less common to observe cyclical indentation of the left atrium or LV, except in patients with loculated effusions that compress those chambers, as may occur after cardiac surgery. Other echocardiographic findings reflect the abnormal pathophysiology: distension of the inferior vena cava and exaggerated reciprocal respiratory variations in mitral and tricuspid diastolic Doppler velocities. Although these echocardiographic abnormalities are suggestive, it is the clinical characteristics of the patient that determine whether tamponade is present and dictate the aggressiveness of therapeutic interventions.

## Management

Although intravenous volume infusion may transiently improve BP, the only effective management of cardiac tamponade is removal of the offending pericardial effusion. This is typically performed by pericardiocentesis, ideally in a cardiac catheterization laboratory, where intracardiac hemodynamics can be monitored to confirm the diagnosis and assess the effect of fluid removal. The pericardiocentesis needle is usually inserted via a subxiphoid approach (to avoid piercing a coronary or internal mammary artery), often aided by echocardiographic guidance. A catheter is then threaded into the pericardial space and connected to a transducer for pressure measurement. Another catheter is inserted percutaneously into the right side of the heart, and simultaneous recordings of intrapericardial and intracardiac pressures are compared. In tamponade, the pericardial pressure is elevated and is equal to the diastolic pressure in each cardiac chamber. In addition, the right atrial pressure tracing demonstrates blunting of the normal  $\gamma$  descent, as described in the aforementioned pathophysiology section.

Following successful pericardiocentesis, the pressures in the cardiac chambers should decline as the pericardial pressure returns to normal. A pericardial catheter is often left in place for 1 to 2 days to allow more complete fluid drainage. For diagnostic purposes, pericardial fluid analysis should include blood counts, cytology and bacterial, fungal, and mycobacterial cultures, although the diagnostic yield of culture of pericardial fluid for *Mycobacterium tuberculosis* is low. If TB is suspected, a more rapid diagnosis from the pericardial fluid can be accomplished by PCR or by the finding of an elevated level of adenosine deaminase (>40 U/L in TB).

Open surgical drainage (via a subxiphoid approach) may be necessary for recurrences of cardiac tamponade or if hemodynamically significant loculated effusions are present. A surgical approach also allows acquisition of pericardial biopsies to aid in diagnosis when the cause of the effusion remains occult. For example, biopsy increases the diagnostic yield for *M. tuberculosis* to 80% to 90%. The creation of a pericardial window allows continuous drainage of pericardial fluid into the pleural space and prevents further recurrences of tamponade (e.g., for malignant effusions).

## Constrictive Pericarditis

Constrictive pericarditis is characterized by the development of abnormal pericardial rigidity that markedly impairs filling of the cardiac chambers.

### Etiology

Any cause of acute inflammation can result in thickening, fibrosis, and calcification of the pericardium over time. The most common conditions responsible for constrictive pericarditis in the United States are prior idiopathic/postviral pericarditis, cardiac surgery, prior mediastinal radiation

**TABLE 83.1 Etiologies of Constrictive Pericarditis (n = 163)**

Postviral/idiopathic	46%
Postcardiac surgical	37%
Prior mediastinal irradiation	9%
Miscellaneous (e.g., collagen vascular disease, tuberculosis)	8%

therapy, and connective tissue disorders (Table 83.1). In developing countries, TB remains an important cause.

## Pathophysiology

In patients who have developed constrictive pericarditis, the rigid pericardium surrounding the heart impairs normal filling and causes elevation and equalization of diastolic pressures within the cardiac chambers. In the earliest phase of diastole (just after the mitral and tricuspid valves open), the ventricles begin to fill quite briskly because atrial pressures are typically elevated. However, as soon as the ventricles fill to the limit imposed on them by the surrounding rigid pericardium (still in early diastole), filling abruptly ceases. As a result, back pressure causes the systemic venous pressure to rise, leading to signs of right-sided heart failure. The subsequent reduced LV filling impairs stroke volume and cardiac output. Typically, systolic function of the ventricles is preserved in constrictive pericarditis. However, if the inflammatory and scarring process has extended to the myocardium, contractile dysfunction may also contribute to the clinical presentation and limit the effectiveness of therapeutic pericardiectomy.

## Clinical Features

Clinical findings in constrictive pericarditis typically develop insidiously over a period of months to years. Symptoms of right-sided heart failure are common, including peripheral edema and increased abdominal girth because of hepatomegaly and ascites. Symptoms of left-sided congestion, such as exertional dyspnea and orthopnea, are less common. Late in the disease, signs of reduced cardiac output become manifest, including cachexia, muscle wasting, and fatigue.

Other findings are notable on examination. The jugular veins typically show marked elevation with two prominent descents during each cardiac cycle ( $x$  and  $y$  descents, as described subsequently), creating a distinctive filling and collapsing pattern that is often evident from across the room. Unlike normal individuals (and those with cardiac tamponade) the degree of jugular venous distension fails to decrease, or may increase further, with inspiration (Kussmaul sign). The latter reflects the inability of the heart to

accommodate the increased venous return that occurs with inspiration. On cardiac examination, an early diastolic high-pitched “knock” at the left lower sternal border or at the apex may be present. It results from the sudden cessation of ventricular filling in early diastole.

Pulsus paradoxus may be identified in some patients with constrictive pericarditis. When present, its mechanism is different from that in cardiac tamponade and relates to failure of transmission of intrathoracic pressure to the cardiac chambers attributed to the surrounding rigid pericardium. Because inspiration in patients with constriction lowers the pulmonary venous pressure, but not left-sided heart pressures, the drive of blood from the pulmonary veins to the left atrium is reduced. Less LV filling translates to a decline in cardiac output and systolic pressure during inspiration.

The EKG generally displays only nonspecific ST and T-wave abnormalities, but atrial arrhythmias such as atrial fibrillation are common. The chest radiograph shows a normal or mildly increased cardiac silhouette. In some patients with chronic constriction (particularly those with TB pericarditis), calcification of the pericardium is present and can be best visualized at the right heart border on the lateral view. Echocardiography may demonstrate a thickened pericardium, but this is often difficult to appreciate on standard transthoracic imaging. Other echo findings include abrupt cessation of ventricular filling and a shuddering motion of the interventricular septum in early diastole, dilatation of the inferior vena cava, and characteristic Doppler abnormalities that reflect abbreviated diastolic ventricular filling: rapid deceleration of the early diastolic mitral inflow “E” wave velocity and reduction of the late diastolic inflow “A” wave velocity. With the decline in left-sided filling during inspiration (as described in the previous paragraph), there is an accompanying fall (>25%) in the mitral inflow “E” wave velocity, shifting of the interventricular septum to the left, and a reciprocal increase in tricuspid valve inflow velocity. Cardiac MR and CT scans are superior to echocardiography in assessment of pericardial anatomy. Pericardial thickness is usually increased at >2 mm in patients with constrictive pericarditis, although up to 20% of patients with proven constriction have normal thickness.

At cardiac catheterization, the characteristic findings of constrictive pericarditis are (1) elevation and equalization of the diastolic pressures of each of the cardiac chambers; (2) the right atrial pressure tracing shows a prominent  $\gamma$  descent (in distinction to the blunted  $\gamma$  descent in cardiac tamponade); (3) the right and left ventricular pressure tracings show a diastolic “dip and plateau” configuration (“square root sign”) as shown in Fig. 83.4, representing unimpeded early diastolic relaxation followed by abrupt cessation of diastolic filling as soon as ventricular volumes reach the limit imposed by the constricting pericardium. These hemodynamic findings may be masked in patients with intravascular volume depletion but can then be uncovered by infusion of an intravenous saline bolus in the catheterization laboratory.

The clinical presentation and hemodynamic findings of constrictive pericarditis can closely resemble those of

• **Fig. 83.4** Hemodynamics of constrictive pericarditis. Simultaneous recordings of right ventricular (RV) and left ventricular (LV) pressures show elevation and equalization of the diastolic pressures, accompanied by an abnormal “dip and plateau” configuration.

restrictive cardiomyopathy (e.g., as caused by cardiac amyloidosis), another uncommon condition that impairs diastolic filling of the heart. It is important to distinguish these entities because treatment approaches to them are very different. Although an endomyocardial biopsy may be necessary (biopsy results are normal in constrictive pericarditis and usually abnormal in the restrictive cardiomyopathies), the distinction can usually be made by less invasive means, as summarized in Table 83.2. As distinct to constrictive pericarditis, patients with restrictive cardiomyopathy often have increased ventricular wall thickness, normal pericardial thickness, evidence of at least mild systolic dysfunction and pulmonary hypertension, and sluggish relaxation even at the very earliest phase of diastole.

## Management

The patient with an acute presentation of constrictive physiology (e.g., soon after cardiac surgery with near-normal pericardial thickness) may improve over a period of weeks to months with antiinflammatory therapy. The only effective management of patients with the more common chronic pericardial constriction is complete surgical removal of the pericardium. A successful operation requires wide resection of the pericardial layers and is technically highly challenging. Even in experienced hospitals, the operative mortality rate is >6%. After surgery, the majority of patients note symptomatic relief. In others, presumably those with associated myocardial stiffness or fibrosis, improvement may be delayed over a period of months. Patients with constriction caused by viral/idiopathic pericarditis have the best outcomes after surgery, whereas results are less favorable in those with radiation-associated constriction.

**TABLE 83.2** Differentiation of Constrictive Pericarditis and Restrictive Cardiomyopathy

	Constrictive Pericarditis	Restrictive Cardiomyopathy
<b>Physical Examination</b>		
Kussmaul sign	Common	May be present
Pericardial knock	May be present	Absent
Pulmonary rales	Uncommon	Common
Electrocardiogram	Nonspecific ST and T-wave abnormalities	Low limb-lead voltage in infiltrative diseases
Chest x-ray Pericardial calcification	May be present	Absent
<b>Echocardiography</b>		
Thickened pericardium	Present	Absent
Thickened myocardium	Absent	Present (may be speckled)
Exaggerated variation in transvalvular velocities	Present	Absent
Doppler tissue imaging at mitral annulus (represents LV relaxation rate at earliest phase of diastole)	Normal (>8 cm/s)	Reduced (<8 cm/s)
<b>CT or MRI</b>		
Thickened pericardium	Usually	Absent
<b>Cardiac Catheterization</b>		
Equalized RV and LV diastolic pressures	Yes	LV often >RV by more than 3–5 mm Hg
Elevated PA systolic pressure	Uncommon	Common
Effect of inspiration on systolic pressures	Discordant: LV ↓, RV ↑	Concordant: LV ↓, RV ↓
Endomyocardial biopsy	Normal	Usually abnormal (e.g., amyloid)

LV, Left ventricle; PA, pulmonary artery; RV, right ventricle.

## Effusive-Constrictive Pericarditis

Some patients with pericardial disease have features that reflect a combination of cardiac tamponade physiology and constrictive pericarditis. Such individuals typically present with pericardial effusion and symptoms, signs, and intracardiac pressure findings typical of tamponade. However, after the pericardial effusion is removed, the elevated intracardiac pressures do not fall to normal, and the

hemodynamics of constrictive pericarditis supervene, with a prominent *y* descent in the right atrial pressure tracing and a “dip and plateau” configuration of the ventricular diastolic pressures. This syndrome is termed *effusive-constrictive pericarditis*, and the most common inciting etiologies are prior idiopathic/postviral pericarditis, mediastinal radiation therapy, and neoplastic and tuberculous pericardial disease. Surgical pericardiectomy is usually required for full relief of symptoms.

## Chapter Review

### Questions

- A 45-year-old previously healthy woman presents to the emergency department with fever, pleuritic chest pain, and a pericardial friction rub. The EKG shows sinus tachycardia, diffuse ST elevations, and PR segment depression in lead II. Echocardiography demonstrates a small posterior pericardial effusion without cardiac chamber compression. Which of the following is correct?

  - Glucocorticoid therapy is indicated to prevent progression of the effusion.
  - The EKG will likely return to normal within 48 hours.
  - Ventricular dysrhythmias are common in this setting.
  - The relapse rate is >15%.
  - Kussmaul sign is an expected physical finding.
- A 56-year-old man presents to a physician's office with exertional dyspnea, marked jugular venous distention with prominent *x* and *y* descents, and peripheral edema. Pulsus paradoxus is not present. He has

a history of Hodgkin disease 18 years earlier, treated with chemotherapy and mediastinal radiation therapy. He is admitted to the hospital, and right-sided heart catheterization is performed as part of the diagnostic workup. Selective hemodynamics are listed in the following table:

Chamber	Pressure (mm Hg)	Normal (mm Hg)
Right atrium (mean)	16	≤8
Right ventricle	30/17	≤30/8
Pulmonary wedge (mean)	16	≤10

Which of the following statements is true?

- Pericardiocentesis should be performed urgently.
  - Therapy should include a diuretic, angiotensin-converting enzyme inhibitor, and a beta-blocker.
  - CT scan would be more helpful than echocardiography in confirming the diagnosis.
  - Sinus bradycardia is likely present.
  - Prior chemotherapy is likely responsible for these findings.
3. Which of the following statements about effusive-constrictive pericarditis is correct?
- Removal of pericardial fluid by pericardiocentesis normalizes the right atrial pressure.
  - Uremia and drug-induced pericarditis are among the most common causes.
  - Presenting physical findings resemble chronic constrictive pericarditis more than cardiac tamponade.

- Glucocorticoid therapy is curative in most cases.
  - Resolution of this condition most often requires total pericardiectomy.
4. Which of the following findings is typical of cardiac tamponade?
- Sinus bradycardia
  - Prominent *y* descent of the jugular venous pulse
  - Kussmaul sign
  - Inspiratory fall in systolic BP >10 mm Hg
  - Diastolic “dip and plateau” configuration of the right ventricular pressure tracing
5. Which of the following statements is true regarding the EKG in acute pericarditis?
- A small minority of patients demonstrate EKG abnormalities.
  - Focal ST segment elevation with reciprocal ST depression in opposite leads is typical in early pericarditis.
  - T-wave inversions develop before the ST elevations return to baseline.
  - PR segment deviation (opposite to the P-wave direction) is present in most cases.
  - Sinus bradycardia is common.

# Arrhythmias

CIORSTI MACINTYRE AND USHA B. TEDROW

In the normal heart the sinoatrial (SA) node serves as the principal pacemaker and determines the heart rate. The SA node consists of groups of pacemaker cells marked by their ability to spontaneously depolarize. These cells are located at the junction of the right atrium and the superior vena cava. The blood supply to the SA node is variable, with the sinus nodal artery arising from the right coronary artery in 60% of cases and from the left circumflex artery in 40% of cases. Following depolarization of the SA nodal cells, the signal traverses the atrium before arriving at the atrioventricular (AV) node. The AV node is marked by its ability to delay impulse propagation (decremental conduction), which allows for coordinated contraction of the atria and ventricles. The AV nodal artery arises from the right coronary artery in 90% of cases and from the left circumflex artery in 10% of cases. After exiting the AV node, the impulse is transmitted through the bundle of His, the right and left bundle branches, and ultimately exits the terminal Purkinje fibers of the conduction system into the myocardium near the apex of the heart.

The autonomic nervous system plays an important role in modulating the function of the cardiac conduction system. The SA and AV nodes are innervated by both the sympathetic and parasympathetic systems. Acetylcholine released by parasympathetic neurons decreases the rate of pacemaker depolarization, suppresses conduction, and increases the refractory period, whereas norepinephrine has the reverse effect.

## Bradyarrhythmias

### Sinus Node Dysfunction

#### *Sinus Bradycardia*

The normal sinus heart rate is between 60 and 100 beats per minute, but there may be wide variation in resting heart rate among individuals. For example, well-trained athletes may have significant vagal tone that results in resting, asymptomatic bradycardia. Sinus bradycardia may alternatively be caused by intracardiac processes such as local ischemia and infiltrative disease, as well as extracardiac conditions such as hypothyroidism, hypothermia, stroke, and periods of enhanced vagal tone such as that seen during vasovagal

syncope. It is important to exclude drug effects as an etiology for sinus bradycardia. Sinus pauses >3 seconds are considered abnormal and warrant intervention especially if the patient is symptomatic with these pauses.

### *Tachycardia Bradycardia Syndrome*

This syndrome is marked by the presence of sinus or other bradycardia alternating with rapid supraventricular tachycardias (SVTs), most often atrial fibrillation (AF). Medical control of the rapid arrhythmia is often limited by worsening bradycardia. Symptoms including light headedness and syncope are most often caused by bradycardia or by offset pauses. An offset pause is defined as the duration between termination of AF or atrial flutter and return of sinus rhythm.

### *Sinoatrial Exit Block*

Sinoatrial exit block occurs when impulse propagation out of the SA node is impaired. First-degree sinoatrial exit block involves delayed but present conduction out of the SA node and so cannot be diagnosed on the surface electrocardiogram (EKG). Second-degree sinoatrial block is marked by intermittent block out of the SA node and resultant dropped P waves on the EKG. Third-degree sinoatrial block, which involves complete block of sinus impulses out of the SA node manifests simply as complete sinus arrest on the surface EKG.

### *Diagnosis and Treatment*

The principal goal of the evaluation and treatment of sinus bradycardia is symptom alleviation. The asymptomatic patient rarely warrants intervention. Symptomatic patients with documented sinus bradycardia or sinus arrest may not require further testing. In the symptomatic patient with suspected SA nodal dysfunction, maneuvers such as carotid sinus massage (CSM) and Holter or other noninvasive monitoring may prove useful to establish symptom rhythm correlation. Electrophysiologic (EP) testing does allow for functional testing of the SA node and more importantly can provide functional characteristics of atrial, AV nodal, and infranodal conduction as well. However, in the modern era, this testing typically adds little to the information obtained from a patient's symptoms and cardiac monitoring.

Once all correctable conditions such as hypothyroidism have been addressed and all potentially causative drugs have been stopped, the mainstay of treatment for sinus node dysfunction is the implantation of a permanent pacemaker. Although a single-chamber atrial pacemaker may suffice, there is often concern of concomitant disease in more distal parts of the conduction system. As such, dual-chamber pacemakers are frequently implanted for symptomatic sinus node disease.

### Atrioventricular Conduction Disorders

Conduction disorders may occur at the level of the atrium, AV node, His bundle, or the infra-Hisian conduction system. Furthermore, impulse conduction may be prolonged, intermittent, or completely absent. Besides drugs and normal degenerative processes, there are several disease states that can cause AV conduction disease. These include myocardial ischemia, congenital AV block, cardiac surgery, infiltrative cardiomyopathies, cardiac sarcoidosis, myocarditis, Lyme carditis, and metabolic derangements among others. Furthermore, there are a number of neuromuscular diseases including myotonic muscular dystrophy, Erb dystrophy, and Kearns-Sayre syndrome that are marked by progressive conduction disease and AV block.

#### First-Degree Atrioventricular Block

First-degree AV block is characterized by a prolonged PR interval (>200 ms) but a preserved 1:1 relationship between the atria and ventricles. The site of conduction delay cannot be ascertained from the surface EKG, but the absence of bundle branch block or a wide QRS does make an infra-Hisian site of block less likely.

#### Second-Degree Atrioventricular Block, Mobitz Type 1

Also referred to as Wenckebach block, this rhythm is marked by a progressive lengthening in the PR interval followed by a dropped QRS. Because of a progressive decrease in the rate of PR prolongation, careful analysis also reveals a shortening of the R-R interval before the dropped beat. The site of block is most often the AV node, although infranodal Wenckebach block may occur as well.

#### Second-Degree Atrioventricular Block, Mobitz Type 2

In this situation, the PR interval remains constant, but there is intermittent conduction from the atria to the ventricles, often in a fixed ratio. Mobitz type II block most often occurs below the AV node at either the level of the His bundle or, more commonly, in the infra-Hisian region. The majority of patients with this type of block show some form of bundle branch block reflective of underlying conduction disease.

#### Third-Degree Atrioventricular Block

In complete heart block, no atrial impulses reach the ventricle. The escape rhythm often provides clues to the site of

block. The presence of a narrow complex escape rhythm suggests block at the level of the AV node and less frequently at the level of the His bundle. A wide complex escape rhythm most often signifies infra-Hisian block.

### Diagnosis and Treatment

The surface EKG remains the mainstay of diagnosis for AV block. Note that in the setting of 2:1 block, it is not possible to differentiate between Wenckebach and Mobitz type II block. However, the presence of Wenckebach in another portion of the EKG or improvement of block with heightened adrenergic tone or with atropine are suggestive of Wenckebach block. Another important point is the differentiation of complete heart block from AV dissociation occurring when the ventricular rate exceeds the atrial rate in the context of normal AV conduction.

First-degree AV block rarely warrants treatment except for the rare cases when the patient is symptomatic with a pacemaker syndrome-like constellation of symptoms. Symptoms may include palpitations, cough, dyspnea, chest discomfort, dizziness, or, in rare circumstances, syncope. These symptoms are caused by nearly simultaneous contraction of the atria and ventricles resulting in backflow of blood into the pulmonary veins and venae cavae. Vagolytic maneuvers such as exercise and atropine should decrease the PR interval if the AV node is the site of delay, whereas exacerbation by these maneuvers or underlying bundle branch disease may reflect an infranodal site of delay. Treatment of patients includes cessation of nodal blocking agents. Only rarely is a pacemaker indicated. Likewise, Wenckebach block rarely requires treatment unless the patient suffers from symptomatic bradycardia or if there is a concern for rapidly progressive AV conduction disease as seen in certain neuromuscular diseases. In contrast, second-degree AV block without an identifiable and reversible etiology warrants consideration for a dual-chamber pacemaker.

The presence of newly diagnosed complete heart block or Mobitz type II block requires immediate attention. The initial assessment should evaluate the clinical and hemodynamic status of the patient; the escape rhythm should be carefully analyzed. Hemodynamic instability, prior syncope, symptomatic escape bradycardia, wide complex escape rhythms, heart rates <40 beats per minute, and pauses >3 seconds all warrant consideration of a temporary pacing wire after transcutaneous pads have been placed. In addition, if the patient is remote from potential permanent pacemaker implantation, a temporary pacing wire should also be strongly considered. When all reversible causes have been addressed, the definitive treatment is pacemaker implantation.

### Supraventricular Tachyarrhythmias

#### Tachyarrhythmias Involving the Sinus Node

Most tachycardias emanating from the sinus node are physiologic in nature and reflect a high catecholaminergic state

caused by exercise, stimulants, stress, and/or extracardiac stressors such as anemia, hypoxia, fever, hyperthyroidism, and hypovolemia.

### **Inappropriate Sinus Tachycardia**

*Inappropriate sinus tachycardia* (IST) refers to a condition characterized by an elevated resting sinus rate and often an exaggerated sinus response to exertion. The etiology of this condition is unclear but is felt to be exacerbated by abnormal autonomic tone.

### **Postural Orthostatic Tachycardia Syndrome**

Postural orthostatic tachycardia syndrome (POTS) occurs primarily in otherwise healthy young women marked by postural orthostatic symptoms including light headedness and weakness on standing without hypotension but with an abnormal postural increase in sinus rate.

### **Sinus Node Reentry**

*Sinus node reentry* refers to a reentrant tachycardia within the sinus node that cannot be distinguished from a regular sinus tachycardia on the surface EKG. However, this tachycardia is often marked by a sudden “jump” in heart rate followed by a return to the previous sinus rate.

### **Diagnosis and Treatment**

The diagnosis of a sinus tachycardia is made by analyzing the P-wave morphology on the surface EKG and, ideally, comparing it with a baseline EKG without arrhythmia. The P-wave and QRS morphology should be identical, although the patient may have a rate-related bundle branch block resulting in an altered QRS morphology. It is imperative to first rule out a secondary or physiologic cause for the sinus tachycardia. Beta-blocker treatment is often effective with IST, and the goal of treatment with POTS is maintenance of intravascular volume with oral fluids, salt, and fludrocortisone. Ablative therapy of the sinus node can be considered in refractory and highly symptomatic patients but often does not lead to symptomatic improvement.

### **Focal Atrial Tachycardia**

*Focal atrial tachycardia* refers to an atrial tachycardia that originates outside of the SA node. The mechanism of these tachycardias may involve reentry, automaticity, or triggered activity. Atrial tachycardias may originate from the right or left atrium. The most common sites of origin in the right atrium are the tricuspid annulus, the crista terminalis, and the ostium (os) of the coronary sinus. By far the most common site of origin of left atrial tachycardias is the myocardial junction of pulmonary veins and the left atrial antrum.

### **Diagnosis and Treatment**

The rates of atrial tachycardia can vary from 100 to 250 beats per minute. Careful analysis of the P-wave morphology

often reveals differences from the native P-wave morphology, although atrial foci close to the SA node may be indistinguishable. Atrial tachycardias are often marked by sudden onset and equally sudden termination as opposed to sinus tachycardia, which tends to show more graduated acceleration and deceleration.

The first line of symptomatic atrial tachycardia is rate control with either beta-blockers or calcium channel blockers, such as verapamil or diltiazem. In those patients with refractory symptoms despite medical treatment, catheter ablation is indicated. In those patients who have failed ablation or who are poor candidates for ablation, class III agents such as amiodarone and sotalol or class IC agents such as flecainide can be used provided that the patient has been deemed suitable for such drugs.

### **Atrial Flutter**

Common atrial flutter is caused by a large macroreentrant circuit with a wavefront revolving around the tricuspid annulus. Atrial rates are typically between 240 and 300 beats per minute, most often with 2:1 conduction to the ventricles, resulting in a ventricular rate of 150 beats per minute. Concerns include rate control, rhythm control, and anticoagulation caused by risk of potential thromboembolic events, similar to AF, discussed later.

### **Diagnosis and Treatment**

In typical counterclockwise atrial flutter, the wavefront proceeds up the atrial septum and down the right atrial free wall. P waves are negative in the inferior leads (often referred to as a “sawtooth” pattern), positive in V1, and negative in V6. The circuit can also revolve in the clockwise direction, giving rise to positive P waves in the inferior leads and a negative deflection in V1. Reentry is dependent on conduction through the cavotricuspid isthmus bounded by the tricuspid valve annulus, inferior vena cava, eustachian ridge, and coronary sinus os. Other atrial tachycardias can mimic atrial flutter, and in patients with prior atrial surgery or ablation, common atrial flutter may have an atypical EKG appearance. Rate control of atrial flutter is often quite challenging, owing to the regular repetitive flutter circuit. Beta-blockers, calcium channel blockers, and digoxin are all reasonable choices but often may result in only a limited degree of rate control. Cardioversion and catheter ablation are reasonable options.

Catheter ablation is performed by placing a series of radiofrequency lesions across the cavotricuspid isthmus, creating a line of conduction block. Success is achieved in >95% of patients, and recurrences are less frequent than in those managed with antiarrhythmic drug therapy.

Approximately 20% to 30% of patients also have atrial disease that leads to AF in the next 20 months. A history of both AF and depressed ventricular function increases the risk of subsequent AF.

## Atrial Fibrillation

AF is the most common supraventricular arrhythmia in the United States, and its prevalence increases with age. AF is an important risk factor for stroke and is a cause of increased mortality and hospitalizations in patients with heart failure. Sleeves of myocardium extending along the pulmonary veins are often important sites for the initiation of AF. Atrial scarring caused by stretch and inflammation also plays a role in the substrate for the maintenance of AF. The resulting arrhythmia is exceedingly rapid (>400 beats per minute) and disorganized in the atrium. The AV node is bombarded with these rapid signals and produces a somewhat slower, irregularly irregular ventricular response. Patients may have episodes that start and stop on their own (paroxysmal) or episodes that require medical intervention for termination (persistent). AF that is refractory to medical intervention to achieve sinus rhythm is termed *permanent*.

### Diagnosis and Treatment

AF on the surface EKG consists of an irregular baseline without clear P waves discernible and an irregularly irregular ventricular response. Therapy is directed at rate control, rhythm control, and anticoagulation.

Rate control can be achieved with beta-blockers, calcium channel blockers, and digoxin. In cases where rate control cannot be achieved with medication, an AV junction ablation with permanent pacemaker implantation can be considered. In this case, the atria remain fibrillating, and the patient becomes pacemaker dependent because of iatrogenic heart block.

Reasons to restore sinus rhythm include symptomatic intolerance of the arrhythmia or a rare or first episode. Rhythm control can be achieved with antiarrhythmic drugs or catheter ablation. Note that among patients with symptomatically tolerated AF, a difference in mortality or stroke risk has not been demonstrated when patients are randomized to a rate control or rhythm control strategy. For those with structurally normal hearts appropriate for rhythm control, the sodium channel blockers flecainide and propafenone can be reasonable options. For those with structural heart disease, amiodarone is the most effective, but the potassium channel blockers sotalol and dofetilide can be reasonable options. Catheter ablation is 80% to 90% effective in maintaining sinus rhythm in patients with paroxysmal AF, but success rates fall to 50% to 60% among those with more persistent arrhythmia. Success rates are also lower for those with left ventricular systolic dysfunction or significant mitral valve disease. Catheter ablation is recommended for paroxysmal AF and selected persistent AF cases with intolerable symptoms and lack of response to, or contraindication to, antiarrhythmic pharmacotherapy.

The risk of thromboembolic stroke in patients with AF is in the range of 6% per year and is further increased by about 40% in patients who also have heart failure. Long-term anticoagulation with warfarin is indicated in those with a CHADS<sub>2</sub> score of  $\geq 2$  (one point each for congestive

heart failure, hypertension, age >75 years, and diabetes and two points for a prior stroke or transient ischemic attack) or a CHA<sub>2</sub>DS<sub>2</sub>-VASc score of  $\geq 2$  (one point each for congestive heart failure, hypertension, diabetes, vascular disease, female sex, and age 65 to 74 years; two points each for age  $\geq 75$  years and prior stroke or transient ischemic attack). In the acute setting, all patients with persistent arrhythmia lasting >48 hours merit short-term anticoagulation with a heparin or direct thrombin inhibitor as appropriate with a bridge to warfarin anticoagulation for a minimum of 6 weeks. Alternatives to warfarin for long-term oral anticoagulation include factor Xa inhibitors and direct thrombin inhibitors. These oral medications offer the ease of fixed dosing without the need to monitor international normalized ratio levels. However, most lack a reversal agent in the event of acute bleeding. Furthermore, the pharmacokinetics may be variable in patients with impaired renal function.

### Atrioventricular Nodal Reentry

Paroxysmal supraventricular tachycardias most commonly include the following three tachycardias: atrioventricular node reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT), and atrial tachycardia. Among the paroxysmal supraventricular tachycardias, AVNRT is the most prevalent in adults. It presents as a narrow complex tachycardia unless there is concurrent rate-related aberrancy. The most common symptoms are palpitations, dizziness, shortness of breath, and chest pain. This arrhythmia can occur at any age but most often manifests itself in young adulthood.

The anatomic AV node consists of a compact portion and adjoining lobes. In patients with AV nodal reentry, the lobe that extends along the tricuspid annulus toward the coronary sinus likely forms a functional pathway for slow conduction. The typical functional fast pathway demonstrates rapid conduction and has a long refractory time, whereas the slow pathway conducts slowly but has a shorter refractory period.

During normal sinus rhythm, conduction typically proceeds down the fast pathway. If an appropriately coupled atrial premature beat occurs, the impulse can block in the fast pathway but can still conduct down the slow pathway (because of the shorter refractory period of the slow pathway). The impulse then can find the fast pathway recovered for conduction, and a reentry circuit can continue.

### Diagnosis and Treatment

The diagnosis of AVNRT is based on the symptom history and documentation of SVT on a surface EKG or on a recording monitor such as a Holter. Typical “slow-fast” AVNRT in which antegrade conduction occurs over the slow pathway and retrograde conduction occurs over the fast pathway is characterized by near-simultaneous atrial and ventricular activation. The P wave is often buried in the QRS complex but can sometimes be seen immediately after the QRS complex. This may manifest as a R-R' in lead V1. In the atypical

• **Fig. 84.1** Wolf-Parkinson-White pattern. Note the short PR interval and delta waves (arrows).

“fast-slow” form of AVNRT, however, retrograde atrial activation is delayed and may be difficult to differentiate from other SVTs such as AVRT or atrial tachycardia.

Treatment is primarily centered on patient stability and symptom relief. In the acute setting, evaluation must focus on the clinical status of the patient. Hemodynamic instability, syncope, respiratory compromise, and/or angina warrant acute termination with adenosine or cardioversion. In the stable patient, vagal maneuvers and carotid sinus massage may be attempted. Medical therapy includes beta-blockers and nondihydropyridine calcium channel blockers. The asymptomatic patient with rare occurrences and self-termination with vagal maneuvers may not warrant any daily treatment. Catheter ablation allows for definitive treatment of AVNRT in the patient with incomplete control with medications or in those patients who do not wish to take medications. There is a small but present risk (0.8%) of complete heart block during AVNRT ablation requiring implantation of a pacemaker.

### Accessory Pathway–Dependent Tachycardia

In the normal heart, the only electrical connection between the atria and ventricles is the AV node and His-Purkinje system. However, in some individuals, additional pathways for impulse conduction exist that are referred to as accessory pathways. These pathways may conduct in the antegrade direction, retrograde direction, or both. Sinus conduction proceeding antegrade over the accessory pathway results in a delta wave and a short PR interval (<120 ms), referred to as a Wolf-Parkinson-White (WPW) pattern (Fig. 84.1). When this pattern is associated with arrhythmias, it is referred to as WPW syndrome. Accessory pathways are most often found in individuals with structurally normal hearts, but there is a significantly higher incidence of accessory pathways in certain conditions such as Ebstein anomaly.

Regular tachycardia that uses an accessory pathway is referred to as AVRT. Except in the rare instances of multiple accessory pathways, the circuit involves the atria, ventricles, AV node, and accessory pathway. When the impulse travels antegrade down the AV node and back up the accessory pathway, it is referred to as orthodromic reentrant tachycardia (ORT), whereas when the impulse travels antegrade down the accessory pathway and back up the AV node it is referred to as antidromic reentrant tachycardia (ART). ORT is manifested by a narrow complex tachycardia whereas ART, which is maximally preexcited, is a wide complex tachycardia. Of note, given that the atria and ventricles are integral parts of the tachycardia circuit, there is an obligatory 1:1 AV relationship in any form of AVRT. Tachycardia that persists in spite of evident variable conduction to the atria or ventricles effectively rules out AVRT.

### Diagnosis and Treatment

The presence of a WPW pattern on a surface EKG reveals the presence of an accessory pathway, although the mere presence of an accessory pathway does not imply that AVRT has occurred or will occur, and furthermore, it may be an innocent bystander in the context of another underlying tachycardia mechanism. The absence of a delta wave does not rule out AVRT because the accessory pathway may be far from the sinus node and/or may only conduct in the retrograde direction—that is, a concealed accessory pathway.

The primary concern with WPW is the possibility of developing AF rapidly conducting over the accessory pathway leading to a rapid ventricular response and possibly ventricular fibrillation (VF). Risk factors for sudden death in WPW include a younger age at diagnosis, prior AF or AVRT, rapidly conducting pathways or multiple pathways, and a history of syncope. An EP study can risk stratify the conduction characteristics of an accessory pathway and thereby determine the suitability of catheter ablation of the

accessory pathway. In the case of a high-risk pathway, the patient may be placed on a sodium channel-blocking drug to stabilize him or her until an EP study can be performed. Furthermore, as in the case of AVNRT, nodal-blocking agents can be used as first-line therapy in AVRT with concealed accessory pathways, but more definitive treatment is achieved with catheter ablation of accessory pathways.

## Junctional Tachycardia

The normal AV junctional escape rate is 40 to 60 beats per minute, but an accelerated junctional rhythm with rates between 70 and 130 beats per minute may occur, most often in the context of irritability of the AV junction. Junctional ectopic tachycardia may be caused by conditions such as recent cardiac valvular surgery, myocardial ischemia, digitalis toxicity, or myocarditis. Rarely primary junctional automaticity can occur in isolation.

It is important to recognize that the entity paroxysmal junctional reciprocating tachycardia (PJRT), a slow-long RP tachycardia, is a bit of a misnomer, actually resulting from a slowly conducting posteroseptal accessory pathway. This entity is an important cause of a tachycardia-induced cardiomyopathy in pediatric patients and is responsive to catheter ablation.

## Diagnosis and Treatment

The diagnosis of junctional tachycardia is made by the observation of QRS morphology identical to that seen during sinus rhythm but with AV dissociation or evidence of retrograde P waves. True junctional ectopic tachycardia typically resolves as the inciting condition improves.

## Ventricular Arrhythmias

There are several features of ventricular tachycardia (VT) that should be considered during evaluation. It is of course important to initially look for clues that the wide complex tachycardia is not supraventricular in origin (Fig. 84.2). The occurrence of three or more ventricular beats is termed *nonsustained VT* (NSVT) unless it lasts for >30 seconds, in which case it is referred to as sustained VT. The rates of VT are generally >120 beats per minute. A ventricular rate <110 beats per minute is referred to as an accelerated idioventricular rhythm (AIVR). VT with a single QRS morphology is referred to as monomorphic VT, whereas polymorphic VT is characterized by a constantly changing QRS morphology. Following the acute stabilization of the patient, it is critically important to ascertain the cardiac history and cardiac function of a patient with VT because this information alone can point to the underlying etiology of the arrhythmia.

## Syndromes Associated With Ventricular Arrhythmias and Sudden Cardiac Death

### Brugada Syndrome

This syndrome is an autosomal dominant syndrome characterized by EKG abnormalities and predisposition to ventricular arrhythmias. The primary mode of diagnosis is the

• **Fig. 84.2** Algorithm to differentiate ventricular tachycardia (VT) from supraventricular tachycardia (SVT) with aberrancy. *A-V dissociation* refers to independent atrial and ventricular activity. *Capture beats* refer to regularly conducted supraventricular beats during ventricular tachycardia whereas *fusion beats* refer to a QRS morphology that is a combination of the ventricular tachycardia and a supraventricular beat conducted down the conduction system. *CAD*, Coronary artery disease; *LB*, left bundle; *RB*, right bundle.

EKG, which shows a complete or incomplete right bundle branch block (RBBB) pattern along with coved ST elevations in leads V1 and V2, in the context of a structurally normal heart. Occasionally this pattern may be concealed at baseline but may be seen with administration of a class IC agent such as flecainide. Risk factors for sudden cardiac death (SCD) include a prior history of ventricular arrhythmia as well as a type I Brugada pattern in the setting of arrhythmic syncope. In this setting, treatment may include placement of an implantable cardioverter defibrillator (ICD).

### Long QT Syndrome

The long QT syndrome is characterized by abnormal repolarization. The QT interval may be prolonged, with abnormal appearance of the T wave on surface EKG. These patients are at increased risk of torsades de pointes, particularly in the setting of exposure to QT prolonging medications or in the setting of fluid and electrolyte imbalance. The most common clinical presentation for symptomatic individuals is syncope. Several genes have been identified to cause

congenital long QT syndrome. Most of these genetic mutations result in abnormalities in potassium, sodium, or calcium channel function. Sympathetic activation has been associated with cardiac events, particularly in the case of type 1 long QT syndrome. Beta-blocker therapy is therefore recommended. In some cases, left cardiac sympathetic denervation surgery or ICD therapy may be considered. Of note, in those cases where bradycardia or pause-dependent arrhythmias are noted, an increased programmed atrial pacing rate on the pacemaker or ICD may prove beneficial.

### Arrhythmogenic Right Ventricular Dysplasia

*Arrhythmogenic right ventricular dysplasia* refers to a genetic disorder characterized by replacement of myocardial tissue primarily involving the right ventricle with fat and fibrosis, thereby predisposing to ventricular arrhythmias and heart failure. Given the right ventricular origin, the ventricular arrhythmias commonly have a left bundle branch block (LBBB) configuration, and the baseline EKG may show ST and T-wave abnormalities in the anterior precordial leads. The condition often declares itself with palpitations, syncope, or sudden cardiac death, and symptoms are often exacerbated with exercise. The primary mode of diagnosis is with imaging technologies such as cardiac MRI. Although medical therapy and VT ablation may suppress VT and improve symptoms, ICD placement may be indicated for the prevention of SCD.

### Cardiomyopathies

Dilated and hypertrophic cardiomyopathies are associated with an increased risk of developing ventricular arrhythmias. Risk factors for sudden death in hypertrophic cardiomyopathy include a family history of sudden death, personal history of VT or prior cardiac arrest, arrhythmic syncope, and ventricular wall thickness  $>3$  cm. Patients with these risk factors should be considered for ICD implantation. Patients with dilated cardiomyopathy are also at increased risk of ventricular arrhythmias and SCD, particularly in the setting of significant left ventricular systolic dysfunction. These arrhythmias are often scar mediated. ICD placement has been shown to be beneficial for primary prevention of SCD when the ejection fraction (EF) is  $<35\%$ .

### Idiopathic Ventricular Tachycardia

Monomorphic VT that occurs in the context of a structurally normal heart is referred to as idiopathic ventricular tachycardia.

### Outflow Tract Tachycardia

Also known as repetitive monomorphic VT, outflow tract tachycardia most often originates from the right ventricular outflow tract (RVOT) and less frequently from the left ventricular outflow tract. RVOT tachycardias manifest with an LBBB morphology and an inferior axis on the surface EKG. These tachycardias are often catecholamine sensitive and may terminate with adenosine.

### Fascicular Ventricular Tachycardia

Fascicular ventricular tachycardia, also referred to as idiopathic left ventricular tachycardia (ILVT), typically originates from the midseptal or inferoapical region of the left ventricle. The left posterior fascicle is most often involved in the tachycardia circuit. The surface EKG pattern is characteristically an RBBB morphology with a superior axis.

### Diagnosis and Treatment

Idiopathic ventricular tachycardias are rarely life-threatening, and as such, ICD therapy is not indicated for these patients. Medications and catheter ablation are often able to suppress the arrhythmia. Outflow tract tachycardias often respond to beta-blockers and verapamil and, in refractory cases, to class III agents such as amiodarone and sotalol. Catheter ablation is increasingly being used to treat outflow tract tachycardias because the success rates are high with relatively low procedural risks. ILVT is characterized by its sensitivity to verapamil both for acute treatment and for chronic suppression. As with outflow tract VT, catheter ablation is increasingly being considered as first-line therapy given the high success rates and low procedural risk.

### Ischemic Ventricular Tachycardia

Coronary artery disease (CAD) is the most common cause of ventricular tachycardia. Ventricular arrhythmias including, polymorphic VT and VF can occur during active ischemia or during an acute coronary syndrome. However, monomorphic ventricular tachycardia typically occurs in the context of an existing myocardial scar that acts as a substrate for ventricular reentry. Scarring associated with CAD is often transmural but spares an endocardial rim of myocardial tissue that survives through direct diffusion from the intracavitary blood pool.

### Diagnosis and Treatment

A wide complex tachycardia in a patient with CAD should be assumed to be VT until proven otherwise. VT that is clinically unstable should be promptly treated with direct-current (DC) cardioversion. When treating clinically "stable" VT, however, medications such as lidocaine, amiodarone, and, less frequently, procainamide can be used in the acute setting. Rule out active ischemia as a trigger for ventricular arrhythmias in the context of an ischemic substrate. Options for the chronic treatment of ischemic VT include medical therapy, ablation, and ICD implantation. If the EF is preserved, then the only role for an ICD lies in secondary prevention. However, if the EF is impaired, an ICD may be indicated for primary prevention of SCD. Drug therapy is often effective in treating ventricular tachycardia. The most common agents used to treat ischemic VT include beta-blockers and class III agents including amiodarone. Class IA and class IB agents, such as quinidine and mexiletine, may also often prove

useful. For the patient with medication-refractory VT or in the patient with drug intolerance, VT ablation is an option that often provides excellent results.

### Bundle Branch Reentry

*Bundle branch reentry (BBR) tachycardia* refers to a specific form of VT that uses the conduction system as the circuit. Typical BBR tachycardia occurs in the context of a significantly dilated left ventricle with baseline LBBB and prolonged His-to-ventricle conduction time. The tachycardia is typically initiated by a premature ventricular contraction that is blocked retrograde in the right bundle but travels up the left bundle and down the now excitable right bundle to complete the circuit. BBR tachycardia can manifest the same QRS morphology as the baseline QRS morphology because it uses the His-Purkinje system as part of the circuit.

### Polymorphic Ventricular Tachycardia

Polymorphic VT (PMVT) is characterized by a continuously varying QRS morphology. Polymorphic VT is classified based on whether it occurs with a normal or prolonged QT interval at baseline. PMVT, in the context of a normal baseline QT interval, may occur with underlying coronary ischemia. It may also occur in a structurally normal heart as a sporadic phenomenon or in the setting of catecholaminergic polymorphic VT syndrome. This syndrome is characterized by exercise or stress-induced onset of ventricular ectopy including polymorphic ventricular tachycardia and classically bidirectional ventricular tachycardia. Beta-blocker solo therapy or combination beta-blocker and flecainide therapy is recommended. In patients with a prior cardiac arrest or with syncope despite medical therapy, an ICD should be considered. Medications, as in the case of digoxin toxicity, may be associated with multiform VT in general and bidirectional VT in particular.

## Chapter Review

### Questions

- A 67-year-old woman with no known heart disease is admitted to the hospital for dyspnea caused by exacerbation of chronic obstructive pulmonary disease. On telemetry, it is noted that she had several sinus pauses up to 3 seconds in duration while sleeping. Upon history, it is noted that the patient has never had symptomatic bradycardia including syncope, near-syncope, or exertion intolerance. On physical examination, there is no evidence of cardiovascular disease. The patient is not on any medications that affect the SA or AV nodes. Which of the following is the best option for management?

  - Order an outpatient 30-day event monitor to assess for bradycardia.
  - Implant a permanent pacemaker based upon telemetry findings.
  - Reassure patient and advise her to seek medical attention if she develops symptoms of bradycardia.
  - Perform an exercise treadmill test to assess heart rate response to exertion.
  - Obtain an echocardiogram to assess for structural heart disease.
- A 46-year-old man who is otherwise healthy except for paroxysmal AF presented to the clinic for follow-up after a 30-day event monitor. He was initially diagnosed 4 years ago when he presented with episodic palpitations and dyspnea and was found on event monitor to have paroxysmal AF with rapid ventricular response correlating with his symptoms. He was initially managed with a rate-control strategy with metoprolol but had only partial improvement in symptoms. Subsequently, flecainide was added, and his symptoms improved for 1 to 2 years. Two months ago, on routine visit, he noted increased frequency and duration of AF symptoms. The 30-day event monitor performed in the last month revealed paroxysmal AF correlating with his symptoms. In the clinic, the patient is asymptomatic, in sinus rhythm, and has no evidence of heart failure. What is the most appropriate next step in management?

  - Admit the patient to the hospital to work up the etiology of his increased burden of AF.
  - Start amiodarone after checking baseline thyroid, liver, and pulmonary function tests.
  - Start digoxin after assessing renal function.
  - Refer the patient for consideration of catheter ablation procedure.
  - Reassure the patient that paroxysmal AF is not life-threatening, and continue current management.
- A 25-year-old man who has had episodic palpitations since high school presented to the emergency department with his usual palpitations and was found to have a regular, narrow complex tachycardia at a rate of 220 beats per minute on 12-lead EKG. He does not have any additional symptoms along with his palpitations, and he appears comfortable. His blood pressure is 126/76 mm Hg. There is no evidence of heart failure on physical examination. The patient has continuous rhythm monitor and percutaneous defibrillation pads in place. Which of the following would not be an appropriate strategy for initial management?

  - Intravenous adenosine
  - Intravenous metoprolol
  - Valsalva or other vagal maneuver
  - Carotid sinus massage
  - DC cardioversion

## Cardiovascular Disease Prevention

JONATHAN D. BROWN AND JORGE PLUTZKY

**A**therosclerotic cardiovascular disease (CVD) remains the leading cause of death in the developed world, causing approximately 600,000 fatalities annually in the United States. For classification purposes, CVD is typically subcategorized into four groups: (1) coronary heart disease (CHD), (2) cerebrovascular disease, (3) peripheral arterial disease (PAD), and (4) aortic disease including aortic aneurysm and aortic dissection. Of these, nearly half of all cardiovascular deaths arise directly from CHD, manifested as acute myocardial infarction (MI)/sudden cardiac death or heart failure, with cerebrovascular disease causing an additional 20% of CVD deaths. Recent advances have helped to identify key risk factors that contribute directly to the initiation and progression of CVD.

This chapter focuses on how cardiovascular risk factors contribute to the initiation and progression of CHD. Cardiovascular risk factors are currently grouped into “traditional” and “nontraditional” types. Traditional risk factors include hyperlipidemia (or dyslipidemia), tobacco use, hypertension, diabetes mellitus, age, male gender, and family history, all of which have been linked to CHD, an association substantiated through multiple large prospective population studies. The categories can be further subdivided into modifiable and nonmodifiable factors, with dyslipidemia, tobacco use, hypertension, and diabetes comprising the former. In spite of their undeniable diagnostic and prognostic value, a portion of the population lacking these traditional risk factors remains at significant residual risk for CHD. As a result, there has been a major effort to identify novel factors that might help assess CHD risk within the population. These so-called nontraditional/novel factors include high-sensitivity C-reactive protein (hs-CRP), homocysteine, lipoprotein(a), and soluble adhesion molecules including soluble intercellular adhesion molecule and fibrinogen. Other candidate risk factors are frequently raised in the literature. The role of nontraditional factors in assessing patient risk for CHD is an evolving process that requires larger prospective clinical trials for validation and assessment of causality. Our discussion here centers on traditional risk factors in CHD management and treatment.

### Hyperlipidemia/Dyslipidemia

#### Normal Lipid Metabolism

The lipid component of blood has emerged as one of the most important, potent, and modifiable risk factors for CHD. Three distinct lipid/lipoprotein molecules are routinely measured in the blood: cholesterol, triglyceride, and fatty acids. Phospholipids comprise another critical but biologically distinct type of lipid possessing a phosphate functional group, but they are not routinely quantified in the clinical laboratory. The average range for total cholesterol and triglyceride in plasma is based on population assessment of their distribution: total cholesterol, 100 to 200 mg/dL, and triglyceride, 50 to 150 mg/dL. These ranges are often referred to as normal values, although what truly constitutes a normal level of these molecules continues to evolve.

The hydrophobic nature of these lipids renders them insoluble in the bloodstream and requires that they be packaged into larger hydrophilic lipoproteins—complex macromolecules composed of a mix of protein, cholesterol, and specific lipids. Lipoproteins are further subfractionated based on charge and mass into five major groups: chylomicron (formed from intestinal absorption of dietary triglyceride), very-low-density lipoprotein (VLDL), intermediate-density lipoprotein, low-density lipoprotein (LDL), and high-density lipoprotein (HDL). Each lipoprotein fraction is composed of different quantities of cholesterol, triglyceride, and phospholipids; chylomicron and VLDL contain the highest triglyceride content, LDL and HDL carry predominantly cholesterol, and HDL also contains significant phospholipid. Triglycerides are three fatty acids attached to a monoacylglycerol backbone. Lipoproteins are also enriched with specific apolipoproteins (“apo-”) that provide structural integrity for these particles, participate in determining metabolism, and serve as ligands for specific cellular receptors facilitating lipoprotein particle removal from the circulation. Examples of apolipoproteins include apolipoprotein B (apoB), apolipoprotein E (apoE), and apolipoprotein CIII (apoCIII). LDL and VLDL are rich in apoB content. HDL is predominantly comprised of apoA-I and apoA-II. Chylomicrons contain apoE, whereas

apoCII and CIII are important constituents of both chylomicrons and VLDL. In the case of LDL, apoB is a crucial protein that binds to the LDL receptor expressed on the surface of hepatocytes, leading to LDL clearance by the liver. As discussed later, dysfunction of these proteins can lead to clinically relevant dyslipidemias.

The liver integrates systemic lipid metabolism beginning with dietary chylomicron uptake from the portal circulation followed by lipoprotein synthesis, packaging, and secretion into the circulation, in particular of VLDL, and ending finally with lipoprotein clearance and excretion of unused or excess lipid through the hepatobiliary system. Once formed, circulating lipoprotein content (cholesterol and triglyceride content) is significantly remodeled in peripheral tissues and in the bloodstream by cell-associated enzymes including lipoprotein lipase (LPL), hepatic lipase, and endothelial lipase, as well as circulating plasma enzymes including CETP (cholesterol ester transfer protein) and PLTP (phospholipid transport protein). Fundamental and often overlooked concepts include the facts that lipoprotein particles, even within a specific type of particle (i.e., VLDL or LDL or HDL), represent a range of different particles and that lipoproteins are in communication with one another. For example, during its transit through the circulation, VLDL undergoes metabolism and gradually loses its triglyceride content as fatty acids are hydrolyzed off by LPL, ultimately leaving behind a VLDL remnant that is enriched in cholesterol. As their names imply, both CETP and PLTP transfer cholesterol and phospholipids between LDL and HDL. The recycling process mediated by HDL lipoprotein is termed “reverse cholesterol transport” and removes atherogenic lipid from the artery. This system’s net effect is to shuttle lipid derived from tissues and the artery wall back to the liver for excretion or recycling. A simple definition of dyslipidemia is a total cholesterol, LDL cholesterol, or triglyceride >90th percentile for the general population or an HDL cholesterol <10th percentile for the general population. Clinically significant dyslipidemias that increase CHD risk can result from defects in any component within these pathways of lipoprotein synthesis, remodeling, or clearance.

### The Cholesterol Hypothesis

As a risk factor for predicting and treating CHD, the relationship between plasma lipid levels and atherosclerosis, the “cholesterol hypothesis,” is rooted in observations made by the German pathologist Rudolf Virchow during the 19th century in which he identified that human atheroma contains cholesterol crystals. This hypothesis has now gained widespread acceptance based, in part, on several cross-sectional studies consistently demonstrating a graded positive association between plasma cholesterol levels and CHD frequency and mortality. As one example, in the Seven Countries Study, investigators found a continuous risk in CHD mortality in the population beginning at approximately 7% risk for a total cholesterol level of 200 mg/dL rising to 30% with cholesterol levels of 300 mg/dL. Importantly, this relationship was evident around the world and independent of other known

risk factors such as hypertension and cigarette smoking. An earlier study by the Lipid Research Council found a similar relationship in which patients without known CHD and total cholesterol >240 mg/dL experienced a doubling of CVD mortality rate from approximately 2.5 to 5 per 1000 patient years. Based on data derived from the Framingham Heart Study, the lifetime risk of total CHD (all clinical manifestations) at age 40 years with a cholesterol  $\geq$ 240 mg/dL is 57% in men and 33% in women, as compared with 31% in men and 15% in women with cholesterol level <200 mg/dL. This increased risk spans across all ages of adulthood, such that a 70-year-old with total cholesterol  $\geq$ 240 mg/dL carries a 10-year risk for CHD of 28% in men and 29% in women, compared to 18% and 5% if total cholesterol is <200 mg/dL.

These data are important to consider from the standpoint of primary prevention given that approximately two-thirds of first major coronary events occur in persons age  $\geq$ 65 years. Moreover, these data combine with the evidence that atherosclerosis begins early in adulthood to argue for earlier intervention and lower thresholds for treatment. One such group receiving increased attention in terms of primary prevention and CVD risk are women, many of whom will manifest CHD primarily in the postmenopausal period although risk factors may have been driving risk much before this. Taken together, these data have led to a major shift in preventive cardiology over the last decade, moving away from notions of secondary and primary prevention, which are inherently artificial, and focusing more on relative risk that is independent of prior history. A major contributor to this risk is LDL cholesterol.

### Low-Density Lipoprotein Cholesterol

Defining a causal relationship between cholesterol and CHD has required a deeper understanding of the aforementioned biochemical pathways involved in cholesterol and triglyceride metabolism as well as more refined tools for measuring cholesterol fractions in the blood. Brown and Goldstein’s seminal work defining the LDL receptor (LDLr) as the major protein responsible for hepatic clearance of circulating LDL, as well as the identification of LDLr loss-of-function mutations in patients who develop severely accelerated CHD (see subsequent discussion on familial hypercholesterolemia), has provided confirmatory experimental evidence for the hypothesis that LDL cholesterol, specifically, contributes causally to atherosclerosis and CHD. LDL cholesterol and the oxidatively modified LDL particle directly promote atherogenesis through a variety of mechanisms, including (1) reduced bioavailability of nitric oxide leading to endothelial dysfunction and altered vascular tone, (2) increased macrophage uptake of lipid and formation of the foam cell within the artery wall, (3) increased expression of inflammatory cytokines that amplify proinflammatory cell recruitment within the atherosclerotic plaque, and (4) increased platelet aggregation.

In addition to oxidation of LDL, the particle size/concentration may impact the risk of atherosclerosis. Epidemiologic data suggest that small, dense LDL may impose a significantly increased risk for CHD. This has been shown

**TABLE 85.1** Primary Prevention Lipid Lowering Trials

Trial	Patient (n)	CHD Risk Factors	Duration (Years)	Drug	LDL-C Baseline	LDL-C Change	Major Coronary Events	Coronary Mortality
WOSCOPS	6595	3+	4.9	Pravastatin	192	-26%	-31%	-33%

HHS	4081	1+	5	Gemfibrozil	Non-HDL-C >200 mg/dL		-34%	NS
WHO Cooperative	10,577		9	Clofibrate				+25% (total mortality)

AFCAPS/TexCAPS, Air Force/Texas Coronary Atherosclerosis Prevention Study; ASCOT/LLA, the Anglo-Scandinavian Cardiac Outcome Trial—8 years after closure of the Lipid Lowering Arm; CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; HHS, Helsinki Heart Study; LDL-C, low-density lipoprotein cholesterol; MI, myocardial infarction; NS, not significant; WHO, World Health Organization; WOSCOPS, West of Scotland Coronary Prevention Study.

in case-control trials in which patients with MI have smaller LDL particle size. It is important to recognize that patients with secondary disorders such as obesity and metabolic syndrome/diabetes mellitus often have small, dense LDL particles that may promote their CHD risk. Although dense LDL is a marker of a more atherogenic lipid profile, the routine measurement of particle size is not recommended as standard practice in most guidelines. In fact, patients with elevated triglyceride values usually have increased small, dense LDL. Guideline recommendations for calculating levels of “non-HDL” (total cholesterol—HDL) as a secondary target for treatment are, in effect, an effort to generate a measure of apoB-containing particles and smaller, dense LDL that may persist after LDL has been controlled and may be further incorporated into the new adult treatment program guidelines (ATPIV) that have been anticipated for some time. The non-HDL goal is 30 points above the LDL goal (LDL goal <100 mg/dL, non-HDL goal 130 mg/dL, etc.). Patients not at non-HDL goal would presumably receive more intensive LDL lowering or attempts to lower triglycerides or raise HDL. The American College of Cardiology/American Heart Association (ACC/AHA) 2013 cholesterol guidelines abandoned LDL goals, focusing on clinical groups warranting statins (known atherosclerotic CVD [ASCVD], LDL >190 mg/dL, diabetes,  $\geq 7.5\%$  cardiovascular risk over 10 years) and appropriate statin intensity; with more data, the 2017 ACC update now notes the evidence supporting LDL targets.

The strong association between LDL and CHD risk is further substantiated by the consistent risk reduction in CHD events in patients treated with LDL-lowering therapy. In particular, primary prevention trials with hydroxymethylglutaryl CoA reductase inhibitors (statins) have demonstrated significant reductions in CHD events in patients across a broad spectrum of plasma cholesterol levels (Table 85.1). Based on these and other randomized prospective clinical trial data, the current cholesterol guidelines target LDL cholesterol as the primary treatment goal for lipid lowering

in CHD risk modification. However, in contrast to previous guidelines (e.g., the 2004 ATPIII guidelines), the latest ACC/AHA guidelines set aside the LDL- and non-HDL-cholesterol targets that were previously recommended (treat patients with CVD to a target of LDL <100 mg/dL [or the optional goal of <70 mg/dL]). Rather, the new guidelines identify treatment for four groups of primary- and secondary-prevention patients and for each of these groups make recommendations on the appropriate “intensity” of statin therapy in achieving relative reductions in LDL cholesterol. The four groups include (1) individuals with clinical ASCVD, (2) individuals with LDL-cholesterol levels >190 mg/dL, (3) diabetic patients without CVD age 40 to 75 years with LDL-cholesterol levels between 70 and 189 mg/dL, and (4) patients without evidence of CVD, an LDL cholesterol level 70 to 189 mg/dL, and a 10-year risk of ASCVD >7.5%. The net effect of these new guidelines will likely be greater exposure to statins in adults without CVD (estimated to be approximately 13 million additional Americans) but especially among older adults age 60 to 75 years without CVD.

### Monogenic Disorders Causing Hyperlipidemia/Dyslipidemia

The growing evidence connecting plasma lipids and CHD risk, as well as the realization that lipid disorders and accelerated atherosclerosis cluster in families, generated interest in classification systems of lipid abnormalities in the larger population. Frederickson, Levy, and Lees first categorized systematically dyslipidemias using measurements of cholesterol and triglyceride coupled with lipoprotein patterns after separation by electrophoresis. This classification included five types of hyperlipoproteinemia:

Type I: elevation of chylomicrons

Type II: elevation of LDL

Type IIb: combined elevation of LDL and VLDL

Type III or broad beta disease: elevation of remnant lipoproteins

Type IV: elevated VLDL

Type V: elevation of both chylomicron and VLDL.

Recent identification of specific gene defects that cause lipoprotein disorders has partially supplanted this lipoprotein phenotype classification. Abnormalities of plasma cholesterol are now viewed as primary disorders arising from monogenetic defects in specific lipid metabolism pathways or as secondary disorders resulting as a consequence of systemic diseases including diabetes mellitus, hypothyroidism, nephrotic syndrome, or obesity among others.

### Disorders of Low-Density Lipoprotein

#### Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is a genetic disorder of LDL cholesterol metabolism inherited in an autosomal dominant manner. The defect localizes to the *LDLR* gene with over 800 distinct mutations now described involving major gene rearrangements, gene deletions, point mutations, insertion of premature stop codons, and mutations of the *LDLR* promoter that affect transcription of the *LDLR* gene. The connection between FH and disruption of the *LDLR* gene provides strong independent evidence for a causal relationship between LDL and CVD. Patients with dysfunctional or absent *LDLR* cannot effectively clear LDL from the plasma, thereby leading to marked elevations in circulating LDL and accumulation of cholesterol in the artery wall. There is a gene dose response in the phenotype such that homozygous and heterozygous mutation carriers manifest different severity of disease. Homozygous FH occurs with a prevalence of 1:1 million in the population. In homozygotes, there are two mutant alleles (compound heterozygotes containing a distinct mutation on each allele also occur and lead to a homozygous phenotype). These patients are characterized by the degree of relative *LDLR* function: mutations are classified as negative if there is <2% *LDLR* activity or defective if there is 2% to 25% *LDLR* activity. Typically, total plasma cholesterol levels are >500 mg/dL and can rise as high as 1200 mg/dL. As a consequence of these extreme elevations in plasma cholesterol, patients develop characteristic clinical manifestations including cutaneous xanthomas and tendinous xanthomas in typical locations including the Achilles tendon or along metacarpophalangeal joints, as well as corneal arcus—all representing abnormal deposition of cholesterol in the skin, tendons, and around the iris of the eye. Progressive accumulation of cholesterol within the coronary arteries incites atherosclerosis and promotes severe, accelerated CHD, typically manifesting in the first two decades of life with MI or angina. Epidemiologically, a strong positive association between *LDLR* mutations and premature CHD exists, reflecting this heightened propensity for atherosclerosis. Heterozygous FH occurs with a frequency of 1:500 in the population and presents a more varied phenotypic picture. Due to the single mutant allele, only approximately 30% to 40% of

these patients develop tendinous or cutaneous xanthomas. Often there will be a family history of hypercholesterolemia and CHD, and these patients typically manifest CHD later in the fourth decade of life. Treatment includes aggressive multidrug pharmacologic therapy aimed at lowering LDL cholesterol, including high potency statins, inhibitors of intestinal cholesterol absorption, and niacin. Two new therapies have now been US Food and Drug Administration (FDA) approved exclusively for homozygous FH treatment: antisense therapy targeting apoB transcription (mipomersen) and a microsomal transfer protein inhibitor (lomitapide). Both agents lower LDL levels significantly but also have offsetting side effects or other barriers to use; these issues are balanced by this exceptionally high-risk, fairly rare group of patients that often require apheresis. Two injectable antibodies to proprotein convertase subtilisin/kexin type 9 (PCSK9), which potently decrease LDL levels by blocking *LDLR* lysosomal degradation, are now approved: evolocumab and alirocumab, discussed further below. Ezetimibe blocks gut cholesterol reabsorption, lowers LDL by ~20%, and decreases cardiovascular events when added to statin therapy (IMPROVE-IT). LDL apheresis (plasma ultrafiltration that removes circulating LDL) remains a definitive approach to patients with very high residual LDL levels; its use is challenging given outdated reimbursement rules, the need for frequent sessions, fistula placement, limited apheresis centers, and complication rates.

#### Familial Ligand-Defective Apolipoprotein B

Although the molecular characterization of *LDLR* mutations provided key mechanistic insight into the FH phenotype, another population of patients with FH-like features was noted to have LDL particles that did not bind with high affinity to the LDL receptor. This group manifested a disease phenotype similar to a heterozygous FH carrier, but they possessed a defect in the LDL particle itself. Subsequent work identified a point mutation causing an arginine to glutamine (R3500Q) amino acid substitution in the apoB gene product (*APOB*), the major protein constituent of LDL that is required for *LDLR*-mediated clearance of LDL in hepatocytes. This mutation significantly reduces LDL lipoprotein binding to its cognate receptor. Subsequent analysis has identified at least one other missense mutation in the *APOB* gene that affects LDL binding to the LDL receptor. This disease also transmits in an autosomal dominant fashion. The frequency of heterozygous familial ligand-defective apoB (FDB) ranges between 1:500 and 1:700. Moreover, because the penetrance of the mutant *APOB* allele is not 100%, FDB patients typically manifest less severe overall disease, including 20% to 25% lower LDL cholesterol compared with FH patients, and have a slightly lower risk of CHD as compared with FH patients with *LDLR* mutations.

#### Proprotein Convertase Subtilisin/Kexin Type 9

Until 2003, only the two autosomal dominant defects described earlier had been linked to hereditary hyperlipidemia. A third autosomal dominant disorder of LDL

cholesterol metabolism had previously been mapped to chromosome 1p, now identified as involving the *PCSK9* gene. This convertase is a serine protease synthesized by hepatocytes and secreted into the circulation where it attaches to the LDLr, targeting it for lysosomal degradation. A missense mutation encodes an activating mutation, thereby promoting excessive degradation of the LDLr in the liver, markedly raising LDL cholesterol levels due to decreased LDLr-mediated endocytosis and largely copying FH phenotypes. Conversely, a population of patients harboring “inactivating” mutations of *PCSK9* has significantly lower lifelong LDL cholesterol levels and a markedly reduced lifetime risk of CHD, without evidence of other abnormalities or issues.

In FOURIER, statin-treated CHD patients (mean baseline LDL 92 mg/dL) receiving the *PCSK9* inhibitor evolocumab had additional decreases of LDL (59%) and in the primary endpoint (15% heart attack, stroke, hospitalization for angina, revascularization, or cardiovascular death) versus controls; cardiovascular death, heart attack, or stroke declined 25%. Alirocumab studies are under way. *PCSK9* inhibitor costs and the vague nature of statin intolerance have limited *PCSK9* inhibitor use.

### Abetalipoproteinemia

This is a rare autosomal recessive disorder affecting the gene for microsomal triglyceride transfer protein (MTTP). Only approximately 100 cases are described worldwide, and the disease is more common in males. MTTP is a heterodimeric protein that plays a central role in beta-lipoprotein assembly, which includes LDL, VLDL, and chylomicron lipoproteins. As a consequence of this defect, these patients cannot absorb dietary fats, leading to developmental problems associated with inadequate nutrition and vitamin deficiencies. Typically, patients present during infancy with gastrointestinal symptoms including vomiting, diarrhea, abdominal bloating, and steatorrhea as well as failure to thrive caused by intestinal malabsorption of lipids. Additional symptoms are related to vitamin A, vitamin E, and vitamin K deficiencies including sensory disturbances, ataxia, movement disorders, muscle weakness, and hematologic problems including anemia and abnormal clotting. Treatment requires a diet low in long-chain triglycerides (>18 carbons) in favor of short- and medium-chain triglycerides. Fat-soluble vitamin and iron supplements are also required.

### Disorders of Triglyceride-Rich Lipoproteins: Chylomicron and Very-Low-Density Lipoprotein

Normal fasting plasma triglyceride levels range between 50 and 100 mg/dL and can rise markedly following a lipid-laden meal when they are absorbed and packaged into chylomicrons for delivery to the liver. The role of plasma triglycerides as a risk factor for CHD independent from elevated LDL cholesterol and low HDL cholesterol has been difficult to prove, in part due to the frequent association of high triglycerides with high LDL and/or low HDL (especially in diabetes). A recent report analyzing two nested case-control studies derived from the prospective studies Reykjavik and ERIC calculated an adjusted odds ratio for CHD of 1.76

and 1.58 for patients with triglyceride levels in the top third of log-triglyceride levels as compared with the bottom third. An additional metaanalysis of 27 prospective studies found a similar odds ratio of 1.72 for risk of CHD in patients with elevated triglycerides. In addition to CHD, severe elevations in triglyceride (>600 mg/dL) can cause pancreatitis necessitating preemptive treatment for some patients irrespective of their CHD risk. Factors contributing to elevated circulating triglycerides include genetic disorders (discussed later), as well as secondary factors including obesity, diabetes mellitus/metabolic syndrome, nephrotic syndrome, hypothyroidism, significant alcohol use, physical inactivity, and certain medications including estrogen replacement, tamoxifen, beta-blockers, and immunosuppressives such as glucocorticoids and cyclosporine.

### Familial Hypertriglyceridemia

Familial hypertriglyceridemia is an autosomal dominant disorder characterized by moderate elevations in plasma triglycerides (typically 200–500 mg/dL) and marked postprandial hypertriglyceridemia. This disorder is often accompanied by insulin resistance, obesity, diabetes mellitus, and hypertension. The abnormality arises due to hepatic overproduction of VLDL, but specific gene defects have not yet been identified. The prevalence of this disorder ranges between 1:50 and 1:100, but it is highly heterogeneous, likely reflecting multiple defects in triglyceride metabolism.

### Familial Hyperchylomicronemia (Buerger-Gruetz Syndrome)

This rare, type I hyperlipoproteinemia arises from loss of LPL function (mutations in apoCII, a cofactor for LPL enzymatic function have also been described) and occurs with a worldwide prevalence of 1:1 million. Over 60 mutations in the *LPL* gene have been identified. As a consequence of LPL inactivity these patients cannot hydrolyze triglyceride from chylomicrons, leading to extreme elevations in this lipoprotein. Fasting triglycerides can reach >1000 mg/dL. Plasma will appear lipemic, and a chylomicron band usually appears on the top surface of the plasma if allowed to stand at 4°C overnight. This degree of triglyceride elevation leads to recurrent pancreatitis and eruptive xanthomas in patients. Homozygous carriers often present in childhood with failure to thrive secondary to nutritional abnormalities. This syndrome can also be associated with xerostomia, xerophthalmia, and behavioral changes. Treatment requires avoidance of long-chain dietary fats and alcohol.

### Disorders of High-Density Lipoprotein

In contrast to positive associations between LDL cholesterol and CHD, multiple epidemiologic studies have consistently identified an inverse relationship between HDL cholesterol level and CHD risk such that patients with elevated HDL cholesterol exhibit protection from atherosclerosis and CHD. The mechanism for this inverse relationship remains an active area of research. Based on this inverse relationship between HDL and CHD, a long-standing hypothesis has posited that raising HDL cholesterol levels will protect

against future CHD. HDL-raising therapies including niacin, a currently FDA-approved medication, as well as novel drugs that inhibit plasma CETP, can significantly raise plasma HDL cholesterol. In the case of CETP inhibition, the HDL effect is marked, achieving 30% to 100% increases. However, when tested in randomized controlled trials, these approaches have thus far failed to demonstrate reductions in CVD endpoints in large cohorts (ILLUMINATE, AIM-HIGH, HPS-Thrive2, and dal-OUTCOMES). The CETP inhibitor anacetrapib did significantly reduce cardiovascular events (REVEAL)—apparently through LDL lowering, not HDL raising—but will not undergo commercial development, given an exceptionally long half-life and alternative therapies. Niacin did not decrease events despite raising HDL in AIM-HIGH while combining niacin and the antiflushing agent laropiprant did not decrease outcomes (HPS2-Thrive). Certain subgroups might benefit from niacin; for example, those with very low levels of HDL and significant risk or patients with elevated lipoprotein(a) whose levels decrease with niacin. However, the use of niacin in general has become harder to rationalize for most patients, especially when combined with challenging tolerability (flushing, worsening insulin sensitivity, and gout).

There are currently no specific, targeted HDL-raising therapies approved for use in the United States. The failure of all these HDL-raising trials points to questions regarding HDL as a therapeutic benefit. A more nuanced hypothesis suggests that HDL “flux” is more relevant and important. In this model, dynamic HDL turnover is more important by virtue of this lipoprotein’s capacity to accept lipid efflux from macrophages in atherosclerotic plaque and offload the cholesterol in the liver for excretion—so-called reverse cholesterol transport, as discussed further above and below.

### Tangier Disease

HDL particles, which begin as lipid-poor disks, acquire cholesterol in the tissue or from transfer of cholesterol from LDL to HDL as mediated by plasma enzymes including PLTP and CETP, ultimately leading to the formation of mature lipid/cholesterol-rich spherical HDL. ApoA1 is the major acceptor protein for the initial cholesterol loading of the HDL particle. Efflux of cell-derived cholesterol requires specific transporters termed *ATP binding cassette* (ABC) transporters, consisting of a large family of membrane proteins that facilitate lipid trafficking between cells and the plasma. At the molecular level, Tangier disease (TD) occurs due to mutations specifically in the *ABCA1* transporter function resulting in the inability of macrophages and keratinocytes to efflux cholesterol to nascent plasma HDL particles. This markedly impairs HDL formation in the plasma compartment, resulting in low plasma levels of total HDL. The defect was originally described in a proband from Tangier Island located in the Chesapeake Bay, Maryland. Inheritance is autosomal recessive. Less than 100 reported cases have been found worldwide, but more than 50 mutations in the *ABCA1* gene have since been identified to date. HDL cholesterol levels are

**TABLE 85.2 Lipid Management: Pharmacotherapy**

Therapy	TC (%)	LDL-C (%)	HDL-C (%)	TG (%)
Statins	19–37	25–50	4–12	14–29

Changes shown are general approximations; results may differ depending on the specific agents used.

*HDL-C*, high-density lipoprotein cholesterol; *LDL-C*, low-density lipoprotein cholesterol; *TC*, total cholesterol; *TG*, triglycerides.

less than the 5th percentile of the normal population. On physical examination, patients with homozygous TD demonstrate enlarged, orange tonsils and hepatosplenomegaly. A closely related disorder called familial hypoalphalipoproteinemia also maps to the *ABCA1* gene, but it is inherited in an autosomal dominant fashion. Phenotypically these patients resemble TD patients. On account of phenotypic variability of heterozygous carriers of *ABCA1* mutations, the association between low HDL in this group and CHD has been mixed. On balance, variation in the *ABCA1* gene appears to confer an increased risk of CHD, and certainly low HDL is one of the most common findings in the plasma lipid panel from patients with known CAD. Individual mutations may ultimately influence the strength of these associations. As an illustration of this effect, a recent analysis derived from three different population studies in Copenhagen examined heterozygous carriers for four *ABCA1* mutations and did not identify increased susceptibility for ischemic heart disease compared with nonmutation carriers (adjusted hazard ratio 0.67). The reason for this finding in spite of low HDL levels is not known, but it may reflect low levels of either total or atherogenic LDL cholesterol or the phenotypic variability associated with these genetic disorders. Despite these questions, low HDL cholesterol levels remain an important risk factor for CHD in the general population, and developing therapies to raise plasma HDL cholesterol remains a major goal in the field of CVD prevention.

A general table regarding expected changes in lipids in response to various pharmacologic agents is provided (Table 85.2).

### Nontraditional Risk Factor: High-Sensitivity C-Reactive Protein

Treatment of hypercholesterolemia has a clear role in reducing risk of CHD in patients with elevated cholesterol. However, half of MIs and strokes occur in patients who have relatively lower LDL cholesterol levels. Inflammatory

biomarkers such as hs-CRP provide additional risk stratification. In the case of hs-CRP, elevated levels predict future vascular events independently of LDL cholesterol level, thereby improving global risk classification approaches. The utility of hs-CRP as a “target” of treatment to lower risk of CHD was recently supported in a randomized, placebo-controlled, primary prevention trial called JUPITER. This study enrolled patients with average cholesterol (LDL cholesterol  $\leq 130$  mg/dL) and an elevated hs-CRP  $\geq 2.0$  mg/L to treatment with rosuvastatin (20 mg) or placebo with a primary endpoint of first major cardiovascular event or confirmed death from cardiovascular causes. The trial was terminated early because of a significant reduction in the primary endpoint in patients treated with rosuvastatin (see [Table 85.1](#)). The hazard ratio was 0.56 for this primary endpoint and was statistically significant across all subgroups including first MI, stroke, or revascularization for unstable angina. Although LDL cholesterol remains the primary goal of therapy, these data raise critical questions regarding the potential use of hs-CRP to risk-stratify patients with intermediate risk. Given prior subgroup analyses from other studies, as well as presumably the cost and logistical issues involved, JUPITER did not include an arm of the study treating patients with low LDL and low CRP. Follow-up studies from JUPITER suggest that the small but significant increased incidence of diabetes also seen in other statin trials is offset by the marked cardiovascular risk reduction. Administering canakinumab, an antibody to the proinflammatory mediator interleukin-1b, significantly decreased cardiovascular events without changing LDL levels, strongly supporting inflammation as a modifiable proatherosclerotic. Trials testing whether methotrexate decreases inflammation and cardiovascular events are under way (CERT).

## Hypertension

Hypertension is a major, common contributor to cardiovascular risk, hence the importance of screening patients. The Framingham Heart Study (FHS) estimates that individuals who are normotensive at age 55 years have a 90% lifetime risk for developing high blood pressure. Importantly, either the systolic or diastolic component is sufficient for a diagnosis, and the higher of the two measurements determines the diagnosis, CHD risk, and aggressiveness of treatment. Hypertension is the most common primary diagnosis in the United States (35 million office visits with this as a primary diagnosis), but current blood pressure control rates are well below 50%. Approximately 30% of patients are unaware that they have hypertension. As a risk factor, the relationship between blood pressure and all CVD including CHD, stroke, and heart failure, as well as kidney disease, is continuous, consistent, and independent of other risk factors. It is also important to realize that hypertension rarely occurs in isolation from other risk factors. According to FHS, only approximately 20% of patients have isolated hypertension. More commonly hypertension is associated with other metabolic abnormalities that may contribute to the degree of

blood pressure elevation including hyperlipidemia, metabolic syndrome, and cigarette smoking, which may result in surges in catecholamine levels. Regardless of the cause, in adults in the age group 40 to 70 years, every increment in 20 mm Hg of SBP or 10 mm Hg diastolic blood pressure (DBP) doubles the risk of CVD across the entire spectrum of blood pressure from 115/75 to 185/115 mm Hg, with ischemic coronary disease the most common organ damage associated with hypertension. SBP is more strongly associated than DBP in these outcomes.

Recent analysis of the National Health and Nutrition Education Survey (NHANES) database has found that the number needed to treat (NNT) to prevent a cardiovascular death was 273 for patients with stage I hypertension and 34 for patients with stage II hypertension if a 12 mm Hg reduction in SBP is achieved over a 10-year period. In patients with multiple cardiac risk factors, the number needed to treat dropped to 27 and 12, respectively, for a similar reduction in SBP. Thus an important way to integrate hypertension into the composite cardiovascular risk assessment is to consider the degree of hypertension, the presence of other cardiac risk factors, and evidence of target organ damage such as ischemic heart disease or heart failure. The association between hypertension and CHD is further strengthened from multiple prospective clinical trials that have demonstrated a consistent reduction in CHD risk with even modestly successful treatment of hypertension. [Chapter 65](#) reviews hypertension and its treatment in detail.

## Cigarette Smoking

A strong association between cigarette smoking and atherogenesis has been observed for many years but was directly assessed in the Atherosclerosis Risk in Communities (ARIC) study. The study included over 10,000 patients who had carotid artery intimal-medial thickness measured (CIMT)—a well-validated noninvasive metric of arterial atherosclerosis burden. In current smokers, there was an associated 50% increase in progression of atherosclerosis as compared with nonsmokers on CIMT. Importantly, the progression rates were similar between current and former smokers, suggesting that some of the effects of smoking may not be reversible after cessation. Mechanistically, smoking is associated with several pathophysiologic effects that likely promote atherosclerosis, including (1) elevation in LDL and triglyceride and reduced HDL; (2) activation of the sympathetic nervous system leading to increases in blood pressure, heart rate, and coronary vasoconstriction; (3) prothrombotic effect through inhibition of tissue plasminogen activator release from endothelium and increased tissue factor expression; (4) endothelial dysfunction including impaired endothelium-dependent relaxation secondary to oxidative stress and reduced bioavailability of nitric oxide; (5) increased inflammation as noted by increases in CRP levels and fibrinogen; and (6) elevations in homocysteine, which may also promote endothelial dysfunction.

Smoking is an important independent risk factor for developing CHD. The incidence of MI is increased 6-fold in women and 3-fold in men who smoke  $\geq 20$  cigarettes per day as compared with people who never smoked. Even more, cigarette smoking increases cardiovascular mortality, with an adjusted hazard ratio of 1.63 in one study. In patients with established CHD who continue to smoke after angioplasty, there is a greater relative risk of death (1.76) and MI (2.08). In the SOLVD trial studying patients with left ventricular dysfunction, smoking significantly increased all-cause mortality (relative risk 1.41) as well as incidence of death, recurrent heart failure requiring admission, or MI (relative risk 1.39). This association between smoking and CHD risk is further strengthened when considered in concert with data revealing the cardiovascular benefits of smoking cessation. Among patients without known CHD, smoking cessation has been associated with a cardiac event rate reduction ranging from 7% to 47%. The cardiac risks associated with smoking are reduced quickly after cessation. In addition, a recent meta-analysis of several prospective studies of patients who have had an acute coronary syndrome with prior CHD found that the relative risk for mortality was 0.64 (confidence interval [CI], 0.58–0.71) in smokers who quit ( $n = 5659$ ), compared with those who continued to smoke ( $n = 6944$ ). An important smoking subgroup is the diabetic population. In patients with type 2 diabetes (T2D), smoking significantly increases the risk for microvascular and macrovascular complications. Specifically, there is a dose-dependent effect of smoking in women with diabetes for CHD: relative risk 1.7 for 1 to 15 cigarettes per day up to 2.68 for  $>15$  cigarettes per day. There is a similar cigarette dose response with respect to mortality in female patients with T2D. Smokers with diabetes have increased risk for neuropathy and are more likely to progress to end-stage renal disease. Taken together, these data establish smoking as an important, independent risk factor for the development of CHD and identify a critical lifestyle intervention that can dramatically reduce CVD both as primary and secondary CHD prevention.

## Diabetes Mellitus

Diabetes mellitus continues to increase in prevalence throughout the world and is a major, independent risk factor for CHD as well as other morbidity including renal disease and microvascular disease. The epidemiologic data for this association are persuasive. As an example, the FHS found that the presence of T2D doubled the age-adjusted risk for CVD in men and tripled it for women. Another study, the Multiple Risk Factor Intervention Trial found that in the 5163 male patients who reported taking medication for T2D, 9.7% died from CVD over a 12-year period compared with 2.6% mortality rate among the 342,815 men who were not taking medications for T2D. The East-West study compared the 7-year incidence of fatal/nonfatal MI in those with versus without diabetes and with or without a history of prior MI. As expected, having both a prior MI and diabetes predicted high risk for future MI ( $-45\%$ ), while having

neither diabetes nor prior MI was low risk (3.5%). However, having diabetes but no prior MI had the same future MI risk (20.2%) as prior MI survivors (18.8%). Although debated, viewing diabetes as a CHD “risk equivalent” emerged, with guidelines endorsing treating diabetes as a high cardiovascular risk group (e.g., warranting statin therapy), even in the absence of overt heart disease. Although this discussion focused on T2D, the relative risk for CVD is even greater for patients with type 1 diabetes mellitus. In the FHS, the cumulative CHD mortality was 35% by age 55 years in type 1 diabetes compared with 8% and 4% in nondiabetic men and women, respectively. Collectively these data establish the strong, positive association between diabetes and CHD. The mechanisms for such interactions between diabetes and CHD are complex and varied.

Despite this impressive CHD risk association, the goal of reducing macrovascular disease in patients with diabetes has remained a challenge, specifically with regard to showing that improved glycemic control improves cardiovascular outcomes. Several randomized placebo-controlled trials have demonstrated that aggressive glycemic control can significantly reduce the risk of microvascular diabetic complications including retinopathy and nephropathy. Although trends in some of these trials suggest a potential CVD benefit, no large prospective antihyperglycemic therapy studied to date has been able to demonstrate significant reductions in CHD events in the patient with T2D. One such trial, ACCORD, showed increased mortality in those undergoing intensive glucose management. The reason for this untoward effect has not been established but was not seen in two other intensive glucose control studies.

CVD benefit has been demonstrated with metformin in a subgroup of patients with obesity (UKPDS). Pioglitazone, a PPAR- $\gamma$ -activating thiazolidinedione drug, has been shown to reduce coronary atherosclerosis and decreased traditional CVD endpoints as a secondary endpoint, although a multifactorial primary endpoint that included PAD did not show a difference (PROACTIVE). More recently, pioglitazone was shown to decrease stroke and other cardiovascular events (IRIS), although known pioglitazone side effects were also present.

New FDA mandates for proving cardiovascular safety with new diabetes drugs have provided extensive new data. Dipeptidyl peptidase IV (DPP-IV) inhibitors saxagliptin and sitagliptin showed cardiovascular safety but no improved cardiovascular outcomes and possible increased congestive heart failure. Both GLP1 agonists and SGLT2 inhibitors have recently shown decreased cardiovascular events in T2D with these glucose-lowering drugs versus usual care, as seen with two agents in each class (GLP1 agonists liraglutide/LEADER, semaglutide/SUSTAIN 6; SGLT2 inhibitors empagliflozin/EMPA-REG, canagliflozin/CANVAS). The cardiovascular benefits were likely independent of glucose control.

In patients with type 1 diabetes, cardiovascular benefits with insulin treatment were not evident until some 20 years of follow-up data were obtained (DCCT-EDCT),

raising questions about whether similar-length studies are needed to uncover benefit in T2D. Metaanalyses do support cardiovascular risk reduction through glucose lowering, although the effects are not on mortality or stroke. Multiple issues may be involved with these results including intervening too late in the diabetes process, offsetting untoward effects of some antidiabetic treatments, the lack of impact on CVD through glucose alone in the absence of broader effects on the diabetic state, and/or the impact of aggressive statin therapy in patients with diabetes. With regard

to other concomitant risk factors including tobacco use, hypertension, and hyperlipidemia, however, patients with diabetes derive a substantial benefit from therapies targeting these factors. This explains why diabetes mellitus shifts the goals of antihypertensive and lipid-lowering therapy toward a more aggressive strategy, in fact treating patients with diabetes as if they have known CHD. At the moment, the most impressive data in reducing CVD risk in patients with diabetes come from a multipronged approach at improving all known risk factors (STENO-2).

## Chapter Review

### Questions

1. A 21-year-old white male comes to you for his first primary care visit. He is asymptomatic and has no past medical history. He informs you that he has been a smoker since the age of 16 years and smokes one to two packs per day. Physical examination is normal. All of the following statements are correct, except:
  - A. You assess the patient's willingness to quit smoking.
  - B. You advise the patient to stop smoking.
  - C. You develop a plan for smoking cessation and arrange follow-up.
  - D. You provide counseling, review pharmacologic therapy, and prescribe him nicotine gum and referral to a formal cessation program.
  - E. None of the above because this is his first visit seeing you
2. Which of the following is the strongest predictor of cardiovascular risk?
  - A. Low HDL
  - B. Low apoA1
  - C. ApoB
  - D. Triglycerides
  - E. CRP
3. All of the following statements regarding hormone therapy and selective estrogen-receptor modulators (SERMs) are correct, except:
  - A. Use of estrogen plus progestin is associated with a small but significant risk of CHD and stroke.
  - B. Use of estrogen without progestin is associated with a small but significant risk of stroke.
  - C. Use of all hormone preparations should be limited to short-term menopausal symptom relief.
  - D. Use of a SERM (raloxifene) does not affect risk of CHD or stroke but is associated with an increased risk of fatal stroke.
  - E. Hormone therapy and SERMs should be used for the primary or secondary prevention of CVD.
4. Which of the following agents have been shown in randomized, prospective clinical cardiovascular trials to significantly decrease cardiovascular events?
  - A. Statin therapy
  - B. PCSK9 inhibitor
  - C. SGLT2 inhibitor
  - D. GLP1 agonist
  - E. All of the above
  - F. None of the above
  - G. A and B

## Adult Congenital Heart Disease

YULI Y. KIM, MICHAEL J. LANDZBERG, AND ANNE MARIE VALENTE

Historically, individuals with complex congenital heart disease rarely lived past childhood. Because of tremendous advances in diagnosis and treatment, now 85% to 90% of children born with congenital heart disease will survive into adulthood. Estimates suggest that over 1 million adults with congenital heart disease currently live in the United States. The majority of these patients do not appear to be followed by adult congenital heart disease (ACHD) specialists. Therefore it is essential that all physicians familiarize themselves with the unique clinical presentations of these patients, including the anatomy, physiology, and natural history, to facilitate proper management and referral.

In 2001 the 32nd Bethesda Conference attempted to address the changing profile of adults living with congenital heart disease by developing guidelines for delivery of care. In this statement, congenital heart defects are grouped into different levels of anatomic complexity (Box 86.1), although every patient can be further categorized based upon physiologic severity of presentation, as well. It was recommended that patients with congenital heart disease of increasing levels of complexity be referred to specialized adult congenital heart centers. In 2015 the American Board of Medical Subspecialties administered the first examination for ACHD board certification. Collaborative care between primary care practitioners, internal medicine cardiologists, and ACHD subspecialty cardiologists is emphasized in joint guidelines from the American College of Cardiology and American Heart Association underscoring the need for partnerships in caring for this complex patient population. In this chapter, we focus on several of the more common congenital heart lesions seen in the adult.

### Simple Lesions

#### Atrial Septal Defect

An atrial septal defect (ASD) is a communication between the atria and is one of the most common congenital heart defects. There are several types of ASDs (Fig. 86.1), the most common of which is a secundum ASD, a defect in the region of the fossa ovalis. Primum ASDs are located near the crux of the heart and are associated with atrioventricular

(AV) canal defects. Sinus venous defects involve a deficiency between the right-upper and middle pulmonary veins and the superior vena cava (SVC type) or the right lower pulmonary veins at the right atrial-IVC junction (IVC type) and are associated with anomalous pulmonary venous drainage. Coronary sinus septal defects are very rare defects that involve unroofing of the septum between the coronary sinus and the left atrium. Defects that are large may lead to presentation in childhood; however, many ASDs are not discovered until adult life when patients present with exercise intolerance, atrial arrhythmias, or dyspnea.

In young adults, the dominant interatrial shunt is from left to right because left atrial pressure and both inflow and outflow resistances exceed those in the right atrium. The degree of subsequent left-to-right shunting determines the amount of right heart volume overload and is dictated by the size of the defect as well as the diastolic properties of the heart. Decreasing compliance of the left-sided cardiac chambers noted with increased aging (because of a multiplicity of contributors including increasing prevalence of diabetes, systemic arterial hypertension, atherosclerosis, and myocardial senescence) may contribute to increased left-to-right shunting and symptomatology, despite stability of defect dimensions, as patients grow older.

Clinical presentation, physical examination findings, and laboratory features are summarized in Table 86.1.

In the past, adult survivors with uncorrected ASDs were demonstrated to have reduced life expectancy. More recently, data suggest increased risk of atrial fibrillation and symptomatic respiratory issues prompting hospitalization in those with uncorrected ASD. Therefore persons with ASD and a significant shunt (evidence of otherwise unexplained right heart dilation  $\pm$   $Q_p/Q_s >1.5:1$ ) should be offered closure. Pulmonary vascular disease leading to pulmonary hypertension develops in 5% to 10% of patients with untreated ASD, although this development may not be solely attributable to increased left-to-right flow. Depending on the degree of pulmonary hypertension and pulmonary vascular resistance, consultation with a pulmonary hypertension expert may be required to determine if and how the shunt is repaired.

Secundum ASD can often be closed percutaneously if anatomically appropriate; results appear both safe and effective. Increasing use and subsequent analyses from national

### • BOX 86.1 Adult Congenital Heart Disease Lesions by Complexity

#### Simple Complexity

Isolated congenital aortic valve disease  
 Isolated congenital mitral valve disease (e.g., except parachute valve, cleft leaflet)  
 Isolated patent foramen ovale or small atrial septal defect  
 Isolated small ventricular septal defect (no associated lesions)  
 Mild pulmonary stenosis  
 Previously ligated or occluded ductus arteriosus  
 Repaired secundum or sinus venosus defect without residua  
 Repaired ventricular septal defect without residua

#### Moderate Complexity

Aorto–left ventricular fistulae  
 Anomalous pulmonary venous drainage, partial or total  
 Atrioventricular canal defects (partial or complete)  
 Coarctation of the aorta  
 Ebstein anomaly  
 Infundibular right ventricular outflow obstruction of significance  
 Ostium primum atrial septal defect  
 Patent ductus arteriosus (not closed)  
 Pulmonary valve regurgitation (moderate to severe)  
 Pulmonary valve stenosis (moderate to severe)  
 Sinus of Valsalva fistula/aneurysm  
 Sinus venosus defect  
 Subvalvar or supra-valvar aortic stenosis (except hypertrophic cardiomyopathy)  
 Tetralogy of Fallot  
 Ventricular septal defect with:
 

- Absent valve or valves
- Aortic regurgitation
- Coarctation of the aorta
- Mitral disease
- Right ventricular outflow tract obstruction
- Straddling tricuspid/mitral valve
- Subaortic stenosis

#### Severe Complexity

Conduits, valved or nonvalved  
 Cyanotic congenital heart (all forms)  
 Double-outlet ventricle  
 Eisenmenger syndrome  
 Fontan procedure  
 Mitral atresia  
 Single ventricle (also called double inlet or outlet, common or primitive)  
 Pulmonary atresia (all forms)  
 Pulmonary vascular obstructive diseases  
 Transposition of the great arteries  
 Tricuspid atresia  
 Truncus arteriosus/hemitruncus  
 Other abnormalities of atrioventricular or ventriculoarterial connection not included above (i.e., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

Modified from the 32nd Bethesda Conference. Reprinted from Warnes CA, Liberthson R, Danielson GK, et al. Task Force 1: the changing profile of congenital heart disease in adult life. *J Am Coll Cardiol*. 2001;37(5):1170–1175.

registries including data from congenital catheterization-based interventions are expected to shed greater light on such outcomes. Surgical closure is required for primum ASD, sinus venosus defects, and coronary sinus septal

• **Fig. 86.1** Anatomic types of interatrial communications (see text for description). ASD 1° denotes primum ASD; ASD 2° denotes secundum ASD. ASD, Atrial septal defect.

defects and should be performed by congenital heart surgeons. The long-term prognosis after repair for patients age <25 years is comparable to that of the general population. Patients repaired at an older age, particularly those age >40 to 50 years, may have decreased comparable long-term survival and may experience higher rates of comorbidities including atrial arrhythmias and right-heart failure.

#### Ventricular Septal Defect

A ventricular septal defect (VSD) is a communication between the ventricles and is the most common congenital anomaly seen in children; it may be an isolated defect or associated with complex cardiac disease. Several classification systems exist for defining VSDs. Fig. 86.2 illustrates the location and the nomenclature for the various types of VSDs.

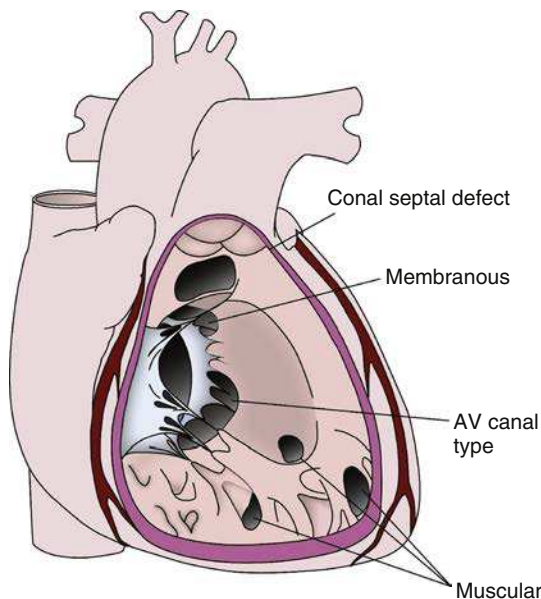

The size and location of the VSD, presence and degree of outflow tract obstruction, and relative resistances in the pulmonary and systemic vasculature are determinants of hemodynamic significance. Accordingly, left-to-right shunting at the ventricular level leads to volume overload to the left-sided chambers. Rarely, excessive flow to the pulmonary vasculature over time may result in changes that can eventually lead to elevated pulmonary vascular resistance with reversal of flow (Eisenmenger syndrome [ES]; see later). Clinical presentation, physical examination findings, and laboratory features are summarized in Table 86.2.

Some VSDs become smaller over time and may close spontaneously, particularly those in the membranous and muscular septum. However, adults with moderate or large VSDs should be offered closure if there are otherwise unexplained symptoms of congestive heart failure, a significant left-to-right shunt ( $Q_p:Q_s >1.5:1$ ), evidence of significant left ventricular (LV) volume overload, elevation of pulmonary

• **Fig. 86.2** Anatomic types of ventricular septal defects. Muscular denotes defects in the muscular septum; atrioventricular (AV) canal-type defects are defects of the inlet septum and are distinct from AV canal or endocardial cushion defects; membranous defects (also referred to as perimembranous or infracristal defects) are roofed by the tricuspid valve and can extend into the inlet, muscular, or infundibular septum; this includes many but not all of the conoventricular defects; conal septal defects are defects of the outlet or infundibular septum (also referred to as supracristal, doubly committed juxtarterial, or subarterial defects). Malalignment ventricular septal defects (not shown) result from deviation of conal septum from the plane of ventricular septum and is associated with outflow tract obstruction such as tetralogy of Fallot.

arterial pressures without significant elevation of pulmonary vascular resistance, or significant aortic regurgitation associated with conal septal, or membranous VSD. Closure of a VSD in the setting of ES can result in right ventricular (RV) failure and sudden death and is therefore contraindicated.

Outcomes for patients with small VSD (without pulmonary hypertension or evidence of LV volume overload) that do not require closure are generally excellent. However, 25-year survival rates correlate to size of the VSD, with decreased survival found in those with larger shunts and pulmonary hypertension. More recently, 40-year survival for those who underwent surgical VSD closure was found to be slightly lower than that for the general population. Long-term complications include biventricular systolic dysfunction and aortic regurgitation, especially in those with VSD associated with other lesions. Complications may include endocarditis, arrhythmias, heart failure, and aortic insufficiency for both repaired and unrepaired patients.

### Pulmonary Stenosis

Right-sided outflow tract obstruction can occur at various levels, including valvar (at the level of the pulmonary valve), supralvalvar (above the level of the pulmonary valve), or subvalvar (either at the infundibular or subinfundibular level). Pulmonary stenosis (PS) may be associated with various genetic disorders including Noonan and Alagille syndromes. Hemodynamically significant PS can lead to RV pressure overload with ensuing RV hypertrophy and failure. Clinical presentation, physical examination findings, and laboratory features are summarized in [Table 86.3](#).

The natural history of valvar PS is quite favorable with survival comparable with the general population. With mild valvar PS (Doppler peak instantaneous gradient <30 mm Hg by echocardiography), there is little progression of disease, and these patients can be followed without intervention. Based on natural history studies that did not include clearly defined criteria for either intervention or follow-up, intervention remains recommended for individuals with severe PS. In the presence of symptoms, peak instantaneous Doppler gradient >50 mm Hg (less gradient if RV dysfunction is present), and less-than-moderate pulmonary

insufficiency, percutaneous balloon valvuloplasty is considered the procedure of choice for repair of valvar PS in the absence of a hypoplastic annulus. Surgical repair using commissurotomy is indicated for more complex lesions, and valve replacement may be necessary if there is significant accompanying pulmonary insufficiency. Patients who have undergone surgical or catheter-based pulmonary valvotomy in childhood have excellent survival; however, many will require reintervention, particularly for sequelae of pulmonary regurgitation, in adulthood.

## Moderate Lesions

### Coarctation of the Aorta

Aortic coarctation is most commonly a discrete narrowing in the aortic isthmus just distal to the left subclavian artery and can be considered a diffuse arteriopathy. A bicommissural aortic valve is present in >50% of subjects with aortic coarctation, and it may be associated with additional left-sided obstructive lesions (Shone syndrome) and VSDs. Intracranial aneurysms, typically small and of unclear clinical significance, may be present in approximately 10% of people with aortic coarctation. There is a high prevalence of aortic coarctation in patients with Turner syndrome.

Hemodynamically, the increased afterload arising from obstruction of flow from the left ventricle may be accompanied by significant hypertension in the aorta and branch vessels proximal to the coarctation site and may be associated with systemic ventricular dysfunction, vessel aneurysm formation, and effects of premature atherosclerosis. Distal to the coarctation, there is diminished flow, and collaterals may develop to supplement areas of relative hypoperfusion. Clinical presentation, physical examination findings, and laboratory features are summarized in [Table 86.4](#).

In patients without aortic obstruction, the aortic pulse should be transmitted at equal speed and intensity from the left ventricle to the radial and femoral pulses that are approximately equidistant from the left ventricle. In patients with significant aortic coarctation, pulse wave propagation is both slowed and diminished distal to the coarctation, thereby delaying and diminishing femoral pulse relative to radial pulse. Standard practice dictates that all pulses should be checked at least once in the evaluation of all patients with systemic hypertension to rule out significant aortic coarctation. Four extremity blood pressures should be measured to assess for gradients.

Significant coarctation has previously been defined as a peak-to-peak gradient of 20 mm Hg across the stenosis as determined in the catheterization laboratory, although few

data support this relatively arbitrary cut point that has been used to signify risk of sequelae. Several factors need to be considered in selecting the most appropriate method for repair including age, anatomy of the transverse and descending aorta, history of prior repair, and institutional expertise. Stent implantation became a treatment option in the early 1990s and may be appropriate in adults and adult-size adolescents. Balloon angioplasty with or without stent implantation is the accepted treatment approach in recurrent coarctation with good acute and intermediate outcomes.

In a past era of few medical therapies for systemic hypertension or heart failure, untreated patients with aortic coarctation had poor survival with an estimated mortality of 75% by 46 years of age and median age of death of only 31 years. Causes of death were related to uncontrolled hypertension, congestive heart failure, infective endocarditis, aortic rupture or dissection, and cerebral hemorrhage. Today, adult survivors after aortic coarctation intervention remain at risk for increased prevalence of atherosclerotic risks factors, premature coronary and cerebrovascular disease, persistent hypertension, heart failure, aortic aneurysm, and recoarctation. ACHD care guidelines recommend lifelong surveillance for adults after coarctation repair and therapy of atherosclerotic risks, with monitoring of blood pressure control to help reduce sequelae. Currently adults who have undergone surgical repair have a 20-year survival rate of 84%.

### Tetralogy of Fallot

Tetralogy of Fallot (TOF) is the most common cyanotic congenital cardiac defect in adults. This conotruncal anomaly results from anterior deviation of the infundibular septum and is characterized by RV outflow tract (RVOT) obstruction, VSD, overriding aorta, and RV hypertrophy.

The vast majority of adults with TOF will have undergone surgical repair in childhood. The surgical strategies for TOF repair have evolved over time. Adults who were operated on

in the late 1950s and 1960s may have first undergone palliation with a systemic-to-pulmonary artery shunt (examples including central Waterston and Pott shunts and the more controlled classic and modified Blalock-Taussig shunts) to augment pulmonary flow before a complete repair. In the 1980s, primary repair was established, which involves an RVOT patch or conduit with removal of infundibular-level obstruction and any additional muscle bundles and VSD closure. Rarely, patients with minimal outflow tract obstruction may elude detection in childhood and because of minimal cyanosis remain unrecognized until later in life. Likewise, on occasion, adults with significant outflow obstruction may have lacked or avoided access to repair and may therefore present for care in later years. The clinical presentation of unrepaired patients with TOF depends largely on the amount of RVOT obstruction, which is a major determinant of the amount of right-to-left shunting across the VSD. Clinical presentation, physical examination findings, and laboratory features are summarized in [Table 86.5](#).

For adults with TOF who survive either unrepaired or are status-post palliative shunt only, a relatively well-balanced situation must be present. These patients need to be monitored for progressive RVOT obstruction, right heart failure, cyanosis, paradoxical emboli, and arrhythmias. In the postrepair patient, management is focused on residual lesions, their location, and severity, including pulmonary regurgitation, branch or more distal pulmonary artery stenosis, recurrent RVOT obstruction, RVOT aneurysm, aortic dilatation, aortic regurgitation and VSD patch leak.

Despite repair, adults with TOF require lifelong follow-up because of potential for right-sided heart failure with associated pulmonary and/or tricuspid regurgitation, aortic dilatation with resultant aortic insufficiency, left-sided heart dysfunction, and atrial and ventricular arrhythmias. Sudden cardiac death in adults with TOF has been well studied, with identification of several electrical, hemodynamic, and mechanical markers of increased risk.

## Ebstein Anomaly

Ebstein anomaly is an abnormality of the tricuspid valve and RV sinus. Failure of delamination of the septal and posterior leaflets of the tricuspid valve results in apical displacement of the tricuspid valve annulus. An associated ASD or patent foramen ovale is found in 80% to 94% of cases, with less frequent association of concomitant mitral regurgitation, LV myocardial, and RV outflow abnormalities. The hemodynamic consequences of the Ebstein anomaly are RV dysfunction and tricuspid valve regurgitation. The right atrium acts as a passive reservoir for this regurgitant flow and progressively dilates. Clinical presentation, physical examination findings, and laboratory features are summarized in [Table 86.6](#). The natural history of this lesion varies from early presentation with profound cyanosis and shock to adult survival, depending on the degree of tricuspid valve involvement, RV dysfunction, degree of shunting across the interatrial septum, and the presence and type of arrhythmias.

Patients with Ebstein anomaly are at risk for arrhythmias and sudden cardiac death. The dilated right atrium creates a substrate for supraventricular tachyarrhythmias, and accessory pathways are common in these patients with Wolff-Parkinson-White syndrome found in 10% to 25%. As survival trends improve for these adults, the profile of noted arrhythmias increasingly includes potential for atrial fibrillation and flutter, as well as ventricular tachycardia and fibrillation.

Medical management consists of congestive heart failure treatment as appropriate. Catheter ablation of accessory pathways or supraventricular arrhythmias should be performed in these patients or at the time of surgical repair. Surgical correction should be considered for patients with decreased exercise tolerance, worsening heart failure symptoms despite medical therapy, intractable arrhythmias, progressive RV dysfunction, and/or cyanosis. Surgical goals

include optimization of RV function, elimination of tricuspid regurgitation, and relief from cyanosis. The tricuspid valve may be repaired or replaced in addition to closure of an interatrial communication.

## Severe Lesions

### Transposition of the Great Arteries

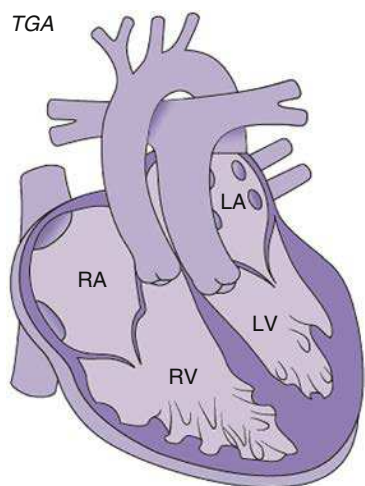

Transposition of the great arteries (TGA) is a form of AV concordance with ventriculoarterial discordance (each great artery arises from the incorrect ventricle). The most common form of TGA is referred to as D (dextro) loop TGA, in which all of the deoxygenated blood returns to the right atrium, right ventricle, and then back to the body through the aorta ([Fig. 86.3](#)). This creates systemic and pulmonary circulations that run “in parallel” (rather than in series) and is incompatible with life unless there is some type of communication between the two vascular circuits (ASD, VSD, or ductus arteriosus). Immediately after this physiology is recognized, if there is not an adequate mixing lesion, an emergent atrial septostomy or definitive repair may be performed.

The adult patient with D-loop TGA has almost invariably undergone prior surgical repair. The atrial switch repair (Senning or Mustard procedure) was pioneered in the 1960s. In these repairs, systemic and pulmonary venous blood are redirected at the atrial level such that systemic venous (deoxygenated) blood is directed to the left ventricle and travels out the pulmonary artery while pulmonary venous (oxygenated) blood returns to the right ventricle and is ejected out the aorta. The arterial switch procedure was more recently introduced and has become the standard of care since the 1980s. In this repair, the great arteries are transected, and the pulmonary artery is connected to the right ventricle with its branches draped anteriorly over the aorta (LeCompte maneuver),

**TABLE 86.6 Ebstein Anomaly**

Anatomy	Clinical Presentation	Physical Examination	Laboratory Features
Apical displacement of the septal and often the posterior leaflet of the tricuspid valve	Varies depending on severity and associated lesions	Cyanosis and clubbing if associated PFO or ASD	Chest radiography; “globe-shaped” heart with clear lung fields
Adherence of the septal and posterior leaflets to the underlying myocardium	Asymptomatic if mild	Jugular venous pulsations with absent v waves	EKG:
Dilation of the “atrialized” portion of the right ventricle	Cyanosis (if associated PFO or ASD)	Widely split S1	• Tall broad P waves of RAE
Redundant, “sail-like” anterior leaflet	Dyspnea	Systolic clicks from redundant anterior leaflet motion	• Incomplete or complete RBBB
Associated with:	Fatigue	Widely split S2	• 1st-degree
• ASD/PFO (80%–94%)	Right heart failure	Musical holosystolic murmur	• Atrial arrhythmias
• WPW (10%–25%)	Palpitations		
	Paradoxical embolization		
	Sudden death		

ASD, Atrial septal defect; PFO, patent foramen ovale; RAE, right atrial enlargement; RBBB, right bundle branch block; WPW, Wolff-Parkinson-White.

• **Fig. 86.3** D-loop transposition of the great arteries (TGA). The aorta arises anteriorly from the right ventricle (RV); the pulmonary artery arises posteriorly from the left ventricle (LV). LA, Left atrium; RA, right atrium.

which has been connected to the left ventricle. The coronary arteries are translocated and reimplemented into the neo-aortic root. Clinical presentation, physical examination findings, and laboratory features are summarized in [Table 86.7](#).

The long-term complications in D-loop TGA are dictated by the type of palliative surgery. Patients who have undergone atrial switch repair have a systemic right ventricle that can progressively dilate and fail with concomitant tricuspid regurgitation. Congestive heart failure is the most common cause of death in this population. After atrial switch for TGA, 25-year survival approaches 75% to 90% (less so with an associated VSD or Mustard procedure). Long-term sequelae include arrhythmia (both tachyarrhythmia and bradyarrhythmia), venous baffle obstruction, baffle leaks, and sudden cardiac death.

An alternative surgical procedure for patients with D-loop TGA, VSD, and pulmonary stenosis is the Rastelli procedure, which allows the left ventricle to be the systemic ventricle. This procedure involves VSD patch closure, which

routes the left ventricle to the aorta and places an RV to pulmonary artery conduit with oversewing of the native stenotic pulmonary valve. Long-term complications from this procedure include subaortic stenosis, conduit obstruction, residual VSD patch leak, and arrhythmias.

Patients who have undergone arterial switch procedures need to be monitored for supra-avalvular and branch pulmonary artery stenosis, neo-aortic dilation, and ensuing regurgitation. These patients must also be monitored for signs and symptoms of coronary ischemia and LV dysfunction, as the coronary arteries have been translocated.

It is important to recognize the rarer group of TGA patients, those with physiologically corrected TGA, or L-loop TGA, which involves both AV and ventriculoarterial discordance. These patients are not cyanotic, and their presentation is dependent not only on systemic RV function but largely on commonly associated lesions, including VSDs, PS, and tricuspid valve abnormalities with regurgitation.

### Single Ventricle and Fontan Circulation

The term *single ventricle* encompasses a wide spectrum of morphologies but is generally defined as one in which systemic venous and pulmonary venous blood enter a functionally single ventricle through a common AV connection. Common anomalies that fall under this definition include tricuspid atresia, hypoplastic left heart syndrome, and double-inlet left ventricle. It is a rare form of congenital heart disease estimated to have an incidence of 54 cases per million live births.

The hemodynamics of the single ventricle circulation depend on a variety of factors including obstruction to systemic or pulmonary outflow, obstruction to inflow, the presence of an interatrial communication, anatomy and nature of venous return, relative systemic and pulmonary vascular resistances, and AV valve regurgitation. The physiology of the single ventricle is unique in this degree of pulmonary and systemic circulation interdependence. Patients are cyanotic and may have undergone prior palliative procedures

to augment pulmonary blood flow with an aortopulmonary shunt.

Children with single ventricle anatomy can undergo palliative surgery to separate the systemic and pulmonary circulations with a functional single ventricle serving as the systemic pump. The Fontan operation achieves this by directing systemic venous blood directly to the pulmonary arteries without a subpulmonary pump. This preload-dependent circulation must rely on passive flow through the pulmonary vasculature with drainage of the pulmonary venous blood into the atrium and then into the systemic ventricle. The hallmarks of this physiology are high central venous pressures and low cardiac output.

Patients with unrepaired single ventricles may have a poor prognosis with early mortality in childhood or adolescence, although some patients with double inlet left ventricles and transposed great arteries with a relatively well-balanced circulation can survive well into adulthood. Therefore most patients encountered in adulthood have had prior surgical palliation, which is usually performed in multiple stages culminating in the Fontan operation. Clinical presentation, physical examination findings, and complications are summarized in [Table 86.8](#).

The survival of patients after the Fontan procedure is 95% at 15 years and 76% at 25 years. Patients are at risk for decreased exercise tolerance, heart failure, recurrent atrial arrhythmias, and sudden death. Long-term complications of adults with Fontan physiology include multiple organ dysfunction, including hepatic disease, renal dysfunction, and

vascular issues. These patients have a unique physiology that predisposes them to many potential complications (including plastic bronchitis and protein-losing enteropathy) and require regular close care by a team of congenital specialists.

### Eisenmenger Syndrome

ES is the clinical phenotype of an extreme form of pulmonary arterial hypertension associated with congenital heart disease. It is posited that over time, in a left-to-right shunt, excessive flow to the pulmonary bed increases pulmonary vascular resistance that eventually results in reversal of the shunt, creating bidirectional or right-to-left flow. Although the classic form of the disease was initially used to describe the long-term consequences of a VSD, it can occur with any congenital defect with an initial left-to-right shunt. With advances in the early diagnosis and management of congenital heart disease, the incidence of ES has declined, although it is still seen in older patients and occasionally in younger patients particularly in those from developing countries where surgical repair is not readily available. The natural history of ES is variable, and although a cause of significant morbidity, many patients survive ≥30 years after the onset of the syndrome. Clinical presentation, physical examination findings, and laboratory features are summarized in [Table 86.9](#).

ES is a multiorgan disease process. Medical care recommendations have included sustaining adequate hydration, avoiding and treating anemia including iron supplementation when appropriate, oxygen supplementation, which

**TABLE 86.8** Single Ventricle and Fontan Circulation

Anatomy	Surgical Palliation	Clinical Presentation	Late Complications Following Fontan
Tricuspid atresia Double inlet left ventricle Hypoplastic left heart syndrome	Modified BTS: subclavian artery to ipsilateral PA to improve pulmonary blood flow Bidirectional superior cavopulmonary anastomosis (Glenn): • SVC to PA • Usually with takedown of a previously placed systemic to PA shunt Total cavopulmonary anastomosis (Fontan): • IVC to PA by intraatrial lateral tunnel or extracardiac conduit; pulmonary blood flow is usually achieved passively, without the assistance of a ventricular pumping chamber	After Fontan: • Mostly NYHA functional class I-II • Usually no murmur • Elevated, nonpulsatile jugular venous waveform • Single S2 • Oxygen saturations usually mid 90s Unpalliated patients: • Cyanosis • Erythrocytosis • Bleeding diathesis • Thromboembolic events • Iron deficiency • Hyperviscosity • Stroke • Cerebral abscess • Renal dysfunction • Gallstones and cholecystitis • Gout • Hypertrophic osteoarthropathy	• Atrial tachyarrhythmia • Sinus node dysfunction • Thromboembolic events and hypercoagulable state • Cirrhosis and Fontan-associated liver disease • Protein-losing enteropathy • Fontan pathway obstruction or leaks • Obstruction in RA to PA anastomosis • Heart failure • Plastic bronchitis Cyanosis may be caused by: • Shunting through a surgically created fenestration or baffle leak • Incompletely incorporated hepatic veins into Fontan baffle • Pulmonary arteriovenous malformations • Systemic venous collateralization with connection to a pulmonary vein or pulmonary venous atrium • Reopening of systemic veins to pulmonary venous atrium • Pulmonary pathology

may improve symptoms if systemic arterial saturation rises with administration (but overall benefit is controversial), and anticoagulation (although this remains controversial because of predisposition to bleeding and occurrence of clinical hemoptysis, which has frequently been associated with pulmonary vascular thrombosis). Elevation of hematocrit above that considered appropriate for degree of cyanosis can be managed in “symptomatic” patients by hydration alone or on occasion by performing phlebotomy with isovolumic replenishment; routine phlebotomy in the asymptomatic adult with ES is contraindicated. Cautious optimization of iron stores has been demonstrated to improve quality of life and functional performance in iron deficient adults with ES. Endocarditis prophylaxis is warranted as are yearly flu shots and Pneumovax vaccination. Pregnancy is sufficiently high risk to both the mother with ES and fetus and is therefore counseled against in the strongest fashion. Contraception for women with ES who are of childbearing age is typically recommended, avoiding use of estrogen.

There is a growing body of evidence to suggest that the effects of pulmonary vascular changes in adults with ES are modifiable. Selective pulmonary vasodilators such as bosentan, in randomized clinical study, or sildenafil, in cohort

assessment, have been shown to be safe and efficacious. Select patients may be candidates for combined heart-lung transplantation or preferably lung transplantation with concomitant repair of the intracardiac defect, if feasible. Timing of these interventions may be difficult because of the relatively long-term survival of these patients after the onset of the disease process.

## Summary

The general internist and cardiovascular specialist face increasing numbers of adults with moderate and more severe complex anatomic forms of congenital heart disease in their practices. Epidemiologic review suggests that such affected individuals present with substantive medical as well as cardiovascular needs.

This chapter has provided an overview of the most general cardiovascular issues faced by ACHD. Care providers are urged to establish continuous relationships with regional ACHD cardiologists and centers of excellence so as to establish optimal communication and care planning for each ACHD patient they encounter and to ensure access to care review as specific or more novel issues arise.

## Chapter Review

### Questions

1. A 44-year-old woman is referred to you for a murmur heard on routine physical examination. On further questioning, she relates that she has noted increased exercise intolerance over the past 3 years but thought it was because she was “getting older.” She has no past medical history and is not on any medications. On physical examination the heart rate is 76 beats per minute and regular, blood pressure is 136/78 mm Hg, and oxygen saturation is 99% on room air. The JVP is estimated to be 10 cm H<sub>2</sub>O. On palpation there is mild lift at the lower left sternal border. The rate is regular with a widely split S<sub>2</sub> that varies minimally with respiration. There is a systolic ejection murmur heard at the left upper sternal border.  
The rest of the examination is unremarkable. The lesion she most likely has is:
  - A. TOF
  - B. ASD
  - C. VSD
  - D. Patent ductus arteriosus
2. A 32-year-old woman is being seen for a new patient evaluation. She does not know her exact diagnosis but tells you she had a “hole in my heart” that was repaired when she was around age 2 years. She was told that she was fixed and has not seen a doctor since childhood. On review of systems, she mentions that she gets frequent palpitations but no presyncope or syncope. On physical examination the blood pressure is 112/68 mm Hg, heart

rate is 72 beats per minute, and oxygen saturation is 98% on room air. You note a right thoracotomy scar, as well as a midline sternal scar. The radial pulse in her right arm is palpable but diminished. The JVP is not elevated. On palpation, there is an RV lift. There is a harsh II/VI systolic ejection murmur at the left upper sternal border with a palpable thrill. In the same location there is a short II/IV diastolic murmur creating a to-and-fro sound. The rest of the physical examination is unremarkable. On electrocardiogram, you note a right bundle branch block with a QRS duration of 176 ms. The most likely diagnosis is repaired:

- A. TOF
  - B. VSD
  - C. ASD
  - D. Patent ductus arteriosus
3. A 24-year-old man is seen in your office for hypertension. His blood pressure in the office is 180/90 mm Hg in the right arm and 176/86 mm Hg in the left arm. There is a loud S<sub>2</sub> and diminished femoral pulses. He mentions frequent headaches and some fatigue in his legs with exercise. Which of the following is *not* associated with this lesion?
    - A. Intracranial aneurysms
    - B. Continuous murmurs heard between the scapulae
    - C. Differential cyanosis
    - D. Bicuspid aortic valve
    - E. Risk of premature coronary artery disease

4. Match the following congenital heart lesions to an associated genetic disorder:
- 4.1. Turner syndrome 4
  - 4.2. Down syndrome
  - 4.3. DiGeorge syndrome
  - 4.4. Noonan syndrome
- A. TOF
  - B. PS
  - C. Primum ASD
  - D. Aortic coarctation
5. A 36-year-old man with an unrepaired VSD comes for routine follow-up. He is originally from Haiti and moved to the United States 5 years ago, and you have been following him ever since. On examination his blood pressure is 110/54 mm Hg, heart rate is 90 beats per minute, and oxygen saturation is 72%, which is his baseline. His examination is notable for mild perioral cyanosis and digital clubbing. His cardiac examination is notable for prominent *v* wave component of the jugular venous pulsation. There is an RV lift and a laterally displaced apex. S1 is single with a widely split S2. The P2 component is

prominent. There is a II/VI holosystolic murmur at the left lower sternal border. The liver is prominent and pulsatile, felt approximately 3 cm below the costal margin. There is 1+ pitting edema in the lower extremities. His hematocrit is 70%. Which of the following are potential complications?

- A. Iron-deficiency anemia
- B. Gout
- C. Hyperviscosity syndrome
- D. Cerebral abscess
- E. All of the above

### Answers

1. B
2. A
3. C
- 4.1. D

## Peripheral Vascular Diseases

SCOTT KINLAY

Peripheral vascular disease encompasses disease of the aorta and arteries of the lower extremities (peripheral artery disease [PAD]), venous insufficiency and thromboembolism (see [Chapter 35](#)), lymphatic disease, and pulmonary vascular disease (see [Chapter 88](#)). Vascular medicine is a growing specialty, which offers an internal medicine perspective on the assessment and management of these disparate manifestations affecting the vascular system. This chapter reviews several peripheral vascular diseases assessed in the American Board of Internal Medicine examination, including PAD, aortic aneurysm and dissection, carotid artery disease, venous insufficiency, and lymphatic disease.

### Peripheral Artery Disease

PAD refers to stenoses in the aorta, iliac arteries, and arteries of the lower limbs. Atherosclerosis is the most common cause of PAD, with other rarer causes including inflammatory vasculitis (see [Chapter 26](#)) and noninflammatory artery disease such as fibromuscular dysplasia and thromboembolism. Patients with PAD have a 3 to 4 times higher risk of cardiovascular (CV) events than non-PAD patients and may have decreased function because of claudication or increased risk of limb loss or amputation with more severe manifestations of limb ischemia.

Over 8 million adults in the United States have PAD. Similar to other manifestations of atherosclerosis, the prevalence increases with age, and it is present in 15% to 20% of adults age >65 years. The prevalence is higher in African Americans. Modifiable risk factors for PAD include cigarette smoking, diabetes mellitus, hypercholesterolemia, and hypertension.

### Clinical Manifestations of Peripheral Artery Disease

The three clinical presentations of PAD include intermittent claudication, critical limb ischemia, and acute limb ischemia (ALI) in descending order of incidence. Approximately 50% of patients with PAD are asymptomatic, 15% have claudication with exercise, 1% to 2% have critical limb ischemia, and a much smaller proportion present with ALI.

Intermittent claudication is a chronic ache, cramp, pain, or fatigue affecting the leg muscle that occurs during walking and is relieved by rest within 10 minutes of stopping walking. However, a third of patients have atypical leg discomfort with exercise. Claudication usually occurs in the calf but may affect the buttocks, thigh, or foot depending on the location of the arterial disease. Critical limb ischemia is a chronic cramping discomfort or pain in the muscles at rest, often relieved by leg dependency (e.g., hanging the leg over the edge of the bed), or ischemic tissue loss consisting of poorly healing ulcers or gangrene. ALI is the sudden decrease in limb perfusion (defined as within 14 days) that threatens limb viability. It is associated with a grave prognosis, with amputation rates ranging between 5% and 30% and mortality rates as high as 18%. In the vast majority of cases, ALI is caused by peripheral embolization of intracardiac thrombus, typically caused by atrial fibrillation.

Limb loss and amputation are rare with intermittent claudication but are higher with critical limb ischemia and especially in ALI. The vascular examination includes measurement of blood pressure in both arms (a difference of 20 mm Hg or more indicating upper arm arterial obstruction); palpation of the arm and leg pulses; auscultation for carotid, abdominal, and femoral bruits; passive limb elevation and dependency to assess elevation pallor and dependent rubor; and removing socks and shoes to identify ulcers or gangrene in the toes or feet.

Rarer causes of PAD other than atherosclerosis should be considered in patients age <40 to 50 years, patients without other evidence of atherosclerosis, and patients with rashes, arthralgias, or unusual symptoms or signs. These include vasculitis, athero- or thromboembolism, fibromuscular dysplasia, arterial entrapment syndromes, vascular tumors, trauma, and radiation-induced arteriopathy.

### Differential Diagnosis

The clinical history helps to distinguish PAD from other conditions. For example, patients with spinal canal stenosis may experience leg discomfort or pain with prolonged standing as well as walking and obtain relief when they flex their trunk (e.g., leaning forward on a shopping cart). Pain from radiculopathy with impingement of the spinal cord

### • BOX 87.1 Diagnostic Tests for Peripheral Artery Disease

- Exercise stress testing and ABI
- Duplex ultrasound imaging
- MR angiography
- CT angiography

roots often originates in the lower back and has a shooting or lightning quality down the back of the leg. Arthritis is associated with limited range of movement, joint pain, or tenderness. Restless leg syndrome is more commonly associated with involuntary leg movements at night. Often these conditions can coexist with PAD, and noninvasive testing may help in the differential diagnosis.

## Management of Peripheral Artery Disease

### Screening for Peripheral Artery Disease

Routine screening for PAD in asymptomatic adults is not recommended by the US Preventive Services Task Force (USPSTF) because of lack of evidence that early detection improves risk factor modification or outcomes. However, the American College of Cardiology (ACC)/American Heart Association (AHA) guidelines recommended targeted screening for groups at higher risk of PAD. These include patients age >65 years and patients age >50 years with smoking or diabetes.

### Noninvasive Tests of Peripheral Artery Disease

Physiologic and imaging tests can identify PAD (Box 87.1).

The ankle brachial index (ABI) is measured for each leg and is the ratio of the highest systolic pressure at the ankle (dorsalis pedis or posterior tibial arteries) to the highest brachial artery pressure. This can be measured in the office using a handheld Doppler device and a standard sphygmomanometer cuff on the upper arm and at the ankle or in the vascular laboratory where it is often combined with measurements at the thigh and calf (segmental leg pressures). The normal ABI is 1 to 1.3. This is because normally the systolic pressure increases progressively with greater distance from the heart as a result of pulse wave amplification. The pedal pulses are further from the heart than the brachial artery; therefore the ABI should be higher than 1. Because there is some variability in blood pressure, an ABI of  $\leq 0.9$  is considered diagnostic of PAD. This criterion has approximately 95% sensitivity and specificity for significant stenoses when compared with angiography.

Segmental leg pressures extend the ABI concept to different locations (and arterial segments) of the leg. A difference between segments (e.g., thigh to calf) of >20 mm Hg suggests a significant stenosis between these segments. Substantial arterial calcification, which can occur in the elderly or with diabetes, may make arteries incompressible or only compressible at very high pressure. ABI >1.3 suggests this cause and is

indeterminate for the diagnosis of obstructive PAD. In this case pulse volume recordings (PVRs) identify changes in the volume of the limb over the cardiac cycle by measuring changes in pressure of a cuff inflated around the limb at low pressure. Dampening or flattening of the recording of the limb volume with each pulse (PVR) indicates obstructive PAD.

Exercise treadmill testing can measure a patient's walking capacity, and postexercise ABI measurements can identify PAD if the resting ABI is not diagnostic, yet symptoms are highly suggestive of PAD. Exercise increases blood flow in the limbs and across stenoses exaggerating the drop in ABI. An exercise ABI <0.9 or a drop in ABI of more than 20% is diagnostic for PAD.

Imaging by duplex ultrasound, CT angiography, or MR angiography shows the location and severity of the stenosis. Imaging is usually considered when the diagnosis is uncertain after physiologic testing or to plan revascularization. CT angiography uses iodinated contrast, which can cause contrast nephropathy particularly in chronic kidney disease. MR angiography uses gadolinium contrast, which can cause nephrogenic systemic sclerosis in end-stage renal failure. Other limitations of MR include metal pacemakers and claustrophobia.

### Prognosis of Peripheral Artery Disease

Prognosis in PAD is related to the increased risk of CV events and to morbidity of poor limb function or limb amputation. In patients with claudication, 15% to 30% will have a nonfatal CV event over 5 years, and another 15% to 30% will die mostly from CV events. The prognosis is worse in patients with critical limb ischemia, where 20% die within 1 year, and another 30% will have a limb amputation. The risk of limb loss or major amputation in claudication is much less because only 1% to 2% progress to critical limb ischemia over 5 years.

### Medical Treatment of Peripheral Artery Disease

Treatment of PAD is directed at preventing the high risk of CV events and improving limb function and symptoms. The former focuses on atherosclerosis risk factor modification and the latter by increasing walking distances in claudication and preventing limb loss in critical limb ischemia.

Asymptomatic and symptomatic PAD is considered a coronary-equivalent risk status in ACC/AHA guidelines. Key risk factor modifications include smoking cessation, lipid lowering, blood pressure control, and glucose control (Box 87.2). These interventions reduce CV events and/or microvascular complications. Intensive lipid lowering (atorvastatin 40–80 mg/d or rosuvastatin 20–40 mg/d) is indicated regardless of cholesterol levels. Antihypertensive therapy theoretically may exacerbate limb symptoms, but it is important to protect the patient from systemic complications of hypertension. Blood pressure targets are the same as non-PAD patients (<130/80 mm Hg in patients with diabetes or renal insufficiency and <140/90 mm Hg for others). Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers decrease the risk of myocardial

### • BOX 87.2 Peripheral Artery Disease Risk Reduction Therapies Targeting Cardiovascular Events

- Physical activity >30 minutes moderately intense physical activity daily
- Weight maintenance/reduction
- Mediterranean diet
- Smoking cessation
- High intensity statin therapy (atorvastatin 40–80 mg/d, rosuvastatin 20–40 mg/d)
- Blood pressure <140/90 mm Hg or <130/80 mm Hg with diabetes or renal insufficiency
- Diabetes control: HbA1c <7%
- Antiplatelet therapy in symptomatic PAD or if otherwise indicated (e.g., angina)

HbA1c, Hemoglobin A1c; PAD, peripheral artery disease.

infarction (MI), stroke, and death in patients with atherosclerosis. Beta-blockers are indicated in PAD patients with MI and stable congestive heart failure. In metaanalyses, beta-blockers did not worsen claudication in patients with PAD. Current targets for glucose control in diabetes include a hemoglobin A1c <7%. Newer studies may challenge the blood pressure and glucose targets in current guidelines.

A Cochrane systematic review found that antiplatelet therapy reduces total and CV mortality in patients with symptomatic PAD by 24% and 46%, respectively. Two recent trials raised doubts about the efficacy of aspirin in patients with asymptomatic PAD and no other indication for aspirin. In the CAPRIE and CHARISMA studies, clopidogrel alone or in combination with aspirin showed minimal or no effect on CV events compared with aspirin alone. However, the PAD subgroups in these studies tended to show greater effects with clopidogrel, but these have not been adopted in clinical guidelines. Vorapaxar, which inhibits platelets through inhibition of the protease-activated receptor-1, decreased the risk of CV events but with an increased risk of bleeding. A subgroup analysis showed that in PAD patients, vorapaxar did not reduce CV events but did decrease the incidence of peripheral artery revascularization and ALI. Vorapaxar is contraindicated in past ischemic stroke because of an increased risk of intracranial hemorrhage.

Treatment directed at limb symptoms include therapies for walking function in claudication and limb preservation in critical limb ischemia. The two medical treatments for claudication are an exercise program and cilostazol. Supervised exercise, particularly walking, improves claudication-free walking distance by 180% and total walking distance (until stopped by claudication) by 120%. These exercise programs typically involve three to five sessions of treadmill or track walking per week for durations of 35 to 50 minutes per session for 3 to 6 months. In the CLEVER trial of patients with iliac disease, a supervised exercise program improved walking distances more than endovascular revascularization. Supervised exercise programs are now covered by Medicare (since 2017)

and may become more accessible to patients with claudication. Home-based exercise programs guided by step-monitors may also provide some benefit. The improvement in exercise function with exercise programs is not related to proportional increases in blood flow into the limb. It is thought their benefit is related to improvement in endothelial function, mitochondrial energetics, improved biomechanics of walking, and perhaps increased collateral development.

Cilostazol and pentoxifylline are the only drugs approved by the US Food and Drug Administration (FDA) for improving walking distance in intermittent claudication. Pentoxifylline is purported to improve hemorheology by decreasing blood viscosity, but clinical trials show only a modest improvement varying from no effect to a 25% improvement in walking distance. Cilostazol is a phosphodiesterase III (PDE3) inhibitor that increases cyclic adenosine monophosphate to cause vasodilation in vascular smooth muscle and inhibition of platelet aggregation. However, it is not clear these are the mechanisms by which it improves walking distance. Metaanalyses report that cilostazol improves walking distance by 40% to 50%, although the response varies between patients. Cilostazol is contraindicated in patients with congestive heart failure, because other PDE3 inhibitors were associated with increased mortality in these patients. Nutritional supplements are not effective. Trials suggesting ACE inhibitors improved walking distance were recently retracted because of data misrepresentation.

### Revascularization Treatment for Peripheral Artery Disease

Arterial revascularization by endovascular or open surgical graft techniques improves walking distance in patients with lifestyle-limiting claudication unresponsive to medical therapy. Revascularization is also the cornerstone of treatment for critical limb ischemia for preventing amputation. Endovascular treatment primarily uses balloon angioplasty with or without stenting. Various forms of atherectomy may be useful in certain locations, but their routine use is not associated with better long-term outcomes. Iliac angioplasty and stenting are associated with 1-year patency of 90% and 3-year patency of 70% with similar outcomes to open surgical grafting. Angioplasty and stenting of the superficial femoral artery are associated with 50% to 60% 3-year patency dependent on the length of treated disease. Drug-coated stents and drug-coated balloons offer lower risks of restenosis and need for repeat revascularization and are likely to become standard endovascular treatments.

Open surgical revascularization includes bypass grafting and endarterectomy. Patency rates depend on the location and the use of vein or synthetic grafts. For example, 5-year patency of above-knee femoral-popliteal bypass using autogenous (patient's) vein is 75% to 80%, and 3-year patency for femoral-tibial bypass using synthetic polytetrafluoroethylene (PTFE) is 25%. Operative mortality for aortobifemoral bypass and infrainguinal bypass at high-volume academic centers is 1% to 3%.

### Approach to Revascularization for Peripheral Artery Disease

The choice of endovascular or open surgical revascularization depends on patient characteristics and comorbidities, the expertise of the endovascular or surgical operator, and the location and extent of disease. Endovascular procedures are associated with a lower risk of death, MI, pulmonary complications, and wound infection than open surgery, particularly in patients with CV or lung comorbidities. However, endovascular treatment below the iliac arteries is associated with higher rates of restenosis and need for reintervention or open surgery. The new drug-eluting stents and drug-coated balloons reduce restenosis and the need for further procedures or surgery in femoral artery disease and increase support for an “endovascular first” approach to revascularization. Obstructive arterial disease at the hip and knee joints is not suitable for stenting because these regions are associated with excessive flexion and extension of the common femoral and popliteal arteries. Stenting in these regions is associated with stent fracture and high rates of restenosis and occlusion but may be justified in patients with critical limb ischemia at high operative risk. Open surgery with patch endarterectomy (common femoral artery) or bypass (popliteal artery) are often used in these locations. Both endovascular and open surgical revascularization are markers of advanced atherosclerosis and associated with restenosis or thrombosis, which can jeopardize limb perfusion. Patients receiving both types of revascularization require close monitoring for these events and for the progression of new disease using clinical history and examination, the ABI, and, in some cases, surveillance duplex ultrasound or other imaging.

### Aortic Aneurysm and Dissection

An aortic aneurysm is an abnormal expansion of the aorta. In adults, the normal thoracic aorta is approximately 3 cm in the ascending thoracic aorta, 2.5 cm in the descending thoracic aorta, and 2 cm in the abdominal aorta. An aortic aneurysm is defined as a maximal (external) diameter of more than 3 cm or a 50% increase compared with a normal segment proximal to the aneurysm.

The pathophysiology of aortic aneurysms differs from atherosclerosis disorders such as PAD. Aortic aneurysm formation involves inflammatory mediators and proteolytic degradation of the elastin and collagen fibers of the medial layer of the artery wall by protease enzymes. Abnormal formation of the medial layer of the aorta in genetic disorders such as Marfan disease can also accelerate aneurysm formation. Weakening of the media decreases aortic tensile strength and promotes expansion and aneurysm formation.

In screening studies using ultrasound or autopsy series, the prevalence of abdominal aortic aneurysm (AAA) >3 cm is up to 5% in men age >65 years and up to 2% in women age >65 years. Smokers and women with multiple atherosclerosis risk factors have higher rates of AAA. Therefore

targeted screening in specific high-risk populations is an important part of aneurysm detection, but some may be identified by clinical symptoms and signs. The three risk factors for abdominal aneurysm are age, cigarette smoking, and men. Aneurysms are rare in patients age <60 years. The risk of aneurysm rupture increases with the external diameter of the aneurysm and escalates dramatically >6 cm diameter with an annual risk of rupture of approximately 25% and a risk of 45% if >7 cm diameter.

Thoracic aortic aneurysms (TAAs) are more common in the aortic root or ascending aorta than descending thoracic aorta, and together account for about 5% to 10% of all aortic aneurysms. Most are caused by cystic medial necrosis, which involves degeneration of the elastin fibers and smooth muscle cells in the medial layer of the aorta. TAAs are more common in patients age >65 years. However, inherited connective tissue disorders such as Marfan disease and Ehlers-Danlos syndrome lead to earlier degeneration and aneurysm formation in young adults. Other conditions that relate to TAA include arteriopathy related to bicuspid aortic valve, aortic dissection, vasculitis (e.g., giant cell or Takayasu), infection, and familial thoracic aorta syndrome. TAA rupture is associated with aneurysm size (diameter >6 cm), cigarette smoking, chronic obstructive pulmonary disease, aortic dissection, and renal insufficiency.

### Clinical Presentation

Most aortic aneurysms are asymptomatic until they present with rupture or dissection, both of which have high mortality rates (>50%). Occasionally AAAs are symptomatic and cause epigastric or lower back pain or local tenderness—symptoms that can herald impending rupture. Physical examination may identify 50% of symptomatic AAAs as an expanding pulsation in the abdomen. Most commonly aortic aneurysms are an incidental finding on imaging studies for other reasons.

### Management

#### Screening

The USPSTF recommends one-time screening for AAA with ultrasound in men aged 65 to 75 years who have ever smoked but does not recommend screening women. This is based on the Multicenter Aneurysm Screening study where screening this population leads to a 42% reduction in mortality from AAA. The ACC/AHA guidelines also recommend screening men age ≥60 years who have siblings or parents with a history of AAA.

#### Diagnosis

Imaging techniques are used to identify aortic aneurysms. These include ultrasonography for AAA and CT or MR imaging for AAA and TAA. Ultrasound is the least expensive and has a sensitivity of virtually 100% for AAA. Contrast is not required for diagnosis of TAA or AAA because

### • BOX 87.3 Indications for Repair of Abdominal and Thoracic Aortic Aneurysms

#### Abdominal Aortic Aneurysm (AAA)

- Asymptomatic >5.5 cm diameter or growth >0.5 cm per year
- Symptomatic AAA regardless of diameter

#### Thoracic Aortic Aneurysm (TAA)

- Asymptomatic >5.5 cm diameter or growth >0.5 cm per year
- Asymptomatic arteriopathy (e.g., Marfan syndrome, bicuspid aortic valve surgery) 4.5–5 cm diameter or growth >0.5 cm per year
- Asymptomatic TAA with a high risk from open surgery and a TAA >6 cm diameter
- Symptomatic TAA regardless of diameter

the external diameter determines aneurysm size. However, contrast studies are required to assess the feasibility of endovascular and surgical repair. Conventional angiography is rarely used and only measures the internal lumen dimension, not the external diameter.

#### Treatment

Smoking cessation is recommended because aneurysmal growth is faster in current smokers. Blood pressure control and statin therapy are recommended because they reduce wall stress and inflammation (mechanisms affecting aneurysmal formation), and optimal control of blood pressure and lipids decreases the risk of CV events. Clinical trials suggest that beta-blockers and angiotensin receptor blockers slow the growth of aneurysms in patients with Marfan syndrome, but there are no trials in other etiologies of aneurysms. Observational studies show that beta-blockers and statin therapy are associated with slower growth rates of aneurysms. ACE inhibitors are also associated with a lower risk of rupture and dissection in one study. Statin therapy is associated with a lower mortality in patients having aneurysm surgery.

Several randomized trials show that elective repair of asymptomatic AAA >5.5 cm decreases mortality (Box 87.3). However, there is no reduction in mortality in trials repairing aneurysms 4 to 5.5 cm in diameter. Current guidelines recommend surveillance ultrasound or CT imaging for aneurysms 4 to 5.4 cm diameter every 6 to 12 months to detect expansion and ultrasound every 2 to 3 years for aneurysms <4 cm diameter. Patients with symptomatic AAA require repair regardless of the aortic diameter.

Elective repair is indicated if the TAA is >5.5 cm. Patients with specific arteriopathies (Marfan syndrome, Ehlers-Danlos syndrome, Loeys-Dietz syndrome, Turner syndrome, bicuspid aortic valve, familial aortic aneurysm) may require repair at diameters of 4.5 to 5 cm. Repair is also indicated if there is a rapid rate of growth (>0.5 cm per year). Patients having bicuspid aortic valve surgery should be considered for ascending aorta repair if the diameter is >4.5 cm. Elective repair of the descending TAA in patients at high surgical

risk who are not suitable for endovascular repair is recommended for diameters exceeding 6 cm.

Open surgical repair of aortic aneurysms involves opening the aneurysm and placing an intervening prosthetic graft (Dacron or PTFE), followed by closing the aneurysm sac over the graft. Branch vessels into the aneurysm sac can be tied off. In the abdomen, a bifurcation graft with limbs extending to the iliac arteries may be used if these arteries have aneurysms or stenoses. The operative mortality is ≤5% for open AAA repair, mostly from cardiac events in the perioperative period.

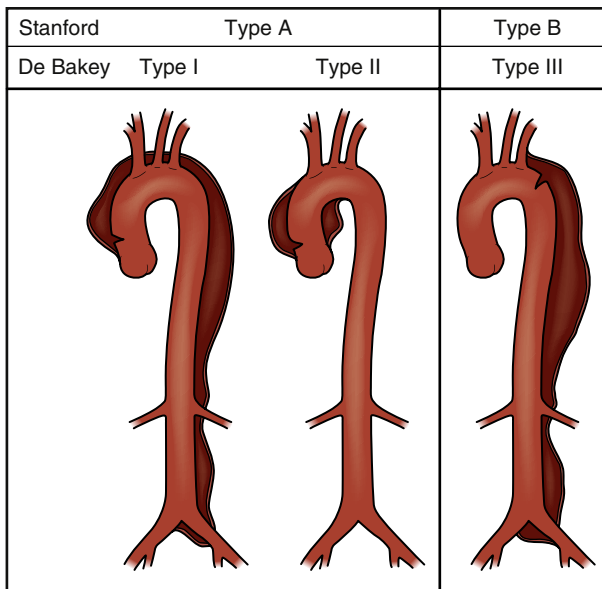

Endovascular AAA repair treatment involves inserting a stent graft made of PTFE, polyester, or other material from the external iliac artery. Sealing the aneurysm from the inside requires adequate landing zones below the renal artery origins and iliac arteries below the aneurysm. Endografts are bulky and need adequate-sized iliac arteries for deliverability. Newer fenestrated grafts may allow stenting over the renal arteries and placement of covered stent grafts from the aortic graft into the renal arteries. Endoleaks occur in 15% or more of cases and refer to a persistence of blood flow outside the endograft but in the aneurysm sac. These may be caused by blood flow from lumbar or inferior mesenteric artery branches that were covered by the stent graft or inadequate sealing at either end of the stent graft. If significant, the aneurysm sac can continue to enlarge and possibly rupture. Therefore surveillance imaging at regular intervals after endovascular repair is required to identify endoleaks and aneurysm expansion. Thrombosis of the iliac limbs of endografts occurs in about 11% of cases and can cause significant limb ischemia. In clinical trials, the initial 30-day mortality is lower with endovascular repair (1%–2%) versus open surgical repair (5%); however, by 2 years there is no difference in mortality (7%–9%).

TAA of the ascending aorta can be surgically repaired with prosthetic graft and grafts with branches for the great vessels if the arch is involved. Open surgical repair of TAA aneurysms is generally reserved for patients with an operative mortality <5%. Increasingly thoracic endovascular aortic repair (TEVAR) is used for aneurysms of the descending thoracic aorta caused by lower perioperative mortality. Perioperative complications with open surgical repair and TEVAR include stroke or MI in 5% to 10% and paraplegia caused by spinal cord ischemia from occlusion of thoracic aorta branches in 1% to 3%. There are no randomized trials comparing open repair with TEVAR for TAA.

#### Thoracic Aortic Dissection

Dissection of the thoracic aorta is an uncommon but life-threatening emergency that requires prompt assessment, medical therapy, and triage to urgent surgical repair. The incidence of aortic dissection is about 1 in 10,000 adults per year, with slightly higher rates in men than women. The causes of dissection are similar to aneurysm formation and associated with cystic medial necrosis of the medial layer of the aorta caused by degenerative or inherited conditions. An

• **Fig. 87.1** Stanford and De Bakey classification of thoracic aorta dissection. (Adapted from Braverman AC. Diseases of the aorta. In: Mann DL, Zipes DP, Libby P, Bonow RO, Braunwald E. *Braunwald's Heart Disease: a Textbook of Cardiovascular Medicine*. 10th ed. Philadelphia: Elsevier; 2016:128.)

intimal tear at the origin of the dissection can be identified in 90% of cases. The classification of thoracic aortic dissection determines the immediate prognosis and need for urgent surgical repair.

### Classification

The Stanford classification designates dissections that involve the ascending aorta before the brachiocephalic artery as type A dissections. Type A dissections can extend into the descending thoracic aorta. Dissections that only involve the thoracic aorta beyond the brachiocephalic artery are Stanford type B dissections (Fig. 87.1). This distinction is important because the mortality rate with type A dissections is about 1% per hour, and urgent surgical repair is indicated. The mortality rate with type B dissection is lower, and surgical repair is indicated for complications such as organ malperfusion (e.g., symptomatic brain, mesenteric, or limb ischemia). The De Bakey classification is sometimes used (type I: ascending and descending aortic dissection; type II: ascending aortic dissection only; type III: descending aortic dissection only). However, the Stanford classification is arguably easier to remember (any ascending dissection: A).

### Clinical Presentation

The classic symptom of dissection is abrupt onset of severe pain, which is worse at inception and often described as tearing in quality. Patients often look ill and often have hypertension. Sudden chest pain occurs in 90% of cases. Other features to raise the suspicion of dissection include hypotension or shock (e.g., because of cardiac tamponade or occlusion of

the right coronary artery), new aortic insufficiency (dilation of the aortic root), focal neurologic deficit, pulse deficit or differences in arm pressures or arm/leg pressures of >20 mm Hg, known thoracic aneurysm, and predisposing genetic/familial conditions (e.g., Marfan, Ehlers-Danlos, Loeys-Dietz, or other familial aortic syndromes).

### Management

#### Diagnosis

Urgent aortic imaging is required to establish the presence of dissection and the presence of type A or B dissection. CT angiography or transthoracic echocardiography is more commonly used than MR angiography, with local experience, speed, and availability determining the imaging mode. The sensitivity of these three imaging modalities is greater than 90%. Invasive retrograde angiography is rarely used because it usually takes longer to complete and has a lower sensitivity (77%).

#### Treatment

First-line therapy includes immediate treatment of elevated blood pressure and heart rate with intravenous (IV) beta-blockers and pain relief with narcotics. Shock and hypotension should raise concerns of tamponade. Pericardiocentesis is not recommended, and fluid resuscitation and urgent surgery are required.

Emergency surgery is indicated for all type A dissections. Repair of the arch is required if it is involved or aneurysmal. Endovascular stents are not approved by the FDA for type A dissections.

Surgery for type B dissections is generally reserved for complications because the operative mortality of surgery is equal or higher than the mortality with medical treatment. Complications indicating need for surgical repair include rupture, extension of the dissection, malperfusion to organs, and Marfan syndrome. In the chronic phase, surveillance imaging is required to assess for aneurysm formation or rapid aneurysmal growth using the same guidelines for repair as for aortic aneurysm (see Box 87.3). There is increasing use of TEVAR for complications caused by chronic type B dissections.

### Carotid Artery Disease

Most carotid disease is caused by atherosclerosis, typically at the origin of the internal carotid arteries in the neck. Ischemic stroke can occur from embolization of thrombus and/or cholesterol from complicated plaques. Less common causes of carotid artery disease include arteritis (Takayasu and giant cell), fibromuscular dysplasia, dissection, and radiation-induced arteriopathy.

Approximately 80% of strokes in the United States are ischemic, and extracranial internal carotid artery stenosis accounts for 15% to 30% of ischemic strokes. The mortality of ischemic stroke is about 10% at 30 days and 15% to 25% at 1 year. Approximately 30% to 50% of stroke survivors

completely or partially lose independence in activities of daily living, and 30% have a decline in cognitive function.

A carotid stenosis >50% is present in about 7% of men and women age >65 years. Risk factors for carotid artery atherosclerosis include age, hypertension, hypercholesterolemia, diabetes mellitus, and cigarette smoking. Patients with carotid atherosclerosis often have atherosclerosis in the coronary and other arterial beds and have higher rates of MI and death than patients without carotid disease.

## Classification

Stroke risk from carotid disease is primarily related to the presence of recent symptoms (minor stroke or transient ischemic attack [TIA]) and, to a lesser extent, the severity of the carotid stenosis. In patients with symptoms, the risk of recurrent stroke with a carotid stenosis >50% is high over the subsequent 2 weeks (30%) but declines to baseline risk 12 weeks after the initial event. This provides a window for revascularization by surgery or stenting to reduce the risk of recurrent events. In contrast, the risk of ischemic stroke in the asymptomatic patient is much lower with a >70% carotid stenosis relating to a 2% to 3% risk of stroke over 1 year. This compares to the background risk of stroke of about 1% per year in asymptomatic patients with <70% stenosis.

## Clinical Presentation

Carotid artery atherosclerosis can present with an ischemic stroke or TIA (symptomatic presentation) or be discovered with imaging triggered by a carotid bruit or as an incidental finding (asymptomatic disease). Carotid bruits are present in 4% of adults and associated with a 3-fold increased risk of ischemic stroke.

## Diagnosis

Duplex ultrasonography with pulsed Doppler is the most common imaging study to evaluate the extracranial carotid arteries. Doppler ultrasound estimates the velocity of blood flow (which increases in a stenosis) and provides an accurate measure of the severity of the stenosis. A systolic velocity of >125 cm/s indicates a stenosis of the internal carotid artery >50%. Velocity criteria for a >70% stenosis vary with most institutions using systolic velocities >250 cm/s and end-diastolic velocities approaching or exceeding 100 cm/s. CT and MR angiography can identify a significant (>50%) carotid stenosis with sensitivities of 70% to 99% compared with conventional angiography. These modalities also show the presence of intracranial disease and the anatomy of the arch, which may determine the mode of revascularization. However, CT and MR angiography may overestimate the severity of the stenosis and so are often used in conjunction with duplex ultrasonography.

## Management

Treatment of carotid atherosclerosis includes medical therapy to reduce atherosclerosis progression and to stabilize

plaque morphology. This includes atherosclerosis risk factor modification and antiplatelet agents to decrease the risk of stroke and cardiac events. Revascularization by carotid endarterectomy or stenting is indicated in selected cases.

Randomized clinical trials showing that lipid-lowering therapy decreased the risk of coronary events also showed about a 20% reduction in stroke risk. The Stroke Prevention by Reduction of Cholesterol Levels trial demonstrated a significant reduction in recurrent stroke in patients with a history of stroke. In patients with TIA or prior stroke, antihypertensive treatment reduces the risk of recurrent stroke by 25%. Antiplatelet agents used for stroke prevention include aspirin, clopidogrel, and dipyridamole-aspirin. The newer P12Y2 antiplatelet agents (prasugrel and ticagrelor) have higher rates of major bleeding and have not been specifically tested for net stroke prevention. In the MATCH trial, clopidogrel combined with aspirin was no more effective than aspirin alone. In the ESPRIT trial, the combination of dipyridamole and aspirin reduced stroke risk more than aspirin alone. In the PROFESS trial, combined dipyridamole and aspirin was no better than clopidogrel. Most recommendations suggest antiplatelet treatment with aspirin, clopidogrel, or dipyridamole-aspirin but not their combination.

Carotid revascularization to prevent stroke is either by carotid endarterectomy or carotid stenting. Older trials comparing carotid endarterectomy to medical therapy in symptomatic patients showed a significant reduction in recurrent stroke, particularly with carotid stenosis >70% (Box 87.4). In the NASCET trial, the risk of ischemic stroke at 2 years was 9% in the endarterectomy group versus 26% in the medical treated group. More recent analyses of these trials suggest that the benefit is greater early after the initial TIA or stroke and is attenuated >12 weeks after the initial event. Carotid stenting provides an alternative for symptomatic patients with higher operative mortality or complicated anatomy (e.g., prior endarterectomy, prior neck radiation).

Carotid revascularization by endarterectomy or stenting is also indicated for asymptomatic patients with a carotid stenosis >70% to 80% although the evidence is less compelling because the risks are lower. In the Asymptomatic Carotid Stent study and the Medical Research Council Asymptomatic Carotid Surgery trial, the 5-year risk of stroke or death was approximately 12% in the medically treated/deferred surgery group versus 5% to 6.5% in the endarterectomy group.

These studies were conducted before the widespread use of intensive statin therapy to lower lipids and ACE inhibitors or angiotensin receptor blockers. There is observational data showing that the risk of ischemic stroke with medical therapy and surgical revascularization is lower with these therapies, and the absolute benefit is likely to be smaller particularly for asymptomatic disease.

Several randomized trials have compared carotid stenting with carotid endarterectomy in symptomatic and asymptomatic carotid disease. In the SAPHIRE and CREST studies conducted in North America, both treatments had

• **BOX 87.4** American College of Cardiology/  
American Heart Association  
Guidelines for Carotid  
Revascularization

### Symptomatic Patients (Recent TIA or Minor Ischemic Stroke Within 6 Months)

- Average- or low-risk surgical/procedural patients (anticipated perioperative stroke/death <6%)
- Carotid stenosis >70% by noninvasive imaging or >50% by catheter angiography
- Carotid stenting is an alternative to carotid endarterectomy
- In patients without contraindications to early revascularization, intervention within 2 weeks of the index event is reasonable

### Asymptomatic Patients

- Anticipated surgical/procedural risk of stroke or death <3%
- Carotid stenosis >70%
- Carotid endarterectomy may be more favored in older patients or where the arterial anatomy is unfavorable to stenting
- Carotid stenting may be favored in patients with neck anatomy unfavorable for arterial surgery or elevated surgical risk
- The effectiveness of revascularization compared with optimal medical therapy for asymptomatic patients is not well established

### In All Patients

- Revascularization is not recommended for total occlusions or stenoses less than 50%

TIA, Transient ischemic attack.

similar outcomes of stroke, death, or MI. European trials suggested lower perioperative stroke outcomes with carotid endarterectomy compared with stenting. However, analyses at a longer follow-up time of over 2 years after treatment show equivalence in mortality, stroke, and MI outcomes. Current trials are comparing surgery or stenting to optimal medical therapy in patients with asymptomatic disease to see if there are any net benefits from revascularization over contemporary optimal medical therapy in asymptomatic carotid disease.

## Renovascular Disease

Renal artery stenosis can cause secondary hypertension or rapidly decreasing renal function. Clues to the diagnosis of renal artery stenosis include onset of hypertension before age 55 years, resistant or malignant hypertension, rapidly increasing creatinine over a several-month period or shorter, and sudden pulmonary edema without a clear cardiac cause (e.g., coronary disease or mitral regurgitation). Although renal artery stenosis is relatively common, stenting often does not improve hypertension or renal function. In many cases, nonadherence to medications and more distal parenchymal disease are more likely factors contributing to the clinical presentation. Over the last decade, three randomized trials showed that stenting renal artery stenoses had

no effect on blood pressure control, renal function, or CV events. In the CORAL trial, even the subgroup of patients with at least an 80% stenosis had no benefit beyond optimal medical therapy. As a result, there is less enthusiasm for renal artery stenting. Case reports and case series do support its use in selective clinical scenarios usually associated with a near-occlusive stenosis. These include flash pulmonary edema without cardiac causes, rapidly declining renal function, and some cases of rapidly accelerating hypertension. Imaging studies to identify renal artery stenosis include duplex ultrasound, CT angiography, MR angiography, and conventional invasive angiography.

## Venous Insufficiency and Lymphedema

### Venous Insufficiency

Chronic venous disease is a spectrum of disease ranging from varicose veins or edema to chronic skin changes and venous ulceration. These typically involve the lower extremities because of the added effects of gravity. Venous valve incompetence or proximal obstruction to venous outflow is a key mechanism causing increased venous pressure. Primary causes relate to degenerative changes in veins leading to dilation and reflux. Secondary causes include deep venous thrombosis and destruction of vein architecture from superficial thrombophlebitis or arterial venous fistula.

Symptoms include discomfort or an aching pain, edema, inflammation of the subcutaneous tissue followed by fibrosis, and venous ulceration, which may be a portal of entry for bacteria and subsequent cellulitis. Symptoms are usually worse later in the day after dependency and relieved by limb elevation. Diffuse pain on exercise relieved by rest and leg elevation are features of venous claudication and often related to proximal obstruction from prior deep venous thrombosis.

Physical examination while standing can reveal varicosities not apparent when the patient is lying down. Chronic skin changes include skin pigmentation, skin fibrosis with white scarring (*atrophie blanche*), and healed or active ulcers. Edema from venous insufficiency without lymphatic involvement typically does not extend into the foot and toes.

Duplex ultrasonography can assess the patency of the deep and superficial veins, competence of the venous valves (presence of reflux), and evidence of proximal occlusion (lack of normal respiratory variation in venous flow). CT venography can identify proximal (iliac vein and inferior vena cava) occlusions.

Compression stockings are the mainstay of treatment for most symptoms and complications of venous insufficiency. Compression therapy can heal 97% of venous ulcers with strict adherence to daily use. Surgical high ligation and stripping of superficial varicose veins have largely been replaced by endovascular techniques. Endovascular treatment includes catheter-based laser and radiofrequency ablation and sclerotherapy using sclerosing agents injected into the incompetent vein. All these techniques

injure the venous endothelium and lead to occlusion of the incompetent superficial vein. Competence of the deep veins is important to success.

## Lymphedema

The lymphatics are blind ended tubules constructed of endothelial cells, which drain fluid from the interstitial space and return it to the venous circulation via the thoracic duct. Lymph nodes intersect the return of lymphatic fluid and are important sources of immune cells and defense from infection. In the lower extremities, lymph flow is primarily by external compression from skeletal muscle. Lymphedema occurs whenever lymphatics are absent or underdeveloped (primary lymphedema) or obstructed (e.g., secondary to damage from active or past infection, tumor, trauma, or surgery).

Primary lymphedema is an inherited disorder and more common in women. Age of onset varies from birth to early adult life.

## Clinical Presentation

The clinical presentation depends on the duration and severity of disease. Initially the edema is soft with pitting

edema. Later in the process, fibrosis and scarring can lead to a woody nonpitting edema. Typically, the edema extends into the foot and toes, and this can help distinguish it from venous insufficiency, although the latter can cause secondary lymphedema. Hyperkeratosis with scaly skin and an increased risk of fungal infections in the toes are also typical of late stage disease.

## Management

The management of lymphedema focuses on decongestive therapy consisting of compression wraps. More recently, compression pumps (intermittent pneumatic compression) are used to inflate a sleeve placed around the limb and “milk” the lymph more proximally. Specialty massage techniques may be required initially to increase drainage. Water-soluble emollients are used to treat hyperkeratosis. Skin care including antiseptic treatment of skin cuts is important to prevent secondary bacterial cellulitis, which can exacerbate lymphatic damage and lymphedema. Similarly, early use of antibiotics for cellulitis is designed to prevent further lymphatic damage.

## Chapter Review

### Questions

1. A 60-year-old man reports that he is experiencing cramping in his left calf after walking approximately three blocks. The cramp resolves after resting for 5 minutes. The symptom has been occurring for 6 months. History is notable only for hypertension. He smokes 1 to 2 packs of cigarettes each day. His only medication is metoprolol. His blood pressure is 138/86 mm Hg, heart rate is 64 beats per minute. The right femoral, popliteal, dorsalis pedis, and posterior tibial pulses are palpable. The left femoral pulse is palpable, but the left popliteal, dorsalis pedis, and posterior tibial pulses are not palpable. Which one of the following treatments is indicated first to improve his symptoms?
  - A. Clopidogrel
  - B. Discontinue metoprolol
  - C. Reduce the number of cigarettes smoked
  - D. Supervised exercise rehabilitation
  - E. Left iliac artery stent
2. A 63-year-old active woman is being seen for the first time by her new primary care physician. She has no specific complaints. She develops calf discomfort after walking 2 miles. Her medications include lisinopril, simvastatin, and metformin. Her blood pressure is 134/78 mm Hg. Her right and left posterior tibial and dorsalis pedis pulses are not palpable. Total cholesterol is 220 mg/dL, high-density lipoprotein cholesterol is 43 mg/dL, triglycerides are 250 mg/dL, and glycosylated Hb is 6.9%. Which one of the following diagnostic tests is indicated to plan further therapy?
  - A. ABI
  - B. MR angiography
  - C. CT angiography
  - D. Treadmill exercise tolerance test
  - E. Duplex ultrasound of the legs
3. A 71-year-old man has a CT examination of the abdomen and pelvis to evaluate cholelithiasis. This detects an incidental infrarenal AAA with a maximal diameter of 4.6 cm. Which of the following is indicated at this time to reduce the risk of AAA rupture?
  - A. No intervention and rescan in 6 months
  - B. No intervention and rescan in 2 years
  - C. Angiotensin receptor blocker
  - D. Repair with an endovascular aortic graft
  - E. Open surgical repair
4. A 75-year-old man presents to the emergency department with sudden severe upper back pain and a blood pressure of 190/105 mm Hg in the right arm and 140/75 mm Hg in the left arm. He has palpable femoral and pedal pulses. Cardiac examination reveals a short diastolic murmur at the left sternal edge. An electrocardiogram shows ST elevations in the inferior leads. What is the next step in management?
  - A. Consult the catheterization laboratory for urgent percutaneous coronary intervention
  - B. Urgent administration of IV thrombolysis
  - C. Urgent chest CT angiogram
  - D. Urgent duplex ultrasound of both brachial and subclavian arteries
  - E. Admit to the intensive care unit for blood pressure control
5. A 72-year-old man has a carotid duplex ultrasound after a left carotid bruit is heard. The report shows a patent

right internal carotid artery, but a 50% to 69% stenosis of the left internal carotid artery. Both vertebral arteries are patent. He has no symptoms of TIA or stroke but has a past medical history of an inferior MI, hypercholesterolemia, and hypertension. He is a former smoker. His medications include aspirin, simvastatin 10 mg/d, atenolol, and hydrochlorothiazide. The next most appropriate treatment for this patient is:

- A. Change aspirin to dipyridamole-aspirin
- B. Change aspirin to clopidogrel

- C. Change simvastatin to atorvastatin 40–80 mg/d
- D. Carotid stenting
- E. Carotid endarterectomy

### Answers

- 1. D.
- 2. A.
- 3. A.
- 4. C.

# Pulmonary Hypertension

BRADLEY M. WERTHEIM, BRADLEY A. MARON, AND WILLIAM M. OLDHAM

**P**ulmonary hypertension (PH) is defined by an elevated mean pulmonary artery pressure (mPAP)  $\geq 25$  mm Hg at rest as measured during pulmonary arterial catheterization. Importantly, this hemodynamic definition encompasses a heterogeneous group of diseases with disparate etiologies, pathobiologies, and management strategies. The World Health Organization (WHO) divides PH into five broad categories based on shared clinical features and mechanism (Fig. 88.1). These include pulmonary arterial hypertension (PAH) (group 1), PH caused by left heart disease (group 2), PH caused by chronic lung disease or hypoxemia (group 3), chronic thromboembolic pulmonary hypertension (CTEPH) (group 4), and PH caused by unclear multifactorial mechanisms (group 5). Although in clinical practice it is often difficult to assign individual patients to a single WHO group (e.g., a patient with heart failure and chronic obstructive pulmonary disease [COPD] with markedly elevated pulmonary vascular resistance [PVR] suggesting a primary vasculopathy), this classification system provides a useful outline for this chapter.

## Epidemiology

Direct measurement of mPAP is required for the diagnosis of PH; however, echocardiography provides a reasonable, and noninvasive, assessment of pulmonary arterial pressures. As a result, much of the epidemiologic data related to PH are based on echocardiographic assessments. Using noninvasive pulmonary artery systolic pressure (PASP) measurements, the reported prevalence of PH ranges from 2% to 14%. This wide range is likely a consequence of different study populations, medical comorbidities, and study designs. The prevalence of PH increases with age, from 3% in subjects age  $<45$  years to 30% in subjects age  $>65$  years. There is no clear association between PH generally and sex or race. Patients with obesity and other cardiovascular or pulmonary conditions are at increased risk of developing the disease. An elevated PASP is associated with a 1.4-fold increase in mortality in the general population.

Group 1 PAH is a particularly severe form of PH characterized by progressive pulmonary arterial wall thickening, luminal narrowing, and increasing PVR culminating in right ventricular failure. PAH affects between 15 to 50

people per million. PAH registries indicate the average age of onset to be between 35 to 55 years with 70% female predominance. Median survival in untreated patients is 3 years although this has increased somewhat with modern pulmonary vasodilator therapy.

Although PH tends to be less severe in groups 2 and 3, substantially more patients are affected. Group 2 PH is generally accepted as the most common form of PH, although accurate prevalence estimates are complicated by differences in study populations and designs. Upwards of 40% of patients with heart failure have PH, and it is more commonly associated with preserved, rather than reduced, ejection fraction. Elevated PASP dramatically increases morbidity and mortality in heart failure patients.

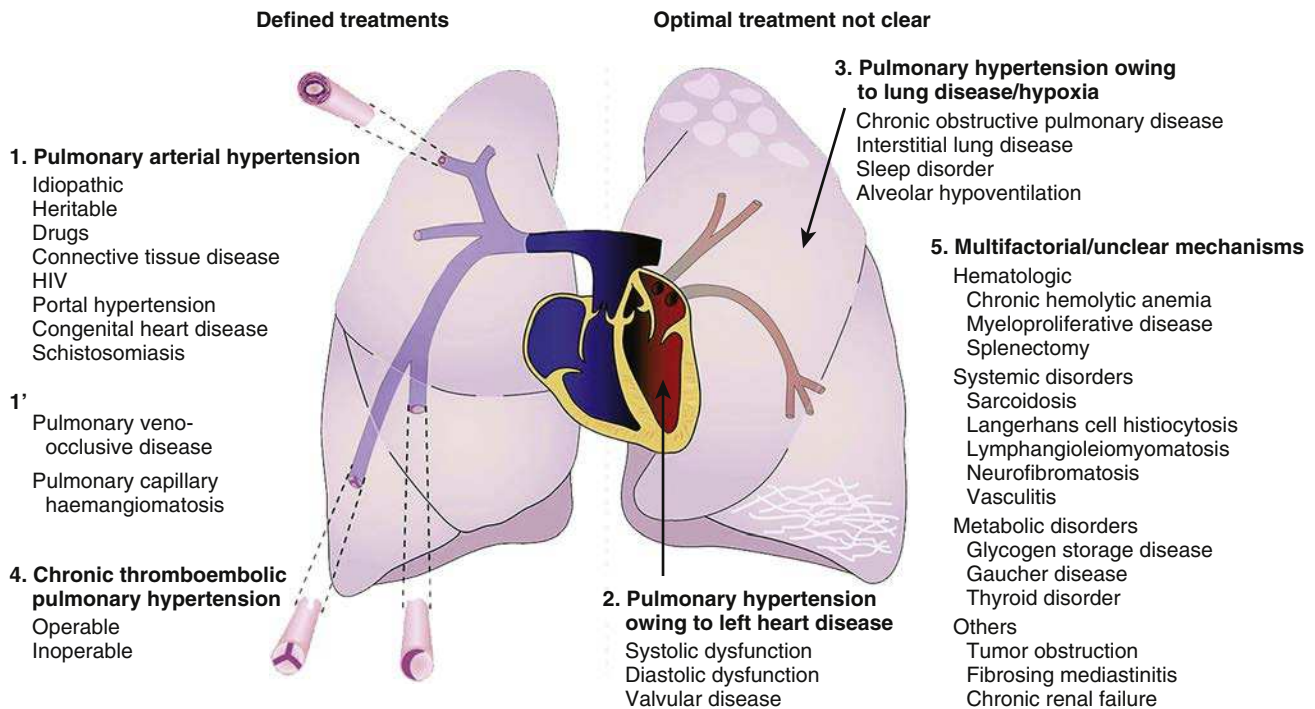

Approximately 25% of patients with lung disease (e.g., COPD, interstitial lung disease, and obstructive sleep apnea) are affected by PH. The prevalence and severity of PH increases with the severity of the underlying pulmonary disease.

CTEPH develops in  $<2\%$  of patients diagnosed with pulmonary embolism (PE). Risk factors include recurrent venous thromboembolic disease, splenectomy, shunt, or foreign bodies. In addition, lupus anticoagulant, antiphospholipid antibodies, and increased factor VIII also increase the risk. Research efforts are under way to identify features predictive of the development of CTEPH following the diagnosis of PE.

Regardless of associated conditions, PH is increasingly recognized as an independent risk factor for morbidity and mortality in affected patients. Therefore it is imperative for clinicians to maintain a high index of suspicion for PH, particularly in at-risk patient populations, and initiate a timely diagnostic evaluation and referral to a center with expertise in the management of PH.

## Pathophysiology

Pulmonary vascular remodeling is the hallmark of PH (Fig. 88.2) and is the pathologic driver of increased PVR. PAH is predominantly a progressive disease of the distal pulmonary arteries, which become increasingly obliterated over time, thereby increasing right ventricle (RV) afterload. A cascade of pathologic changes occurs including inappropriate pulmonary

• **Fig. 88.1** World Health Organization classification of pulmonary hypertension. (From Kiely DG, Elliot CA, Sabroe I, Condliffe R. Pulmonary hypertension: diagnosis and management. *BMJ* 2013;346:f2028.)

• **Fig. 88.2** Pulmonary vascular remodeling in pulmonary artery hypertension. The pulmonary artery demonstrates intimal and medial hypertrophy, luminal narrowing, and perivascular inflammatory infiltrate characteristic of idiopathic pulmonary arterial hypertension. (Courtesy Dr. Sarah Vargas, Boston Children's Hospital.)

arterial vasoconstriction, perivascular inflammation, concentric hypertrophic remodeling of the vascular media, pulmonary artery smooth muscle cell proliferation, fibrillar collagen deposition in the blood vessel wall and adventitia, in situ

thrombosis, and aberrant angiogenesis giving rise to pathognomonic “plexiform” lesions. Adverse vascular remodeling decreases the cross-sectional area of the pulmonary circulation. The depletion of alveolar-capillary interface introduces ventilation/perfusion mismatch, which perpetuates hypoxemia. An increased dead space to tidal volume ratio leads to inefficient ventilation and increased work of breathing. In addition, exertional hypoxemia can be seen in the setting of diffusion limitation because of decreased red blood cell transit time through the aberrant pulmonary circulation.

The molecular pathogenesis of PAH is complex, and a variety of mechanisms contribute to pulmonary vascular remodeling. One hallmark of the disorder is an imbalance in mediators of pulmonary vasodilation and vasoconstriction, with a decrease in the vasodilatory molecules nitric oxide and prostacyclin and an increase in the vasoconstrictor peptide endothelin-1. Most targeted therapies for PAH act on these signaling pathways. Proliferating pulmonary vascular cells in PAH also exhibit metabolic changes that have been observed in some malignancies, and there is evidence that diseased pulmonary artery endothelial cells are derived from common progenitor cells. In addition, vascular and perivascular inflammation is characteristic of PAH, and many proinflammatory mediators contribute to disease pathogenesis. Recent data by Chen et al. (*Circulation*, 2017) suggest that nicotinamide phosphoribosyltransferase (NAMPT), a cytozyme that regulates intracellular nicotinamide adenine dinucleotide levels and cellular redox state, promotes pulmonary vascular remodeling and that inhibition of NAMPT could attenuate PH. Therapies targeting metabolism and inflammation are not yet available for the treatment of PAH, but these are active areas of research.

• **Fig. 88.3** Prevalence distribution of World Health Organization group 1 pulmonary arterial hypertension. These data are derived from the 2015 update to the US-based multicenter registry to evaluate early and long-term PAH disease management (REVEAL registry) and are consistent with what has been observed in other cohorts.

## Classification

Historically, PH was classified as either primary (unknown cause) or secondary (known cause). In 1998 WHO proposed a reclassification of PH based on similarities in pathology, hemodynamics, and treatment strategies. This system has been refined several times, most recently in 2013 (see Fig. 88.1). This classification provides a useful framework for the clinical evaluation of a patient with suspected PH.

### Group I: Pulmonary Arterial Hypertension

PAH is a distinct form of PH, characterized by a “precapillary” pattern of elevated PVR in the absence of left atrial hypertension. PAH is defined as mPAP  $\geq 25$  with a pulmonary artery wedge pressure (PAWP)  $\leq 15$  mm Hg and a PVR  $>240$  dyn·s·cm<sup>-5</sup> (3 Wood units). Under the WHO classification, PAH is further subcategorized as idiopathic (formerly “primary PH”), heritable, drug and toxin mediated, or PAH associated with a predisposing condition (Fig. 88.3). These conditions include connective tissue disease, congenital heart disease, portal hypertension, and chronic infections such as HIV and schistosomiasis. Rare conditions such as pulmonary venoocclusive disease (PVOD) and pulmonary capillary hemangiomatosis are also included in WHO group 1, although the pathophysiology and management are distinct from PAH.

Mutations in bone morphogenetic protein receptor type 2 (*BMPR2*) account for the majority of cases of heritable PAH. These mutations are found in 70% of those with a family history of PAH, although the variable clinical

penetrance, between 20% and 80%, suggests a complex relationship with other risk-modulating factors. Patients with *BMPR2*-associated PAH present approximately 10 years earlier, have more severe hemodynamic compromise at diagnosis, and have shorter time to lung transplantation or death than their idiopathic PAH counterparts. Interestingly, about 15% of patients thought to have idiopathic PAH given a negative family history have been found to carry heritable germline mutations in the *BMPR2* gene.

In addition to mutations in *BMPR2*, mutations in activin A receptor such as type 1 (*ACVRL1*) and endoglin (*ENG*) have been described in heritable PAH. These genetic findings implicate over activation of transforming growth factor (TGF)- $\beta$  signaling pathways in disease pathogenesis. These mutations also account for the prevalence of PAH in patients with hereditary hemorrhagic telangiectasia. Beyond TGF- $\beta$  signaling, mutations in a potassium channel (*KCNK3*), a negative regulator of protein translation (*EIF2AK4*), and a membrane scaffolding protein (*CAVI*) have been recently identified. These findings underscore the complex and multifactorial molecular pathophysiology of the disease.

PAH caused by the stimulant appetite suppressants amfepramine and dexfenfluramine is the prototypical examples of drug-induced and toxin-induced diseases. Although these medications are no longer commonly used, PAH has been associated with methamphetamines, cocaine, and chemotherapeutic agents, among others (Table 88.1).

Connective tissue disease, especially systemic sclerosis, is a strong risk factor for the development of precapillary and postcapillary PH. The prevalence of PAH in systemic sclerosis is estimated at 5% to 9% and is a major cause of mortality

**TABLE 88.1 Risk of Drugs and Toxins for Pulmonary Arterial Hypertension**

Definite	Possible
Appetite suppressants Toxic rapeseed oil	Amphetamines Methamphetamines L-tryptophan Cocaine Phenylpropanolamine St. John's wort Dasatinib Interferon

in this population. Compared with patients with idiopathic PAH, systemic sclerosis-associated PAH confers a poorer prognosis and response to vasodilator therapy despite a less severe hemodynamic profile. Potential drivers of this trend may include increased prevalence of comorbid left ventricular systolic and diastolic dysfunction, which affect one-third of patients with systemic sclerosis; interstitial lung disease; renal or gastrointestinal complications; intrinsic right ventricular dysfunction, which is independent of the degree of RV afterload; and PVOD. PAH may also be seen in other rheumatologic conditions including systemic lupus erythematosus and mixed connective tissue disease including the antisynthetase syndrome, rheumatoid arthritis, and Sjögren syndrome. The true prevalence of PAH in these diseases is less clear because estimates are based on echocardiographic rather than invasive assessments of pulmonary arterial pressures. The antiphospholipid antibody syndrome may also increase the risk of CTEPH.

PAH is a common complication of congenital heart disease as a consequence of left-to-right shunting (e.g., atrial or ventricular septal defects, a patent ductus arteriosus, or more complicated malformations). Pulmonary vascular remodeling and endothelial dysfunction occur in response to increased pulmonary blood flow, thereby increasing PVR and pulmonary artery pressures. As the disease progresses, pulmonary pressures may exceed systemic pressures, leading to reversal of blood flow through the shunt (i.e., Eisenmenger syndrome). Eisenmenger syndrome is a multisystemic disease characterized by cyanosis, thrombosis, embolism, ischemia, and sudden death. Optimal treatment involves repairing the defect and restoring normal flows as early in life as possible; however, 10% of adults with congenital heart disease have PH, and 4% develop Eisenmenger syndrome. PAH is associated with substantial increases in morbidity and mortality in patients with congenital heart disease. Treatment is similar to other forms of PAH.

Patients with liver disease may have elevated pulmonary artery pressures for three reasons: (1) volume overload associated with elevations in PAWP; (2) high cardiac output as a consequence of intrapulmonary vasodilation (i.e., the hepatopulmonary syndrome); and (3) increased PVR caused by pathologic changes indistinct from idiopathic PAH and associated with portal hypertension (i.e., portopulmonary hypertension). Portopulmonary hypertension is seen in 5% to 9% of patients with advanced liver disease and is associated with

worse survival compared with idiopathic PAH. Portopulmonary hypertension also increases perioperative mortality in the setting of liver transplant. Aggressive medical management is warranted to achieve mPAP <35 mm Hg to allow for liver transplantation in otherwise eligible patients.

PAH prevalence in HIV-infected patients likely ranges from 0.5% to 10% in the HIV-infected population using echocardiographic criteria. The impact of antiretroviral therapy on the natural history of HIV-associated PAH is not known.

Although uncommon in developed nations, PAH associated with schistosomiasis is one of the most common etiologies of PAH worldwide (approximately 200,000 patients affected). Three disease mechanisms have been suggested: (1) egg embolization to the lung with direct inflammatory destruction of pulmonary vascular beds; (2) autoimmune inflammatory arteritis; and (3) an arteriopathy similar to portopulmonary hypertension as patients with chronic schistosomiasis develop hepatosplenic disease that is a prerequisite for the development of PAH. Treatment of schistosomiasis-associated PAH includes eradicating the parasite and pulmonary vasodilator therapy.

In the 1980s the median survival age of untreated PAH patients was <3 years. In the modern era, survival has improved, likely because of attention to early diagnosis, better supportive care, and the advent of pulmonary vasodilator therapy. In the REVEAL registry, 5-year survival data for incident patients was 68%, idiopathic; 74%, congenital heart disease; 34%, portal hypertension; 47%, connective tissue disease (40%, systemic sclerosis; 64% others); and 73%, HIV infection. Aggregate 5-year survival for newly diagnosed patients was 61%. New York Heart Association functional classification predicted long-term outcome, with 72% of class I patients alive at 5 years, compared with 44% of those in class IV.

PVOD and pulmonary capillary hemangiomatosis are distinct pathologic entities that are currently included as group 1 of the current WHO classification scheme. PVOD is a rare cause of PH characterized by progressive obliteration of the pulmonary venules and small veins. Clinically, PVOD is indistinguishable from PAH in terms of presentation, although it can be associated with radiographic abnormalities on high resolution chest CT scan and increased hemosiderin-laden macrophages on bronchoalveolar lavage and is associated with a lower diffusion capacity for carbon monoxide ( $DL_{CO}$ ) compared with PAH. Thus a high index of suspicion must be maintained in at-risk patients, including those treated with chemotherapeutic agents, those with hematologic or solid organ malignancies, those with autoimmune diseases, and those who have undergone stem cell or solid organ transplantation. Typically, PVOD is diagnosed based on clinical worsening after initiation of pulmonary vasodilator therapy. As a consequence of pulmonary arterial vasodilation, transcapillary hydrostatic pressure increases leading to pulmonary edema formation, which can be life threatening. A minority of patients respond to pulmonary vasodilator therapy; however, survival beyond 2 years after

diagnosis is uncommon, and lung transplantation is presently the only true therapy for this disease.

Pulmonary capillary hemangiomatosis is a similarly rare disorder causing PH defined by extensive proliferation of pulmonary capillaries with the alveolar septa, which can infiltrate the walls of small arteries and veins. The disease is truly indistinguishable from PVOD outside of histologic assessment of lung biopsy specimens, including the potential severe adverse consequences of pulmonary vasodilator therapy.

### Group 2: Pulmonary Hypertension Caused by Left Heart Disease

PH caused by left heart disease is considered the most common form of PH. It is distinguished by a “postcapillary” hemodynamic pattern with  $mPAP \geq 25$  and  $PAWP \geq 15$  mm Hg, also known as *pulmonary venous hypertension*. In group 2 PH, the transpulmonary gradient ( $mPAP-PAWP$ ) is narrow, and PVR is typically normal or only minimally elevated. The disease often arises in the setting of heart failure with preserved or reduced left ventricular systolic function, cardiomyopathy, or valvular heart disease. Therapy for patients with this type of PH generally focuses on the underlying cardiac lesion and maintaining euvolemia.

### Group 3: Pulmonary Hypertension Caused by Lung Disease or Hypoxemia

This group comprises PH attributed to chronic parenchymal lung disease and/or hypoxemia and includes those with sleep-disordered breathing and PH in the setting of chronic exposure to high altitude. Therapy may include supplemental oxygen or addressing reversible causes of PH (e.g., positive airway pressure for patients with obstructive sleep apnea).

### Group 4: Chronic Thrombotic Pulmonary Hypertension

CTEPH is a potentially curable form of pulmonary vascular disease characterized by thrombosis and increased vascular fibrosis of medium and small pulmonary arteries. CTEPH has been described as a long-term complication of PE; the incidence of CTEPH in this context is 1% to 5%. It is unclear why many patients resolve their acute thromboembolism, while others go on to develop CTEPH. Detailed pathobiology of the condition has yet to be elucidated. The principal treatment for CTEPH is surgical endarterectomy, which is often curative. However, the burden of vascular obstruction must occupy proximal vessels for endarterectomy to be anatomically feasible. The surgery includes median sternotomy and deep hypothermic circulatory arrest. Surgical outcomes may be better at high-volume centers. For CTEPH patients with obstruction that is inoperable or refractory to endarterectomy, selected pulmonary vasodilators are clinically indicated. Balloon pulmonary angioplasty may also be another

therapeutic alternative for patients who are poor operative candidates or have distal disease.

### Group 5: Pulmonary Hypertension Caused by Unknown or Multifactorial Mechanisms

Group 5 includes patients with PH owing to unknown or multifactorial mechanisms and includes hematologic disorders (splenectomy, chronic hemolytic anemias, hemoglobinopathies), metabolic diseases (Gaucher disease, glycogen storage diseases), chronic kidney disease, tumor emboli, and fibrosing disorders of the mediastinum. Standardized therapy for WHO group 5 PH does not exist and, typically, is targeted to the pathophysiology of disease on an individualized basis.

### Clinical Presentation

PH can be a challenging condition to diagnose because the presenting symptoms of dyspnea, fatigue, and exercise intolerance are nonspecific and common. Even with increased recognition of the disease, a 3- to 5-year delay between symptom onset and PH diagnosis is reported. Successful recognition of PH requires a high index of clinical suspicion and must occur before the onset of right heart failure to improve outcome. Early in its course, symptoms are predominantly exertional and may not occur at rest. PH should be considered in the setting of progressive symptoms or when symptoms do not respond to conventional therapies for other diseases. For example, many PH patients are treated for years with inhaled beta-agonists for “asthma” before their eventual diagnosis. Exertional arterial desaturation, lightheadedness, angina, and syncope are hallmarks of more advanced disease. These are thought to reflect subendocardial right ventricular ischemia and reduced cardiac output. Similarly, lower extremity edema, abdominal distention, anorexia, ascites, and weight gain can be seen in the setting of RV dysfunction.

Other atypical symptoms are reported. Hemoptysis can be seen in some instances, especially in the setting of aortopulmonary collateralization as seen in certain congenital heart diseases. Hemoptysis may also be more common in PVOD or pulmonary capillary hemangiomatosis. Dilation of the proximal pulmonary artery can present with hoarseness from compression of the left recurrent laryngeal nerve or with angina and myocardial ischemia owing to compression of the left main coronary artery. Some patients also have a dry cough.

PH should be considered in the differential diagnosis for exercise intolerance, dyspnea, and right-sided congestive heart failure, especially when accompanied by significant hypoxemia. PH should also be considered in the setting of chronic heart or lung disease when disability or hypoxemia appears out of proportion to the underlying condition. Although historically associated with younger persons, especially women (approximately 2:1 women to men), and those with connective tissue diseases, PAH can be seen

throughout the entire life span, owing to the diversity of predisposing conditions, greater awareness of the disease, and improved therapies.

## Diagnostic Evaluation

### Focused History

The diagnostic evaluation of suspected PH begins with a comprehensive history and physical, with attention to the character, quality, and duration of symptoms discussed earlier. In addition, the line of inquiry should attempt to identify specific etiologies of the disease using the WHO classification as a framework.

A medical history of heart, lung, liver, or rheumatologic disease should raise the question of PH in affected patients presenting with exertional dyspnea. A complete history of congenital heart disease includes the type of malformation, the type of operative repair if performed, and the age at the time of repair. Patients with a personal or family history of deep venous thrombosis or PE are at risk for CTEPH. A history of exposure to amphetamines, anorexigens (fenfluramine, dexfenfluramine), and tyrosine kinase inhibitors (dasatinib), in addition to illicit drugs, should be elicited. Because PAH may be heritable, a family history of pulmonary vascular disease or risk factors is relevant. Given the low penetrance of familial disease, the family history should extend beyond direct relatives when possible. A travel history can suggest PAH arising in the setting of chronic infection; schistosomiasis is endemic to Asia, Africa, and South America, and histoplasmosis can cause fibrosing mediastinitis associated with PH. Similarly, the social history should include risk factors for HIV and tuberculosis. A detailed review of systems will guide the need for additional diagnostic testing and should also focus on heart, lung, liver, and rheumatologic systems.

### Physical Examination

The physical examination may influence the likelihood of PH, although findings are insensitive and should not be used to exclude the diagnosis. Salient findings may include an RV heave, a pulmonary artery tap, an accentuated pulmonary component of the second heart sound (i.e., a loud P<sub>2</sub>), a right-sided S<sub>3</sub> or S<sub>4</sub>, a murmur of tricuspid regurgitation, and distended jugular veins with prominent atrial or ventricular waves (from poor RV compliance or tricuspid regurgitation, respectively). Hepatojugular reflux may reflect volume overload in the setting of RV failure. In addition, RV failure can be suggested by peripheral edema, hepatomegaly, and ascites. Pericardial effusion can be seen in advanced PH, is a marker of poor prognosis, and may be suggested by distant heart sounds. Telangiectasias or cutaneous hemangiomas may suggest hereditary hemorrhagic telangiectasia or systemic sclerosis. In addition, calcinosis, Raynaud phenomenon, or sclerodactyly may also suggest connective tissue disease associated PAH. Stigmata

of cirrhosis may point to a diagnosis of portopulmonary hypertension. Inspiratory crackles and digital clubbing can be signs of interstitial lung disease, although crackles can herald pulmonary edema caused by left heart failure, and clubbing may be seen in congenital heart disease and other processes.

### Office Testing

The electrocardiogram in PAH may include atrial arrhythmias (atrial fibrillation and atrial flutter are common), right axis deviation, right bundle branch block, right ventricular hypertrophy, precordial ST-segment elevation or depression, and T-wave inversions, as well as right atrial enlargement.

Chest radiography may demonstrate loss of the retrosternal clear space (corresponding to RV enlargement), prominence of the proximal pulmonary arteries, and peripheral oligemia caused by “pruning” of diseased arterioles.

RV failure may present on laboratory testing with an elevation in the B-type natriuretic peptide (BNP or NT-proBNP) or abnormalities in renal or hepatic function. Rheumatologic testing for antinuclear and extractable antigens should be considered in the appropriate context.

### Echocardiography

Transthoracic Doppler echocardiography can provide considerable insight into the likelihood of PH, as well as the mechanism, and is accepted as the most useful screening test. Pulmonary artery systolic pressure can be approximated using the peak tricuspid regurgitation jet velocity, modified Bernoulli equation, and estimated right atrial pressure. In some institutions, RV systolic pressure (RVSP) is reported. Assuming no pulmonic stenosis, PASP can be regarded as interchangeable with RVSP. Although echocardiographically derived PASP is an accessible and practical screening test, it correlates poorly with invasive measurements of pulmonary artery pressure. Thus right heart catheterization is the gold standard for diagnosis and therapeutic guidance. Careful attention should be given to right- and left-sided morphology and function, and these findings may be even more informative than the PASP per se. Right atrial and ventricular enlargement, impaired RV function, interventricular septal flattening in systole or diastole, and a poorly filled left atrium and left ventricle (LV) with hyperdynamic LV function may suggest PAH, whereas left atrial enlargement, systolic or diastolic dysfunction, and significant mitral or aortic valve pathology is consistent with PH in the setting of left heart disease.

### Pulmonary Artery Catheterization

Pulmonary artery catheterization is required for the diagnosis of PH. Patients with echocardiographic evidence of PH should be referred to a clinician and center with expertise in right heart catheterization and the care of patients with pulmonary vascular disease. Careful hemodynamic

measurements are required because these data comprise the cornerstone of PH management. Retrospective study suggests catheterization can be accomplished safely in such hands with a periprocedural mortality <0.1% and a serious nonfatal complication rate of 1%. In the appropriate context, right heart catheterization can be accompanied by pulmonary angiography, left heart catheterization, and testing with exercise, provocative maneuvers, or pulmonary vasodilator. In particular, inhaled nitric oxide should be administered to assess for pulmonary vasoreactivity. Nitric oxide, prostacyclin analogues, or adenosine preferentially dilates pulmonary arteries and is used to assess vasoreactivity in selected patients in clinical practice. Vasoreactive patients will demonstrate a decrease in mPAP by at least 10 mm Hg to attain an absolute value <40 mm Hg without a change in cardiac output. Although uncommon (10%–15% of patients), vasoreactive patients are candidates for treatment with calcium channel antagonists and have a more favorable prognosis.

### Adjunctive Studies

Based on features of the history and physical examination, additional studies may be warranted to classify patients with PH based on WHO grouping. Pulmonary function testing, including spirometry, lung volume measurement, and diffusion capacity, should be obtained to assess for obstructive or restrictive lung diseases that may be associated with WHO group 3 PH. In addition, a reduced  $DL_{CO}$ , although nonspecific, can be a sign of pulmonary vascular disease, especially when its reduction is out of proportion to other indices of parenchymal lung disease. In PAH, spirometry and lung volumes are often normal, with an isolated reduction in  $DL_{CO}$  observed.

Polysomnography can diagnose obstructive sleep apnea, which can precipitate or exacerbate PH; however, obstructive sleep apnea typically causes only mild elevations in mPAP. Therefore other processes, such as idiopathic PAH or left heart disease, should be considered in the setting of moderate or severe elevations in pulmonary pressures.

Ventilation/perfusion (V/Q) scintigraphy should be pursued when considering a diagnosis of CTEPH, and it is generally regarded as a more sensitive test than CT angiography for this condition. Unmatched perfusion defects on V/Q scan in the setting of PH should prompt evaluation for surgical thromboendarterectomy at an expert center.

Exercise testing can support a PH diagnosis or assess functional status when disease is established. Submaximal exercise testing with 6-minute walk distance has long been used as the primary clinical endpoint in pulmonary vasodilator trials. It is a simple and reproducible test that correlates with hemodynamic parameters and survival in PAH. Formal cardiopulmonary exercise testing offers a more detailed evaluation. Reduced oxygen uptake at peak exercise, respiratory inefficiency, low end-tidal carbon dioxide, and arterial hemoglobin desaturation can suggest a diagnosis of pulmonary vascular disease and inform prognosis. At select

centers, invasive cardiopulmonary exercise testing may be performed with pulmonary and radial arterial catheters in place to assess for exercise-induced PH. Although not currently included in the definition of PH owing to difficulties defining the normal range of hemodynamic responses to exercise and standardizing the testing protocol, exercise-induced PH may represent an early form of disease.

## Management

PH management begins with meticulous general medical care. Comorbidities should be addressed to prevent deleterious influence on the pulmonary vasculature, RV, or volume status. Care of this patient population can be challenging, and referral to an experienced center is strongly encouraged, especially when vasodilator therapy is used.

### Background Therapy

#### Diuretics

As in other forms of congestive heart failure, diuretics are a cornerstone therapy to prevent and relieve vascular congestion in PH. Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) are typically initiated in those PH patients who demonstrate clinical manifestations of heart failure. Potassium-sparing agents can be added to decrease the need for potassium supplementation, and there are data to suggest that aldosterone antagonism with spironolactone or eplerenone may be beneficial. The thiazide diuretics metolazone or chlorothiazide may be added to potentiate diuresis in patients who become refractory to loop diuretic monotherapy. Some patients, especially those with PAH, are prone to volume overload but also to volume depletion, as the hypertrophied, poorly compliant RV becomes dependent on higher filling pressures.

#### Oxygen

Hypoxemia increases PVR and may worsen RV function. Exertional, and eventually resting, hypoxemia is a common finding in patients with pulmonary vascular disease. Oxygen should be prescribed to those patients with an arterial saturation <88% at rest or with exertion, although there are no randomized, controlled trials in PH to support this practice. A high-altitude simulation test should be considered in those patients planning air travel or travel to high elevations to assist with oxygen titration. Sleep-disordered breathing should be considered and treated when appropriate.

#### Anticoagulation

Historically, anticoagulation with warfarin was a mainstay therapy for PAH, owing to concern that in situ thrombosis or thromboembolism may perpetuate vascular remodeling and eventual RV failure. The modern perspective is more circumspect because the original data in favor of anticoagulation were from small observational studies, and more recent reports have shown mixed results and even harm in some PAH populations, such as those with connective tissue disease. Therefore the decision to pursue anticoagulation in

PAH should be individualized, not reflexive. Nonetheless, anticoagulation remains a crucial therapy in the treatment of CTEPH.

### Antiarrhythmic Medications

Supraventricular arrhythmias are common in PH and are a frequent precipitant of decompensated RV failure and hospitalization. Care should be given to balance the rate-controlling properties of antiarrhythmic medications such as beta-receptor antagonists and calcium channel antagonists against their negative inotropic effects on the RV. Electrical cardioversion can be considered. Ventricular arrhythmias are uncommon in PH outside of left heart disease.

### Rehabilitation and Exercise

Exercise training can improve exercise capacity, quality of life, and functional status in PH. Indeed, the benefits of exercise training can exceed those achieved with pulmonary vasodilator therapy alone in terms of distance achieved on a 6-minute walk test. Exercise has not been shown to improve pulmonary hemodynamics.

### Pregnancy and Reproductive Health

Pregnancy is associated with a significant risk of mortality in PAH, perhaps up to 50%. Patient education and reliable contraception are essential. Termination should be considered in the event of a pregnancy. Endothelin receptor antagonists, such as bosentan, macitentan, and ambrisentan, are teratogenic, and their use must be avoided at all costs in patients of childbearing age without a definitive contraception plan. In women with PAH, progestin-only hormonal contraception is favored over estrogen-containing formulations caused by the prothrombotic potential of the latter. Intrauterine device placement can be considered, although care must be taken to avoid vasovagal reaction upon insertion because this can precipitate hemodynamic instability.

### Immunization

Patients with PH should be vaccinated annually for influenza. In addition, all patients should receive the 23-valent pneumococcal vaccine and revaccination after 5 years. Patients with compromised immune systems should also receive the 13-valent vaccine. This includes patients with sickle cell disease, other hemoglobinopathies, HIV infection, malignancies, chronic renal failure, and nephrotic syndrome, among others, or those on immune-modulating therapies such as chronic steroids, radiation, or methotrexate.

### Iron Supplementation

Iron deficiency is common in PH and may be associated with decreased exercise capacity. Intravenous repletion may be required in patients with impaired gastrointestinal absorption.

### Psychosocial Care

PH is a disease of progressive decline. Prognosis can be variable but should be discussed openly with patients. Mental

**TABLE 88.2** Therapies for Pulmonary Hypertension

Pulmonary Vasodilators	Additional Therapies
PDE5 inhibitors	Calcium channel antagonists
Sildenafil (oral)	Diuretics
Tadalafil (oral)	Oxygen
sGC stimulator	Exercise training
Riociguat (oral)	Anticoagulation
Endothelin receptor antagonists	Antiarrhythmics
Bosentan (oral)	Immunization
Ambrisentan (oral)	Contraception
Macitentan (oral)	Iron supplementation
Prostacyclin analogues	Lung transplantation
Epoprostenol (inhaled, IV)	
Treprostinil (oral, inhaled, SQ, IV)	
Iloprost (inhaled)	
Selexipag (oral)	

IV, Intravenous; PDE5, phosphodiesterase 5; sGC, soluble guanylate cyclase; SQ, subcutaneous.

health concerns should be elicited and addressed. Referral to palliative care can be considered in the setting of advanced disease. Clinicians are encouraged to discuss end-of-life care preferences with their patients in clinic, before acute decompensation requiring hospitalization and/or intensive care.

### Vasodilators

Pulmonary vasodilator therapy is indicated for patients with PAH (group 1) and CTEPH (group 4) who are not surgical candidates or those with residual CTEPH after pulmonary endarterectomy. Vasodilator therapy has not been shown to improve outcomes in other forms of PH. Outside of PAH, these medications may cause harm when used inappropriately. Nonetheless, vasodilators may be considered on an individualized basis in patients with severe symptoms. All patients on pulmonary vasodilator therapy should be managed by a PH referral center. Pulmonary vasodilators fall into four broad categories based on their mechanism of action (Table 88.2).

#### Calcium Channel Antagonists

A small percentage of PAH patients with positive vasoreactivity testing at the time of right heart catheterization may benefit from long-term therapy with diltiazem, nifedipine, or amlodipine. However, this therapy is often limited by systemic hypotension, lower extremity edema, and bradycardia.

#### Cyclic Guanosine Monophosphate Potentiators

Pulmonary artery endothelial cells release nitric oxide in response to shear stress, which traverses the cell membrane and targets other cells types including pulmonary artery smooth muscle cells and platelets. Inside the smooth muscle cell, nitric oxide activates soluble guanylyl cyclase,

#### No. at risk

Combination therapy	253	229	186	145	106	71	36	4
Pooled monotherapy	247	209	155	108	77	49	25	5

• **Fig. 88.4** Kaplan-Meier curves for time to clinical failure in patients on combination therapy with ambrisentan and tadalafil versus pooled monotherapy with either agent. The primary endpoint was defined as death, pulmonary artery hypertension–associated hospitalization, disease progression, or poor long-term clinical response. (From Galìè N, Barberà JA, Frost AE, et al. Initial use of ambrisentan plus tadalafil in pulmonary arterial hypertension. *N Engl J Med*. 2015;373(9):834–844.)

which converts guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). cGMP stimulates smooth muscle cell relaxation and is hydrolyzed to form inactive GMP via phosphodiesterase (PDE) enzymes. The phosphodiesterase 5 isoform (PDE5) is present at greatest concentration in the corpus cavernosum of the penis and the pulmonary vascular bed. Sildenafil and tadalafil are oral therapies that increase the concentration of bioactive cGMP by inhibiting PDE5. As monotherapy, these drugs improve functional status in PAH. Side effects include hypotension, headache, and flushing. PDE5 inhibitors are contraindicated in patients with a clinical indication for organic nitrates or riociguat caused by the risk of life-threatening hypotension that may occur with simultaneous use of these drugs.

Riociguat stimulates production of cGMP by soluble guanylyl cyclase independently of nitric oxide. Riociguat is approved for use in PAH or inoperable CTEPH or CTEPH with residual PH after pulmonary thromboendarterectomy. Riociguat can cause hypotension, syncope, headache, and hemoptysis and is contraindicated in those patients taking nitrates or PDE5 inhibitors.

### Endothelin Receptor Antagonists

Ambrisentan, bosentan, and macitentan are oral medications that attenuate the vasoconstrictive and proliferative effects of the endothelin-1 peptide. In clinical trials, these have been shown to improve functional status and increase time to clinical worsening. Long-term outcomes are improved when used in combination with PDE5 inhibitors. Common side effects include edema, abnormal liver function tests (especially bosentan, which requires monthly liver

transaminase monitoring), anemia, and headache. All are teratogenic and contraindicated in pregnancy (pregnancy category X).

### Prostacyclin Analogues

Prostacyclins for PAH are available for oral (treprostinil), inhaled (iloprost, treprostinil, epoprostenol), continuous subcutaneous (treprostinil), and continuous intravenous (treprostinil, epoprostenol) dosing regimens. Selexipag is a nonprostanoid oral prostacyclin receptor agonist. These medications promote vasodilation and have antiplatelet and antiproliferative effects. Intravenous prostacyclins slow PAH disease progression and improve mortality in patients with severe symptoms (New York Heart Association functional class III and IV). Common side effects include systemic hypotension, nausea, vomiting, headache, myalgias, and jaw pain. Abrupt withdrawal of prostacyclins may lead to a “rebound” pulmonary hypertensive crisis. Prostacyclins delivered by continuous intravenous infusion require placement of a long-term vascular access catheter, which may predispose to catheter-associated thrombosis or infections.

### Combination Therapy

Traditionally, vasodilators were added sequentially in response to disease progression. However, the landmark AMBITION trial, published in 2015, challenged this paradigm. Results from the AMBITION trial demonstrated superiority of initial combination therapy with ambrisentan plus tadalafil when compared with monotherapy with either agent alone in treatment-naïve PAH patients (Fig. 88.4). In a time-to-event analysis, upfront combination therapy decreased risk of death, PAH-associated hospitalization,

disease progression, or poor clinical response by 50%. The efficacy of upfront triple therapy with PDE5 inhibitor, endothelin receptor antagonist, and prostacyclin is an active area of investigation.

## Lung Transplantation

Bilateral lung or heart/lung transplantation is the ultimate therapy for patients with PAH. Patients should be

considered for transplant with rapidly progressive disease or poor functional class despite maximal parenteral therapy. In addition, patients with PVOD or pulmonary capillary hemangiomatosis should be considered for transplant given the poor response of these diseases to pulmonary vasodilator therapy. PAH accounts for <5% of lung transplants per year, and these patients have the highest 30-day postoperative mortality of all transplant diagnoses approaching 20%. The 5-year survival posttransplant is approximately 50%.

## Chapter Review

### Questions

1. A 48-year-old woman with a history of unprovoked PE 2 years prior presents to clinic with progressive dyspnea and fatigue. She takes warfarin, and international normalized ratio monitoring demonstrates satisfactory time within therapeutic range. She desaturates from 96% on room air to 90% on ambulation. Physical examination is notable for a prominent P2. A Doppler echocardiogram demonstrates right ventricular and atrial enlargement, mildly reduced right ventricular systolic function, an estimated pulmonary artery systolic pressure of 50 mm Hg, and normal left ventricular morphology and function. Right heart catheterization is notable for an mPAP of 45 mm Hg, normal PAWP, elevated PVR, and a mildly reduced cardiac output. What is the most appropriate next step?
  - A. CT angiogram
  - B. Ventilation/perfusion scan
  - C. Transesophageal echocardiogram
  - D. Cardiopulmonary exercise test
2. A 56-year-old man with a history of hypertension, hyperlipidemia, and systemic lupus erythematosus presents to clinic with a 3-year history of progressive shortness of breath. Pulmonary function testing shows a forced respiratory volume in 1 second ( $FEV_1$ ) of 80% predicted, forced vital capacity (FVC) 94% predicted,  $FEV_1/FVC$  ratio of 0.79, total lung capacity of 98% predicted, and  $DL_{CO}$  50% predicted. Which of the following diagnoses is most likely?
  - A. Deconditioning
  - B. COPD
  - C. PAH
  - D. Interstitial lung disease
3. A 72-year-old woman with a history of type II diabetes and hypertension is evaluated for exertional dyspnea and is found to have pulmonary hypertension by right heart catheterization. Medications include hydrochlorothiazide, amlodipine, lisinopril, and insulin glargine. Which of the following findings could suggest heart failure with preserved ejection fraction as a cause of her pulmonary hypertension?
  - A. Left atrial enlargement on echocardiogram
  - B. Murmur of tricuspid regurgitation
  - C. RV hypertrophy
  - D. Elevated jugular venous pressure
4. A 45-year-old woman is diagnosed with idiopathic pulmonary arterial hypertension by a comprehensive evaluation including right heart catheterization. She feels slightly limited by dyspnea in her ordinary activities of daily living. She has no lightheadedness, angina, or recent syncopal events. She is participating in pulmonary rehabilitation. Which medication regimen is indicated in this context to decrease her risk of death, PAH-associated hospitalization, disease progression, or poor clinical response by 50%?
  - A. Macitentan
  - B. Continuous intravenous treprostinil
  - C. Ambrisentan and tadalafil combination therapy
  - D. Warfarin
5. Which of the following is true regarding phosphodiesterase type 5 inhibitors?
  - A. The concomitant administration of organic nitrates or riociguat is contraindicated.
  - B. They have been demonstrated to decrease congestive heart failure–related hospitalization in patients with heart failure with preserved ejection fraction.
  - C. They are used to treat PAH as upfront combination therapy with calcium channel antagonists to decrease the risk of death, PAH-associated hospitalization, disease progression, or poor clinical response.
  - D. They are classified as pregnancy category X.

### Answers

1. B
2. C
3. A
4. C
5. A

## Electrocardiogram Refresher

ANJU NOHRIA

The term *electrocardiogram* (EKG) has its origins from over 100 years ago when it was introduced in 1893 by Willem Einthoven at a Dutch Medical Society meeting. Einthoven subsequently received the Nobel Prize for developing the EKG. The standard 12-lead EKG was introduced in 1942. Despite the emergence of many tools to evaluate cardiac structure and function, the EKG remains an important, if not the most important, test. The EKG is crucial for interpretation of cardiac rhythm, conduction system abnormalities, and for the detection of myocardial ischemia. The EKG is also important in the workup of valvular heart disease, cardiomyopathy, pericarditis, and hypertensive disease. Last, the EKG detects electrolyte and metabolic abnormalities that may affect the heart, including disorders of potassium ( $K^+$ ), calcium ( $Ca^{2+}$ ), and magnesium and can be used to monitor drug treatment (specifically antiarrhythmic therapy).

At its very basic, the EKG is a plot of voltage measured by the leads on the vertical axis against time on the horizontal axis. The electrodes are connected to a galvanometer that records a potential difference. The needle (or pen) of the EKG is deflected a given distance depending on the voltage measured. The EKG waves are recorded on special graph paper, which is divided into 1-mm<sup>2</sup> grid-like boxes. Each 1-mm (small) horizontal box corresponds to 0.04 seconds (40 ms), with heavier lines forming larger boxes that include five small boxes and therefore represent 0.2-second (200-ms) intervals (at the usual paper speed of 25 mm/s). Vertically, the EKG graph measures the height (amplitude) of a given wave or deflection, as 10 mm (10 small boxes) equals 1 mV with standard calibration.

### Electrocardiogram Fundamentals

The normal rate and intervals are shown in Fig. 89.1, and the mean QRS axis in the frontal plane is given in Fig. 89.2.

Although it is rarely necessary to calculate the exact axis, recognition of an abnormal axis is important. This can be accomplished by looking at the net area under the QRS curves in leads I, aVF, and II (Table 89.1).

A normal EKG is shown in Fig. 89.3. Incorrect lead placement can produce a number of variant configurations. For example, with right-left arm lead reversal, there

is a negative P wave with negative QRS complexes in leads I and aVL (Fig. 89.4B), although the precordial leads are unaffected. With arm-leg lead reversal, there is a far-field signal in one of the bipolar leads (II, III, or aVF) that records the signal between the right and left legs. This is seen as a lack of signal in that lead except for tiny QRS complexes (Fig. 89.4C).

### P Wave Abnormalities

Under normal circumstances, atrial activation starts in the sinus node and spreads radially through the right atrium, interatrial septum, and left atrium. The P wave axis in the frontal plane is therefore directed inferiorly and leftward and is between 0 degrees and 75 degrees. The P wave is always upright in I and II and inverted in aVR. It is usually upright in III and aVF but may be biphasic or flat. It can be biphasic in V1 and V2, with the first part reflecting right atrial depolarization and the second part reflecting left atrial depolarization. The normal P wave has a duration <0.12 seconds and an amplitude  $\leq 2.5$  mm.

• **Fig. 89.1** Normal rate and intervals. Provided regular rhythm, heart rate = 1500/# of small boxes between two consecutive R waves or 300/# of large boxes between two consecutive R waves; Heart rate = 60 to 100 beats per minute; PR = 0.12 to 0.20 seconds; QRS  $\leq 0.12$  seconds; QTc (QT/ $\sqrt{RR}$ )  $\leq 0.45$  seconds in men and  $\leq 0.47$  seconds in women. (From Walker HK, Hall WD, Hurst JW. *Clinical Methods: The History, Physical and Laboratory Examinations*. Chicago: Butterworth-Heinemann; 1990.)

• Fig. 89.2 Einthoven's triangle.

**TABLE 89.1** Calculation of the QRS Axis in the Frontal Plane

Axis (Degrees)	Lead I	aVF	Lead II
Normal (0 to +100)	+	+	
Normal variant (0 to -30)	+	-	+
LAD (-30 to -90)	+	-	-
RAD (>100)	-	+	
R superior axis (-90 to +180)	-	-	

### Right Atrial Enlargement

In right atrial enlargement (RAE) (Fig. 89.5A), the P wave is tall and peaked in lead II (>0.25 mV), or the positive deflection in lead V1 or V2 is  $\geq 0.15$  mV. RAE is commonly seen with cor pulmonale, pulmonary hypertension, and congenital heart disease.

### Left Atrial Enlargement

In left atrial enlargement (LAE) (Fig. 89.5B), the P wave in lead II may be broad ( $\geq 0.12$  s) or notched (peak-to-peak interval  $>0.04$  s), or the P wave in V1 has a negative component that occupies more than one small box. LAE is commonly seen in mitral valve disease, hypertension, or other causes of left ventricular hypertrophy (LVH).

## Cardiac Conduction Abnormalities

In normal cardiac conduction, the electrical impulse is generated in the sinus node and spreads through the atria to the atrioventricular (AV) node. In the AV node, conduction slows, allowing time for the atria to contract before ventricular activation occurs. After the impulse passes through the AV node, it is conducted rapidly to the ventricles through

the bundle of His, bundle branches, distal Purkinje fibers, and the ventricular myocardial cells to allow synchronized contraction of the right and left ventricles.

## Atrioventricular Conduction Abnormalities

### First-Degree Atrioventricular Block

First-degree AV block (Fig. 89.6A) represents an increase in AV nodal conduction time and is defined as prolongation of the PR interval ( $>0.20$  ms) with a 1:1 AV ratio. Isolated first-degree AV block usually has no clinical consequences and does not require treatment.

### Second-Degree Atrioventricular Block

Second-degree AV block is diagnosed when there is intermittent failure of one or more of the atrial impulses to conduct to the ventricles. Second-degree AV block is divided into Mobitz type I (Wenckebach) and Mobitz type II block.

In Mobitz type I block (Fig. 89.6B), the P-P interval is constant. There is progressive prolongation of the PR interval and shortening of the R-R interval, leading to a nonconducted P wave. The R-R interval containing the nonconducted P wave is  $<2$  (P-P) interval. If Mobitz type I block is accompanied by a narrow QRS complex, the block is usually located in the AV node. If it is associated with a wide QRS, the block may occur in the AV node (75%) or infranodally (25%) within the His bundle or one of the bundle branches. Because it is usually localized to the AV node, it does not progress to complete heart block and does not require treatment unless the patient is symptomatic.

Mobitz type II block (see Fig. 89.6B) is characterized by sinus rhythm with intermittent nonconducted P waves. The PR interval in conducted beats is constant, and the R-R interval containing the nonconducted P wave is exactly 2(P-P) interval. In most instances, Mobitz type II block is associated with a wide QRS complex, and the block is located below the His bundle. In a smaller proportion of cases, Mobitz type II block is associated with a narrow QRS complex, and the block is located within the His bundle or, less commonly, within the AV node. Patients with Mobitz type II block may be asymptomatic or may experience lightheadedness or syncope depending on the ratio of conducted to nonconducted P waves. Because the block is generally distal to the His bundle, it can progress to complete heart block and usually requires treatment with pacemaker insertion.

### Third-Degree Atrioventricular Block

Third-degree AV block (Fig. 89.6C) or complete heart block is characterized by failure of the atrial impulses to reach the ventricles. In third-degree AV block, the atrial rate is usually greater than the ventricular rate because ventricular conduction is taken over by a subsidiary pacemaker, either within the AV node (junctional escape) or within the Purkinje fibers (ventricular escape). If the subsidiary pacemaker is located within the AV node, the QRS complex is narrow, and the ventricular rate is usually between 40 and 60 beats per minute. If the subsidiary pacemaker is located within the Purkinje fibers, the QRS complex is wide, and the ventricular

• **Fig. 89.3** Normal electrocardiogram. Its features are within the specified normal range, based on a large healthy population sample.

• **Fig. 89.4** Incorrect lead placement. The figure depicts a normal electrocardiogram (EKG) (A) and the alterations in limb lead appearance with incorrect lead placement (B and C).

• **Fig. 89.5** Atrial enlargement. (A) Right atrial enlargement with tall P waves in II and V1. (B) Left atrial enlargement with broad and notched P waves in II and a large inverted secondary component of the P wave in V1.

rate is usually <40 beats per minute. Third-degree AV block, especially when associated with a wide QRS, carries a poor prognosis and should be treated with a pacemaker.

### Atrioventricular Dissociation

AV dissociation is present when there is independent activation of the atria and ventricles from different pacemakers. Although third-degree AV block is a form of AV dissociation, AV dissociation can also occur in the presence of intact

AV nodal conduction. In this case, the rate of ventricular activation, either from the AV node (junctional tachycardia or accelerated junctional rhythm) or from the ventricle (ventricular tachycardia or accelerated ventricular rhythm), exceeds the rate of atrial activation leading to AV block. This contrasts with third-degree AV block where the atrial rate is usually greater than the ventricular rate. Occasionally, there can be simultaneous activation of the ventricle from two separate pacemakers (fusion complex) or premature activation of the ventricle by an anterograde supraventricular impulse (capture complex) that can also help exclude third-degree heart block.

### Intraventricular Conduction Abnormalities

If the QRS duration is >0.12 seconds, there is usually an abnormality of ventricular conduction.

#### Right Bundle Branch Block

In right bundle branch block (RBBB), the electrical impulse from the bundle of His does not conduct along the right bundle branch but proceeds normally down the left bundle

• **Fig. 89.6** Atrioventricular conduction abnormalities. (A) First-degree AV block with PR  $>200$  ms. (B) Second-degree AV block. Because the ratio of conducted P waves is 2:1, it is not possible to differentiate between Mobitz I and Mobitz II block. (C) Complete heart block with no atrioventricular communication and atrial  $>$  ventricular rate.

• **Fig. 89.7** Right bundle branch block in a patient status postcardiac transplant.

branch (Fig. 89.7). Thus the interventricular septum and left ventricle (LV) are depolarized in a normal fashion, and the right ventricle (RV) is depolarized later by means of cell-to-cell conduction that occurs from the interventricular septum and LV to the RV. This delayed and slower activation of the RV is manifest in the EKG by the following criteria:

1. QRS duration  $\geq 0.12$  seconds;
2. A secondary R wave ( $R\neq$ ) in the right-sided precordial leads, with  $R\neq$  greater than the initial R wave ( $rSR\neq$  or  $rSR\neq$  pattern in V1 and V2);
3. A wide S wave in the QRS complex of left-sided leads (I, V5, and V6);
4. Delay in the onset of the intrinsicoid deflection in the right precordial leads (R peak time in V1)  $>0.05$  seconds.

RBBB may be present in patients with hypertension, rheumatic heart disease, acute and chronic cor pulmonale,

myocarditis, cardiomyopathy, degenerative disease of the conduction system, congenital heart disease, Brugada syndrome, Kearns-Sayre syndrome, ventricular preexcitation, after cardiac surgery, and rarely in patients with coronary artery disease. The prognosis depends on the underlying disease, ranging from benign in those who have an RBBB after cardiac surgery to potentially fatal in those with Brugada syndrome.

#### **Incomplete Right Bundle Branch Block**

Incomplete RBBB is often seen with RV hypertrophy (RVH) and is diagnosed when the waveforms are similar to RBBB but with QRS duration  $<0.12$  seconds. Occasionally, an  $rSr\neq$  pattern is present in V1 as a normal variant. However, in this case, the  $r\neq$  is usually smaller than the initial r wave.

• **Fig. 89.8** Left bundle branch block in a patient with cardiomyopathy.

### Left Bundle Branch Block

Left bundle branch block (LBBB) (Fig. 89.8) occurs when there is interruption of conduction in the main left bundle branch or simultaneous disease in the anterior and posterior fascicles of the left bundle branch. The impulse then travels from the AV node down the His bundle and right bundle branch to the RV and then from the RV to the interventricular septum and LV through myocardial cell-to-cell conduction. This delayed and slower LV activation leads to the following EKG features:

1. QRS duration  $\geq 0.120$  seconds;
2. Broad, monophasic R wave in left-sided leads I, aVL, V5, and V6;
3. Absence of Q waves in I, V5, and V6;
4. Delay in peak R time (intrinsicoid deflection)  $> 0.06$  seconds in V5 and V6;
5. Wide, deep S waves in the right precordial leads (V1–V3).

LBBB is most often present in patients with hypertensive heart disease, coronary artery disease, and dilated cardiomyopathy. Because the left bundle branch receives a dual blood supply from the left anterior descending artery and right coronary artery, its blockade usually implies an extensive lesion in patients with coronary artery disease.

LBBB can also be seen in patients with aortic stenosis, degenerative disease of the conduction system, and in some cases of rheumatic heart disease involving the LV. Presence of an LBBB in patients with LV systolic dysfunction confers a poor prognosis.

### Incomplete Left Bundle Branch Block

Incomplete LBBB is often seen with LVH and is diagnosed when the waveforms are similar to LBBB but with QRS duration  $< 0.12$  seconds.

### Hemiblocks

The left bundle branch is divided into two: the anterior and posterior fascicles. The anterior fascicle supplies the anterior and lateral walls of the LV, and the posterior

fascicle supplies the inferior and posterior walls of the LV. Normally, after leaving the bundle of His, the impulse travels simultaneously down both fascicles, resulting in synchronous contraction of the LV. However, if the anterior fascicle is diseased (left anterior hemiblock, LAHB), the impulse travels down the posterior fascicle, activating the inferior and posterior walls before the anterior and lateral walls, causing asynchronous contraction of the LV. Conversely, if the posterior fascicle is diseased (posterior hemiblock, LPHB), the impulse travels down the anterior fascicle, activating the anterior and lateral walls before the inferior and posterior walls. The etiologies for LAHB and LPHB are similar to those for complete LBBB. However, isolated LAHB is much more frequent than isolated LPHB.

In LAHB, the late QRS vectors are shifted leftward and superiorly and are manifest by the following EKG criteria: left axis deviation ( $-30$  to  $-90$  degrees); qR complex in I and aVL (lateral leads) and rS complex in II, III, aVF (inferior leads); and normal or prolonged QRS duration.

In LPHB, the late QRS vectors are shifted rightward and inferiorly and are manifest by the following EKG criteria: right axis deviation ( $+90$  to  $+180$  degrees); a deep S wave in I (left-sided lead) and Q waves in II, III, and aVF (inferior leads); and normal or prolonged QRS duration.

### Bifascicular Block

Bifascicular block is present when there is either (1) simultaneous RBBB and LAHB; (2) simultaneous RBBB and LPHB; or (3) simultaneous LAHB and LPHB. Patients with RBBB and either fascicular block tend to have additional disease within the conduction system and may progress to complete heart block.

### Trifascicular Block

Trifascicular block is present when there is disease in the right bundle branch and in both fascicles of the left bundle branch, resulting in complete heart block.

• Fig. 89.9 Left ventricular hypertrophy in a patient with long-standing hypertension.

## Ventricular Hypertrophy

### Left Ventricular Hypertrophy

The EKG criteria for diagnosing LVH (Fig. 89.9) derive mainly from the increased LV mass, which results in exaggeration of the leftward and posterior QRS forces. Furthermore, the increased thickness of the LV wall prolongs the time needed for LV depolarization and thus may increase the QRS duration. Because depolarization is prolonged, repolarization is often abnormal, resulting in ST-T abnormalities. The increased LV mass can also result in subendocardial ischemia, further compounding the ST-T abnormalities. If present, the ST segment and T wave are directed opposite to the dominant QRS waveform.

There are several EKG criteria for the diagnosis of LVH. However, for practical purposes, voltage criteria alone are most often used to diagnose LVH (Table 89.2). The sensitivity of LVH diagnosed by EKG criteria in the general population age >65 years is very low compared with echocardiography as the gold standard (5.9%–25.8%). Furthermore, the sensitivity increases with age and decreases with female gender and obesity. However, the specificity is very high (>90%) for all the voltage criteria outlined in Table 89.1, and the presence of LVH by EKG criteria predicts increased cardiovascular mortality.

LVH is seen mostly in patients with pressure overload secondary to hypertension, aortic stenosis, or coarctation of the aorta. However, it can also be seen in conditions of volume overload such as mitral regurgitation, aortic insufficiency, and patent ductus arteriosus.

### Right Ventricular Hypertrophy

Because the EKG vectors reflect the dominant LV, an increase in RV mass affects the EKG in proportion to the

**TABLE 89.2** Commonly Used EKG Voltage Criteria for Left Ventricular Hypertrophy

Name	Criteria
Cornell voltage	R in aVL + S in V3 >25 mm (men) and >20 mm (women)
Sokolow-Lyon voltage	S in V1 + R in V5 or V6 ≥35 mm R in aVL ≥11 mm R in aVF ≥20 mm R in V5 or V6 ≥26 mm
Lewis index	(R in I + S in III) – (R in III + S in I) ≥17 mm
Minnesota code 3.1	R in V5 or V6 >26 mm R in either I, II, III, or aVF >20 mm R in aVL >12 mm
Gubner and Ungerleider	R in I and S in III ≥22 mm
Sum of 12 leads	Sum of max R and S amplitude in each of the 12 leads ≥179 mm

extent of RVH (Fig. 89.10). Because lead V1 is most proximal to the RV, it is most sensitive to the changes in RV mass. The right-sided leads may show increased voltage, delayed activation, and abnormalities in repolarization with RVH. The following EKG criteria can be used to diagnose RVH:

1. Right axis deviation (>110 degrees);
2. R/S ratio >1 in V1 (in the absence of a posterior myocardial infarction or RBBB);
3. R wave ≥7 mm in V1 (not the R<sub>s</sub> in RBBB);
4. rSR<sub>s</sub> in V1 with R<sub>s</sub> >10 mm;

• **Fig. 89.10** Right ventricular hypertrophy in a patient with primary pulmonary hypertension.

5. S wave  $\geq 7$  mm in V5 or V6; or
  6. RBBB with right-axis deviation (exclude RBBB with LPHB if RAE present or if repolarization abnormalities seen in right-sided leads).
- RVH is usually the result of conditions such as mitral stenosis, chronic cor pulmonale, or congenital heart disease.

### Combined Ventricular Hypertrophy

Combined ventricular hypertrophy is usually manifested as LVH with right-axis deviation or with RAE.

## Myocardial Infarction/Ischemia

### Prior Transmural or Q Wave Infarction

In a transmural infarction, the area of myocardial necrosis becomes electrically silent. The remaining vectorial forces tend to point away from this area, and thus an electrode facing the area of infarction records a negative deflection (Q wave) during depolarization. The specificity of the EKG for the diagnosis of transmural myocardial infarction is greatest when the Q waves occur in two or more contiguous leads or lead groupings (Table 89.3). In general, a Q wave is considered pathologic when it has a duration  $\geq 0.03$  seconds and an amplitude  $>25\%$  of the following R wave. Because the posterobasal portion of the LV is difficult to see on the standard 12-lead EKG, a posterior infarction is usually recognized through reciprocal changes in the anterior leads (Fig. 89.11). In patients without RVH, this is usually reflected by an initial R wave duration  $\geq 0.04$  seconds in V1–V2 with an R/S ratio  $\geq 1$ .

### Acute Myocardial Infarction

Tall and peaked T waves (hyperacute T waves) in at least two contiguous leads (Fig. 89.12) provide an early sign of myocardial infarction that may precede ST-segment

**TABLE 89.3** Lead Groups for Localization of Myocardial Infarction

Location of Infarction	EKG Leads
Septal	V1, V2
Anteroseptal	V1–V4
Anterolateral	I, aVL, V4–V6
Lateral	I, aVL, V5, V6
Inferior	II, III, aVF
Posterior	V3R, V4R, and/or wide R wave in V1

From Thygesen K, Alpert JS, White HD, et al. Universal definition of myocardial infarction. *Circulation*. 2007;116:2634–2653.

elevation. New ST-segment elevation at the J point in two or more contiguous leads is more specific than ST-segment depression in localizing the site of myocardial ischemia or necrosis (Figs. 89.13–89.15). ST-segment elevation  $\geq 2$  mm in men and  $\geq 1.5$  mm in women for V2–V3 and/or ST-segment elevation  $\geq 1$  mm in all other leads is considered pathologic. Reciprocal ST-segment depression is often seen in the opposite leads. In patients with inferior ST elevation (II, III, aVF), ST depression  $>1$  mm in leads V1 and V2 suggests a concomitant posterior infarction. Conversely, ST elevation  $>1$  mm in V1 in association with ST elevation in II, III, and aVF suggests a right ventricular infarction. In this instance, it is recommended to record right precordial leads because ST elevation  $>1$  mm in V4R with an upright T wave in that lead is the most sensitive EKG sign for a right ventricular infarction. ST elevations usually resolve within 2 weeks of a myocardial infarction, and persistence of ST elevation over longer periods of time should raise the possibility of a ventricular aneurysm.

• **Fig. 89.11** Old posterior myocardial infarction.

• **Fig. 89.12** ST-T changes during an acute myocardial infarction. Initial tall hyperacute T waves (A) are followed by ST elevations (B). The T waves may begin to invert before the ST segment returns to baseline (C) and remain inverted after the ST segment normalizes (D).

• **Fig. 89.13** Acute inferior myocardial infarction in a 56-year-old woman with epigastric discomfort.

The diagnosis of acute myocardial infarction is difficult in the presence of an LBBB. In this setting, comparison with a previous EKG may be helpful. Concordant (i.e., in the same direction as the QRS vector) ST-segment depression  $\geq 1$  mm in V<sub>1</sub>, V<sub>2</sub>, or V<sub>3</sub> or in II, III, or aVF and elevation of  $\geq 1$  mm in V<sub>5</sub> can indicate myocardial ischemia in the presence of an LBBB. Extremely discordant ST deviation ( $>5$  mm) is also suggestive of myocardial ischemia in the presence of an LBBB.

In the presence of a preexisting RBBB, new ST elevation or Q waves should suggest myocardial infarction.

It is important to note that ST-segment elevation is not limited to acute myocardial infarction: other conditions such as an early repolarization pattern, LVH, coronary vasospasm, acute pericarditis, acute pulmonary embolus, hyperkalemia, and Brugada syndrome can present with ST-segment elevation in association with other characteristic features.

• **Fig. 89.14** Acute lateral myocardial infarction in a 38-year-old smoker.

• **Fig. 89.15** Acute anterior and lateral myocardial infarction in a 62-year-old man with hypertension and hyperlipidemia.

The presence of conduction abnormalities (varying forms of heart block or bundle branch block) with acute myocardial infarction may lead to a poor prognosis. The right coronary artery supplies the sinus node in 60% of people, the AV node in 90% of people, and the bundle of His via its AV nodal branch. Therefore sinus bradycardia or varying degrees of AV block can occur after an inferior myocardial infarction caused by heightened vagal tone, and these are usually transient in nature. Complete heart block accompanied by a wide QRS escape rhythm in the presence of an inferior myocardial infarction may signify block below the AV node and impaired collateral circulation to an occluded left anterior descending artery. The right bundle branch is supplied primarily by septal perforators from the left anterior descending artery and may receive collaterals from the right coronary or left circumflex arteries. The left anterior fascicle is supplied solely by septal perforators from the left anterior descending artery and is particularly susceptible to ischemia. The proximal portion of the posterior fascicle receives blood from the AV nodal branch of the right

coronary artery and the septal perforators of the left anterior descending artery, and the distal portion receives blood from the anterior and posterior septal perforating arteries. Unlike inferior myocardial infarction, the presence of conduction abnormalities in association with an anterior myocardial infarction indicates proximal left anterior descending artery occlusion and necrosis of the conduction system. Anterior myocardial infarction can be associated with the development of Mobitz type II block, complete heart block, RBBB, LAFB, or, rarely, LPFB. The presence of bifascicular block, with or without PR prolongation, increases the risk of complete heart block.

### Myocardial Ischemia

Myocardial ischemia can present as abnormally tall T waves, symmetric and deep inverted T waves  $\geq 1$  mm, horizontal or downsloping ST depression  $\geq 0.5$  mm, nonspecific ST and T wave abnormalities, pseudonormalization of abnormal T waves, or the presence of QT prolongation in conjunction

• **Fig. 89.16** Hyperkalemia in a patient with end-stage renal disease.

with one or more of the ST-T abnormalities described earlier. Unlike ST elevation and Q waves, ST-T abnormalities are not specific for localizing the area of myocardial ischemia. The EKG findings of myocardial ischemia can be seen in a variety of conditions including intracranial bleeding, electrolyte disturbances, pericarditis, myocardial disease, pulmonary embolus, spontaneous pneumothorax, myocardial contusion, ventricular hypertrophy, ventricular conduction defects, drug effects, and following tachycardia. These EKG changes should therefore be interpreted in the appropriate clinical context.

## Electrolyte Abnormalities

### Hyperkalemia

Hyperkalemia (Fig. 89.16) initially causes acceleration of the terminal phase of repolarization. As the serum  $K^+$  exceeds 5.5 mEq/L, the T waves become tall and peaked. Hyperkalemia reduces the resting transmembrane potential, leading to decreased sodium ( $Na^+$ ) influx and slowing of intraatrial and intraventricular conduction. Because the atrial myocardium is more sensitive to hyperkalemia, P wave flattening and PR prolongation often occur before changes in the QRS complex are seen. As the serum  $K^+$  concentration increases, the P wave becomes wider and eventually disappears ( $K^+ > 8$  mEq/L). Widening of the QRS complex is usually seen at  $K^+ > 6.5$  mEq/L. This differs from the QRS widening seen in bundle branch blocks in that both the initial and terminal portions of the QRS complex are affected, and wide S waves are seen in the left precordial leads. When the serum  $K^+$  exceeds 10 mEq/L, ventricular depolarization becomes exceedingly slow such that portions of the ventricular myocardium undergo repolarization before depolarization is complete. Thus as the QRS complex widens further, it blends with the T wave, giving a sine wave appearance. At serum  $K^+ > 12$  to 14 mEq/L, ventricular asystole or ventricular fibrillation can be seen. With severe hyperkalemia, ST-segment elevation resembling a pseudoinfarction pattern may occasionally be present.

### Hypokalemia

Hypokalemia increases the resting membrane potential and the duration of the action potential (Fig. 89.17). In particular, it increases the duration of the refractory period. The typical EKG findings of hypokalemia are seen in 78% of people with a serum  $K^+ < 2.7$  mEq/L but may be seen once  $K^+$  falls below 3.5 mEq/L. These include decreased T wave amplitude, ST-segment depression  $\geq 0.5$  mm, and prominent U waves ( $> 1$  mm or taller than the T wave in the same lead). Severe hypokalemia can lead to ventricular dysrhythmias including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. It can also lead to increased automaticity of ectopic atrial pacemakers and can be associated with paroxysmal atrial tachycardia, multifocal atrial tachycardia, atrial fibrillation, and atrial flutter. The incidence of both atrial and ventricular arrhythmias in the presence of hypokalemia is increased in patients receiving digitalis therapy.

### Hypercalcemia

Hypercalcemia shortens the plateau phase of the action potential and decreases the effective refractory period, thus shortening the ST segment (Fig. 89.18). This is manifest on the EKG as a shortened QTc interval. The relationship between serum  $Ca^{2+}$  levels and the QTc interval is not linear. The QTc interval is inversely proportional to serum  $Ca^{2+}$  up to a level  $\leq 16$  mg/dL. At  $Ca^{2+} > 16$  mg/dL, the T wave widens, and the QTc interval begins to normalize. Rather than the QTc interval, the QaTc interval (the interval from the beginning of the QRS complex to the apex of the T wave) is more closely correlated with serum  $Ca^{2+}$  concentrations, and a QaTc interval  $< 0.27$  seconds is seen in  $> 90\%$  of patients with hypercalcemia. Cardiac arrhythmias are uncommon in hypercalcemia.

### Hypocalcemia

Hypocalcemia prolongs the duration of the plateau phase of the action potential and increases the effective

• **Fig. 89.17** Hypokalemia in a heart failure patient on furosemide and metolazone.

• **Fig. 89.18** Hypercalcemia in a patient with multiple myeloma.

refractory period, resulting in lengthening of the ST segment (Fig. 89.19). This is manifested on the EKG as prolongation of the QTc interval. Although the QTc duration is proportional to the extent of hypocalcemia, it rarely exceeds 140% of normal. A QTc duration >140% of normal suggests that an additional electrolyte abnormality is present, and a QU interval is probably being measured. Cardiac arrhythmias are uncommon in patients with hypocalcemia.

## Drug-Induced Electrocardiogram Changes

### Acquired Long QT Syndrome

Several drugs lengthen cardiac repolarization and prolong the QTc interval. This prolongation of the QTc interval can result in a pause-dependent polymorphic ventricular tachycardia or torsades de pointes. Agents that are generally

accepted to have risk of causing torsades de pointes are listed in Box 89.1. Some of these agents (e.g., class Ia and III antiarrhythmics terfenadine, erythromycin, cisapride) directly block Na<sup>+</sup> and K<sup>+</sup> channels, resulting in repolarization abnormalities. Other drugs such as phenothiazines and haloperidol prolong the action potential. Other drugs not included in Box 89.1 may prolong the QTc but have not been clearly associated with torsades de pointes (e.g., alfuzosin, atazanavir, foscarnet, ranolazine), although others such as the azoles inhibit the hepatic cytochrome P-450 enzyme and decrease the metabolism of some QTc-prolonging agents, thus potentiating their effects. An extensive list of these agents can be found at <http://www.torsades.net>. Older age, female gender, impaired renal and hepatic function, structural heart disease, and slow heart rate can also facilitate drug-induced QTc prolongation. Patients with suspected or diagnosed congenital long QT syndrome are particularly susceptible to these drugs. A QTc duration >0.45 seconds in

• **Fig. 89.19** Hypocalcemia in an intoxicated man in the emergency department.

• **BOX 89.1** Drugs With Increased Risk of Torsades De Pointes

### Cardiac Drugs

Quinidine, disopyramide, procainamide, sotalol, ibutilide, azimilide, dofetilide, amiodarone, phenylamine, bepridil

### Noncardiac Drugs

Arsenic trioxide, astemizole, chloroquine, cisapride, droperidol, halofantrine, haloperidol, levomethadyl, macrolides, methadone, pentamidine, phenothiazines, probucof, terfenadine, tricyclic antidepressants, sparfloxacin

From Arizona Center for Education and Research on Therapeutics.

men and  $>0.47$  seconds in women is considered abnormal. Although these cutoffs are somewhat arbitrary, in general a QTC  $>0.5$  seconds should be considered a contraindication for using drugs that prolong cardiac repolarization.

### Digitalis Toxicity

Digitalis has both direct and indirect effects on the heart. It exerts its direct actions via inhibition of the sarcolemmal  $\text{Na}^+, \text{K}^+$ -ATPase pump and its indirect actions via baroreceptor sensitization and increased vagal tone. In therapeutic doses, digitalis decreases the automaticity of the sinus node, slows conduction at the AV node, and shortens the ventricular refractory period. The effects on ventricular repolarization are responsible for the characteristic ST-T changes seen in patients on digitalis therapy. These include a decrease in T wave amplitude, shortening of the QT interval, ST-segment depression, and an increase in the U wave amplitude. The most typical finding is sagging of the ST segment such that the first part of the T wave is dragged down, making the T wave biphasic or negative (Fig. 89.20).

Given the narrow therapeutic range of digitalis, clinical manifestations of toxicity have been reported in as many as

23% of people taking digitalis. The hallmark of digitalis-induced cardiac toxicity is increased automaticity with concomitant conduction delay. Although, no single dysrhythmia is always present, premature ventricular beats (often multifocal and in a bigeminal or trigeminal pattern), various degrees of AV block, paroxysmal atrial tachycardia with block, atrial fibrillation with block, junctional tachycardia, and bidirectional ventricular tachycardia are common. Both hyperkalemia and hypokalemia potentiate digitalis-induced arrhythmias, and hypokalemia should be corrected in patients presenting with digitalis-induced ventricular tachycardia. Even though a serum digitalis concentration  $>2$  ng/mL is considered supratherapeutic, it does not correlate well with toxicity in every patient. Recognition of arrhythmias, withdrawal of drug therapy, and close monitoring are usually sufficient. However, in some cases with life-threatening arrhythmias, administration of the F(ab) fragment of antidigoxin antibodies may be warranted.

### Tricyclic Antidepressant Poisoning

The primary mechanism for tricyclic antidepressant cardiac toxicity is fast  $\text{Na}^+$  channel blockade resulting in an increase in the duration of the action potential and refractory period as well as slowing of AV conduction. The EKG changes include prolongation of the PR, QRS, and QT intervals, nonspecific ST-T abnormalities, AV block, right axis deviation of the terminal 0.04 seconds of the QRS complex (T 40 ms axis), and the Brugada pattern (downsloping ST elevation in V1–V3). Sinus tachycardia is the most common arrhythmia caused by the anticholinergic effects of tricyclic antidepressants. However, AV block with unstable ventricular arrhythmias or asystole can also be seen. Life-threatening arrhythmias and death usually occur within 24 hours of toxic ingestion. A QRS duration  $>0.1$  seconds predicts seizure activity, and a QRS duration  $>0.16$  seconds predicts the development of ventricular arrhythmias. Alkalinization

• **Fig. 89.20** Typical ST changes in patient with atrial fibrillation and on digitalis therapy.

of blood with  $\text{Na}^+$  bicarbonate is recommended in patients with a QRS duration  $>0.1$  seconds because it helps dissociate the tricyclic antidepressant from the fast  $\text{Na}^+$  channels and also improves the gradient for  $\text{Na}^+$  entry into the cell.

## Miscellaneous Conditions

### Chronic Obstructive Pulmonary Disease

In chronic obstructive pulmonary disease (COPD), hyperinflation of the lungs leads to flattening of the diaphragm and clockwise rotation of the heart along its longitudinal axis. Therefore there is a rightward shift in the P and QRS axes in the frontal plane. Posterior displacement of the QRS forces and insulation of the heart by the hyperinflated lungs also lead to diminished QRS voltage in the limb leads and in V5–V6. Evidence of P pulmonale is commonly seen in patients with COPD. The presence of both P wave and QRS changes increases the specificity of the EKG for COPD.

### Acute Pulmonary Embolism

The EKG is relatively insensitive for the diagnosis of acute pulmonary embolus because 26% of patients with severe PE have no EKG abnormalities. The EKG findings in acute pulmonary embolus relate to acute dilatation of the RV. This is associated with clockwise rotation of the heart along its longitudinal axis and RV conduction delay. Although the SI, QIII, and TIII criteria have been classically described, they are present in only 11% to 50% of patients with acute pulmonary embolus. The presence of at least three of the following EKG criteria was able to accurately diagnose RV strain secondary to acute pulmonary embolus in

approximately 75% of patients with a clinical suspicion of pulmonary embolus. These include: (1) incomplete or complete RBBB; (2) S waves in I and aVL  $>1.5$  mm; (3) transition zone shift in the precordial leads to V5; (4) Q waves in III and aVF but not in II; (5) QRS  $>90$  degrees or indeterminate; (6) limb lead voltage  $<5$  mm; and (7) T wave inversion in III and aVF or in V1–V4 (Fig. 89.21).

### Acute Pericarditis

The EKG changes in pericarditis (Fig. 89.22) are produced by an injury current caused by inflammation of the pericardial surface, including the atria (PR depression) and the ventricles (ST elevation). The evolutionary change of the EKG in pericarditis can be divided into four stages:

- Stage 1: Diffuse PR depression and ST elevation (except for PR elevation and ST depression in aVR) with either normal T waves or T waves with increased amplitude
- Stage 2: Isoelectric ST segments with upright T waves
- Stage 3: Symmetric and inverted T waves
- Stage 4: Normalization of the EKG

The EKG changes in pericarditis are differentiated from those in patients with ischemic heart disease by the diffuse nature of the ST elevation, abnormal relationship of the PR segment to the baseline (TP segment), and return of the ST segments to baseline before the occurrence of T wave changes.

### Hypothermia

Hypothermia is defined as a core body temperature  $<95^\circ\text{F}$  ( $35^\circ\text{C}$ ). As the body temperature falls, there is progressive slowing of the sinus rate and prolongation of the PR and

• **Fig. 89.21** A 30-year-old man with protein C deficiency and acute pulmonary embolus.

• **Fig. 89.22** A 24-year-old man with viral pericarditis.

QTc intervals. The most typical EKG finding is the Osborn or J wave, also known as the “camel hump” sign (Fig. 89.23). The J wave is an extra deflection at the junction of the terminal QRS complex and the beginning of the ST segment. The J wave is consistently found at body temperatures  $<25^{\circ}\text{C}$ , and the amplitude of the J wave increases as body temperature declines. Tremor artifact is commonly seen in patients with hypothermia and is felt to be secondary to shivering. Atrial fibrillation is present in 50% to 60% of

cases and appears at a body temperature  $<29^{\circ}\text{C}$ . In severe hypothermia, bradycardia, asystole, and ventricular fibrillation can also occur.

### Central Nervous System Disorders

Subarachnoid and intracerebral hemorrhages commonly produce EKG abnormalities. These are felt to be the result of increased sympathetic stimulation, which affects ventricular

• **Fig. 89.23** A 45-year-old homeless man with hypothermia. (From the American College of Cardiology. Mason JW, Froelicher VF, Gettes LS. ECG-SAP III 2001.)

• **Fig. 89.24** A 76-year-old woman with confusion after fall.

repolarization. The most common EKG findings are large, upright or deep, symmetrically inverted T waves, prolongation of the QRS complex, and prominent U waves (Fig. 89.24). ST-segment elevation or depression, mimicking myocardial ischemia, may also occur. Diffuse ST elevations such as those seen in pericarditis can also be present. In some cases, abnormal Q waves suggestive of myocardial infarction may also be seen. Rhythm disturbances may also occur.

### Atrial Septal Defects

In atrial septal defects, there is left-to-right shunting of blood at the atrial level with volume loading and dilatation of the

right atrium and RV. Patients may present with sinus rhythm or atrial fibrillation (Fig. 89.25). First-degree AV block is commonly present, with a higher incidence in primum defects compared with secundum defects. Some patients may show evidence of RAE. An rSR' pattern in lead V1 with a QRS duration <0.11 seconds representing right ventricular outflow tract hypertrophy is seen in the majority of patients with either primum or secundum defects. The frontal plane QRS axis is the most helpful differentiating factor between primum and secundum atrial septal defects. In primum atrial septal defect, there is abnormal left ventricular conduction, and the QRS axis is shifted to the left. Conversely, in secundum atrial septal defect, the QRS axis is shifted to the right.

• **Fig. 89.25** A 62-year-old man with new-onset atrial fibrillation and right-sided heart failure with secundum atrial septal defect.

### Dextrocardia

Dextrocardia is described as malposition of the heart in the right side of the chest. Lead I is the most telling lead in dextrocardia because the P wave, QRS complex, and T wave are inverted in this lead. Leads aVR and aVL are reversed, as are

leads II and III. Lead aVF is unaffected. In the precordial leads, the usual placement of V1 to V6 shows decreasing R wave amplitude. A repeat EKG with reversal of the left and right arm electrodes and placement of the precordial leads in the equivalent positions on the right chest results in a normal-looking EKG.

# Board Simulation: Cardiology

ELDRIN FOSTER LEWIS

The American Board of Internal Medicine is focused mainly on management strategies. Cardiology represents the largest proportion of questions on the examination. The clinical symptoms and the clinical settings are very important. Thus patients presenting to the emergency department (ED) or in the field with an acute process are more likely to have a major clinical event as compared with those patients presenting for routine clinical visits. The stem is important as well when interpreting electrocardiograms (EKGs). There may be opportunities to narrow down choices to two best answers. These questions are not necessarily the format that you may see on the American Board of Internal Medicine examination. Typical areas covered include acute coronary syndrome management, atrial fibrillation, valvular disease, vascular disease (e.g., aortic dissection), chronic heart failure management, arrhythmias, hypertension, and preoperative assessments.

## Questions

1. A 57-year-old female presents to the clinic for a follow-up visit after an acute myocardial infarction (MI) suffered 2 months ago for which she underwent primary coronary intervention of an occluded proximal left anterior descending (LAD) artery with placement of a drug-eluting stent. She notes intermittent sharp chest pain that is worsened at night without radiation. Pain is different in quality from 2 months ago. She denies dyspnea or palpitations. She stopped smoking at the time of her MI. On physical examination, her blood pressure (BP) was 152/94 mm Hg, heart rate (HR) was 70 beats per minute, and respiratory rate was 16 breaths per minute. The examination was notable for a III/VI holosystolic murmur at the apex with a diffuse apical impulse, clear lungs, and no jugular venous distension (JVD). EKG revealed NSR and Q waves in V1-V4, which is unchanged from prior tracing. Laboratory results include sodium 142 mmol/L, blood urea nitrogen 12 mg/dL, creatinine 0.8 mg/dL, erythrocyte sedimentation rate 24 mm/h, white blood cell 8.2 K/uL, and hematocrit 41%. What is the most likely diagnosis?
  - A. Recurrent anterior wall MI
  - B. Pericarditis
  - C. Acute mitral regurgitation
  - D. Ventricular aneurysm
  - E. Pulmonary hypertension
2. A 49-year-old man presents to the ED with progressive dyspnea, palpitations, and dizziness. He was healthy until 4 years ago when he required a permanent pacemaker for progressive atrioventricular (AV) block. He denies chest pain, easy bruisability, or hoarseness. Examination reveals mild JVD, soft apical S3 gallop, and I/VI holosystolic murmur at apex. Echocardiogram demonstrates left ventricular ejection fraction (LVEF) of 25% with mild-to-moderate mitral regurgitation. Coronary angiography revealed no epicardial coronary artery disease (CAD). There is no evidence of lupus, and Lyme titers are negative. In addition to starting guideline-directed medical therapy, what is the next best step?
  - A. Electrophysiology (EP) study to rule out ventricular tachycardia
  - B. Place an implantable cardioverter defibrillator (AICD)
  - C. Endomyocardial biopsy
  - D. Bone marrow biopsy
  - E. Fluorodeoxyglucose positron emission tomography (FDG PET) scan
3. A 66-year-old female with a history of lymphoma received radiation therapy in addition to chemotherapy with doxorubicin 9 years ago. She now presents to her primary care office with worsening dyspnea and right-sided heart failure signs. She has no traditional cardiac risk factors. Examination reveals a BP of 100/75 mm Hg, HR of 85 beats per minute, prominent X descent with venous distension, nonpalpable impulse, ascites, and 3+ edema. Echocardiogram reveals EF of 55% with septal bounce with no regional wall motion abnormalities. Which of the following statements is not true?
  - A. Radiation therapy can cause valvular disease.
  - B. Cardiac MRI can be helpful in characterizing this disease.
  - C. The patient is not at significant risk for CAD.

- D. Kussmaul sign can be present in both conditions.
- E. Ventricular interdependence is both sensitive and specific for constrictive pericarditis.
4. A 53-year-old woman with a 32-pack-year history of smoking (stopped 2 years ago), hypertension, and diabetes mellitus (DM) presents to your office for a routine visit. Fasting lipid profile reveals total cholesterol 206, high-density lipoprotein (HDL) 33, low-density lipoprotein (LDL) 128, and triglycerides 152. In addition to diet modifications, routine exercise, and BP control, what would you do to manage this patient?
- Refer for exercise test, and start statin if positive.
  - Start simvastatin 10 mg nightly.
  - Start proprotein convertase subtilisin/kexin type 9 (PCSK-9) inhibitor.
  - Start atorvastatin 80 mg nightly.
  - Start niacin 1 g daily with aspirin.
5. A 78-year-old woman with a permanent pacemaker presents to your office with 1 week of intermittent palpitations without associated symptoms. EKG reveals normal sinus rhythm at 76 beats per minute with occasional atrial premature beats. Interrogation of her pacemaker suggests three episodes of “mode switching” since last interrogation, each lasting approximately 3 to 4 minutes suggestive of atrial fibrillation. Vital signs revealed HR of 82 beats per minute and BP of 128/84 mm Hg with an otherwise unremarkable physical examination. She has moderate-to-severe aortic stenosis (calculated aortic valve area 1.2 cm<sup>2</sup>) on echocardiogram. Which is the best management strategy?
- Start dofetilide to maintain normal sinus rhythm.
  - Schedule 24-hour Holter monitor and start anticoagulation if it reveals atrial fibrillation.
  - Start warfarin and target international normalized ratio (INR) 2 to 3.
  - Start dabigatran or apixaban.
  - Start aspirin and clopidogrel.
6. A 39-year-old woman who is 31 weeks pregnant presents to the ED with mild dyspnea on exertion. Examination reveals BP 110/70 mm Hg, HR 95 beats per minute, clear chest, jugular venous pressure 7 cm water, and III/VI holosystolic murmur at apex. Echocardiography confirms moderate mitral regurgitation. She has no evidence of pulmonary hypertension. Management options include which of the following?
- Start low-dose furosemide.
  - Arrange for emergent delivery of fetus.
  - Plan mitral valve repair before delivery.
  - Left and right heart catheterization
  - Proceed with pregnancy with close follow-up.
7. A 61-year-old man presents to the ED with palpitations without associated symptoms. He has a history of MI 3 years ago. Echocardiogram reveals normal left ventricular (LV) size, LVEF 55%, mild tricuspid, and mild regurgitation. EKG reveals atrial fibrillation with ventricular rate of 110 beats per minute and nonspecific T-wave changes. Which of the following is a first-line therapy for rhythm control?
- Amiodarone
  - Atrial fibrillation ablation
  - AV nodal ablation and permanent pacemaker placement
  - Propafenone
  - Sotalol
8. A 72-year-old man presents to the ED following a motor vehicle accident in which he was wearing a seatbelt. He describes the onset of palpitations while driving and awakens finding himself on the side of the road. Medical history is notable for MI 6 years ago and hypertension. Physical examination is remarkable for mild facial lacerations. What is the most likely cause of this event?
- Ventricular tachycardia
  - Epilepsy
  - High-degree AV block
  - Neurocardiogenic syncope
  - Hysterical fainting
9. A 66-year-old man with history of hypertension and DM presents to the ED with left leg pain and mild chest pain after returning from a trip to Italy. Examination reveals a positive Homans sign in the left leg. A femoral deep venous thrombosis (DVT) was confirmed by lower extremity noninvasive studies. CT angiography was normal. What is the best management strategy?
- Initiate low-molecular-weight heparin, and maintain for 2 days before unopposed warfarin.
  - Start warfarin, and send home overlapping with apixaban.
  - Maintain warfarin for 6 months.
  - Start rivaroxaban.
  - Consider V/Q scan to exclude acute pulmonary embolism (PE).
10. A 58-year-old woman with a history of ischemic dilated cardiomyopathy with LVEF 25% presents to your office with increasing fatigue. She was started on carvedilol 3 weeks ago, and it was titrated upward. She denies chest pain, palpitations, or orthopnea but noted worsening dyspnea without a change in her weight. Medications include lisinopril 40 mg daily, carvedilol 25 mg twice daily (maximal doses), and furosemide 20 mg daily. Vital signs include BP of 110/76 mm Hg, pulse of 66 beats per minute, and respirations of 16 breaths per minute. Physical examination demonstrated no JVD at 45 degrees with clear

- chest examination, no audible S3 or S4 gallop, and no peripheral edema. EKG revealed normal sinus rhythm with nonspecific ST-T wave changes and interventricular conduction delay with QRS duration of 110 ms. Brain natriuretic peptide (BNP) is 700 pg/mL. What is the next best step?
- Refer for cardiac resynchronization therapy.
  - Refer for cardiac transplantation.
  - Increase furosemide.
  - Reduce dose of carvedilol.
  - Start digitalis.
11. A 59-year-old black woman presents for a routine clinical visit for a physical. Her examination is notable for a BP of 154/70 mm Hg, HR of 77 beats per minute, physiological splitting of the second heart sound, and no S3 gallop. She has no other comorbid conditions. In addition to lifestyle changes and dietary sodium restriction, which of the following is the best approach for management?
- Initiate angiotensin-converting enzyme (ACE) inhibitor.
  - Initiate spironolactone.
  - Initiate thiazide diuretic.
  - Initiate hydralazine.
  - Use any antihypertensive to achieve a systolic BP <120 mm Hg.
12. A 59-year-old man presents to the ED with systolic BP of 224 mm Hg and diastolic BP of 110 mm Hg. Which of the following findings are *not* characteristics of a hypertensive crisis?
- Retinal hemorrhages
  - Microangiopathic hemolytic anemia
  - Azotemia and proteinuria
  - Normal mental status
  - All are characteristics of hypertensive crisis.
13. A 36-year-old woman with a history of rheumatoid arthritis presents to the hospital with acute chest pain, which worsens in the supine position, with associated low-grade fever. Physical examination revealed a friction rub but was otherwise unremarkable. EKG reveals diffuse ST elevations and PR depression, and an echocardiogram revealed a small pericardial effusion without tamponade physiology. What is the best approach for management of her acute pericarditis?
- Ibuprofen 800 mg 3 times a day
  - Nonsteroidal antiinflammatory drug (NSAID) + colchicine
  - Prednisone 60 mg daily
  - Colchicine 1 mg daily
  - Pericardiocentesis
14. A 64-year-old man underwent a heart transplantation 2 years ago and has posttransplant hypertension, diabetes, and weight gain. A biopsy in the recent past was negative for cellular rejection, and he has no CAD documented at last angiogram 4 months ago. There have been no changes in his background medicines, which includes triple immunosuppression therapy, diltiazem, lisinopril, and pravastatin. He presents today with acute kidney injury, noting an elevation of the serum creatinine from 1.2 mg/dL 2 months ago to 2.3 mg/dL today. Which of the following is the most likely cause of his kidney injury?
- Tacrolimus
  - Contrast nephropathy from angiogram
  - Mycophenolate mofetil
  - ACE inhibitor
  - Azathioprine
15. A 28-year-old woman presents to the ED with long-standing intravenous drug abuse and new fever, rigors, loud holosystolic murmur at apex, and clear lungs. EKG reveals type 2 second-degree AV block, and echocardiogram reveals moderate mitral regurgitation with a vegetation approximately 5 mm in size on the anterior leaflet with significant mobility. Blood cultures grew *Staphylococcus aureus* within 12 hours. There is no decompensated heart failure. What is the most likely reason for urgent surgical intervention?
- New heart block
  - Rapid positivity of blood cultures with *S. aureus*
  - Mobile vegetation that is 5 mm in size
  - Moderate mitral regurgitation
  - Prevention of embolic event
16. A 63-year-old male who had not seen a doctor in 7 years presents to the ED with acute chest pain for the past 2.5 hours with diaphoresis, nausea, and dyspnea. EKG reveals ST elevations in leads V1 through V6 and I and aVL. Cardiac troponin I is 0.04 (upper limit of normal 0.03). Urgent cardiac catheterization reveals an occluded proximal LAD stenosis, and he underwent successful angioplasty with the placement of a drug-eluting stent. An echocardiogram demonstrates LVEF 35% with mild mitral regurgitation. Which drug is not appropriate for initiation of his care?
- Carvedilol 25 mg twice daily
  - Spironolactone 25 mg daily
  - Clopidogrel 75 mg daily
  - Atorvastatin 80 mg nightly
  - Fondaparinux 7.5 mg daily
17. A 57-year-old male with a history of hypertension presents to the ED with acute chest pain radiating to his back with hypotension and a new, large left effusion on chest x-ray (CXR). Systolic BP is different in the two arms. Appropriate steps in management include:
- Treat with sodium nitroprusside.
  - Start a loop diuretic.
  - Surgical repair for proximal dissection
  - Surgical repair for distal dissection
  - Narcotics for pain relief

18. Which of the following is *not* a contributing factor to the development of essential hypertension?
- Obesity
  - Alcohol consumption
  - Salt intake
  - Cigarette smoking
  - Lack of exercise
19. A 71-year-old woman with long-standing hypertension, diabetes, and hyperlipidemia presents to you with dyspnea. Laboratory results were checked and were notable for an elevated N-terminal pro B-type natriuretic peptide (NT-proBNP) at 1500 pg/mL. Acute heart failure was excluded by examination, echocardiogram, and CXR. What is the least likely cause of her elevated NT-proBNP?
- Older age
  - Body mass index (BMI) of 35
  - Pulmonary embolism
  - Estimated glomerular filtration rate of 30 mL/min/1.73 m<sup>2</sup>
  - Pulmonary hypertension
20. A 54-year-old man is scheduled for right hip replacement. He presents to your clinic for preoperative assessment. He has a past medical history of hypercholesterolemia, hypertension, benign prostate enlargement, and CAD with a stent placement in the LAD artery 2 years ago because of angina with single vessel disease. He exercises daily by walking 2 miles without limitations or symptoms. What is the best option for preoperative management?
- Perform a stress test (Standard Bruce Protocol) without imaging to risk stratify before surgery.
  - Proceed to surgery without further testing.
  - Perform a pharmacologic stress test with imaging to risk stratify before surgery.
  - Perform a stress test (Standard Bruce Protocol) with echocardiography to risk stratify before surgery.
  - Repeat coronary angiography.

### Answers

- B. This is not an uncommon problem faced by the clinician. Patients may develop delayed pericarditis from an acute MI (Dudzinski DM, Mak GS, Hung JW. Pericardial diseases. *Curr Prob Cardiol.* 2012;37:75–118). Chronic pericarditis is more commonly seen in women following acute MI and can be debilitating. Pericarditis is often associated with pleuritic chest pain often radiating to the ridge of the trapezius, and the EKG often has diffuse PR depression and ST elevation, although one can see regional pericarditis in situations such as post bypass surgery. The pain can occur between 1 day and 6 weeks post-MI and can be difficult to distinguish from recurrent angina. Diagnosis can often be confirmed with cardiac MRI. An acute anterior wall MI is less likely given the stable clinical presentation in the outpatient clinic and atypical (and positional) nature of chest pain, although silent injury may occur in some patient populations. Pulmonary hypertension may occur as a consequence of heart failure post infarct. This is likely too early. Although chest pain is possible, it typically occurs with exertion. The lack of JVD, ascites, peripheral edema, and right ventricular heave decreases the likelihood of pulmonary hypertension. Acute mitral regurgitation typically presents with acute cardiogenic shock and/or heart failure post infarct. Persistent ST elevation after an acute MI is classically described in patients with a LV aneurysm, although it can be the result of a large infarct as well. LV aneurysms more commonly occur after an occluded vessel in which there was not adequate collateral blood supply. It is not typically a cause of pleuritic chest pain. Management of pericarditis is challenging in the setting of need for dual antiplatelet therapy. Colchicine has been used as an alternative for managing chronic pericarditis.
- E. This patient has sarcoid cardiomyopathy. A young patient with AV conduction disease, sinus node disease, or atrial or ventricular arrhythmias should be considered for cardiac involvement of sarcoidosis. This diagnosis is rarely made in part because of inadequate vigilance when patients present with early signs of conduction disease. An EP study would not be indicated as first-line therapy in the absence of signs of malignant arrhythmias; the sensitivity and specificity of an EP study are lower in patients with nonischemic cardiomyopathy, making the negative predictive value too low to feel comfortable with management being driven by the findings. An AICD for primary prevention of sudden cardiac death would not be indicated until the LVEF remains low after 3 months of treatment with guideline-directed medical therapy. Although an endomyocardial biopsy may be required to definitively diagnose cardiac sarcoid, the lesions are patchy and can be missed on a biopsy. A bone marrow biopsy would be helpful to evaluate cardiac amyloid; however, the clinical presentation is not consistent with this finding. An FDG PET scan can be helpful in identifying active sarcoid (Patel AR. Detection of cardiac sarcoidosis: a balancing act between symptoms and imaging findings. *JACC Cardiovasc Imaging* 2017. [Epub ahead of print]). A typical pattern is uptake in the basal septum. This imaging modality can be useful in following response to therapy. Cardiac MRI would be an alternative imaging; however, the pacemaker would preclude this option if it is not MRI compatible. Treatment of cardiac sarcoid is typically with prednisone or methotrexate. However, when the LVEF is severely reduced, there is less likelihood of recovery of LV function and one may consider need for heart transplantation if disease progresses.

3. C. This patient is at risk for a cardiomyopathy caused by doxorubicin exposure, and there can be a delay in the development of LV dysfunction, especially in younger patients. Echocardiography excludes this etiology. Radiation exposure places her at risk for CAD, constrictive pericarditis, restrictive cardiomyopathy, and valvular disease. Classically, patients develop CAD ~10 years postradiation exposure and have a unique pattern with stenosis in the ostia of the major coronary arteries, possibly caused by more intense radiation exposure in these areas. Her right-sided heart failure symptoms suggest restrictive versus constrictive physiology. Cardiac MRI can be helpful, as well as echocardiography with Doppler interrogation, chest CT to evaluate pericardial thickness, and cardiac catheterization (gold standard).
4. B. The management of hyperlipidemia has been somewhat controversial given the recent guidelines published in 2014 (Stone NJ, Robinson JG, Lichtenstein AH, et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association task force on practice guidelines. *Circulation*. 2014;129:S1–45). Given her DM, she is at high risk and thus her LDL and total cholesterol levels are not at target. For all patients with hypercholesterolemia, it is recommended to exercise and modify diet to improve lipid profile. However, there are some patient populations that should receive pharmacologic therapy. The ATP III LDL-C guidelines take into consideration the risk of the patient to establish target goals and interventions. Patients with established coronary heart disease (CHD) or who have a CHD risk equivalent (i.e., DM, peripheral arterial disease, abdominal aortic aneurysm, carotid disease,  $\geq 2$  risk factors with 10-year risk of  $>20\%$ ) are considered high risk. Risk factors include smoking, hypertension, HDL  $<40$  mg/dL, family history of early CAD, and older age (males age  $\geq 45$  years, females age  $\geq 55$  years). Based on the PROVE-IT trial, patients with an acute MI could be treated with atorvastatin 80 mg nightly. Generic drugs are available for other secondary prevention as well as primary prevention patients. PCSK-9 inhibitors are a class of drugs that inhibit a proprotein convertase involved in the degradation of LDL receptors in the liver by the use of a monoclonal antibody and thus increase the clearance of LDL cholesterol. Niacin is good to raise HDL. However, there are no data that it improves outcomes. Exercise testing is not required to decide on use of a statin.
5. C. Patients with evidence of transient atrial fibrillation on interrogation of a pacemaker or defibrillator are at higher risk for stroke even in the absence of confirmed atrial fibrillation. Thus patients should be assessed for thromboembolic risk using CHADS<sub>2</sub> VASc score after this finding without further diagnostic testing. She is at high risk for thromboembolic events given her age and sex. The decision regarding aspirin versus warfarin is based on risk of thromboembolic complications risk, bleeding risk, and potential contraindications for therapy (e.g., recurrent falls). The ACTIVE study was recently stopped early because of worse outcomes in patients with atrial fibrillation randomized to aspirin + clopidogrel compared with warfarin (ACTIVE Investigators, Connolly SJ, Pogue J, et al. Effect of clopidogrel added to aspirin in patients with atrial fibrillation. *N Engl J Med*. 2009;360:2066–2078). Warfarin should be used for (1) patients with mechanical heart valves; (2) patients at high risk of stroke (prior stroke, transient ischemic attack, systemic embolism, or history of rheumatic mitral stenosis); and (3) patients with more than one moderate risk factor (i.e., age  $\geq 75$  years, hypertension, heart failure, LVEF  $\leq 35\%$  or fractional shortening  $\leq 25\%$ , and DM). Aspirin (81–325 mg daily) is recommended as an alternative to vitamin K antagonists in low-risk patients or in those with contraindications to oral anticoagulation. Several studies have demonstrated efficacy of newer oral anticoagulants, including apixaban and dabigatran. However, patients with concomitant valvular disease should not use these agents; her aortic stenosis would exclude her. It is not recommended to start dofetilide to maintain normal sinus rhythm because she is mostly in sinus rhythm. An antiarrhythmic agent can be considered if her atrial fibrillation is symptomatic, associated with clinical deterioration or poor rate control, or becoming more persistent. She would require an admission to the hospital to monitor the QTc if this were initiated. A 24-hour Holter monitor would not be required for her given the pacemaker that demonstrates transient atrial fibrillation.
6. E. This patient is near term and does not have a load-bearing valvular lesion. Valvular heart lesions associated with high maternal and/or fetal risk during pregnancy include severe aortic stenosis with or without symptoms, aortic insufficiency with New York Heart Association (NYHA) functional class III–IV symptoms, mitral stenosis with NYHA functional class II–IV symptoms, severe mitral regurgitation with NYHA functional class III–IV symptoms, aortic and/or mitral valve disease resulting in severe pulmonary hypertension (pulmonary pressure  $>75\%$  of systemic systolic BP), aortic and/or mitral valve disease with severe LV dysfunction (LVEF  $<40\%$ ), mechanical prosthetic valve requiring anticoagulation, and aortic insufficiency in Marfan syndrome.
7. E. The choice of strategy for managing atrial fibrillation is based on the presence or absence of structural heart disease (Al-Khatib SM, Arshad A, Balk EM, et al. Risk stratification for arrhythmic events in patients with asymptomatic pre-excitation: a systematic review

for the 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association task force on clinical practice guidelines and the heart rhythm society. *Circulation*. 2016;133:e575–586). This patient has known CAD, and thus the first-line agents should be either dofetilide, dronedarone, or sotalol. Sotalol is thus the best choice listed. Amiodarone is a second-line agent for this patient if the three other agents fail or if they cannot be safely used. This is driven mostly by the side-effect profile of amiodarone. In patients with heart failure, dronedarone should be avoided given the excess risk of death and/or heart failure progression. Sotalol can be used but is often not tolerated with beta-blockers, a mainstay of therapy. Thus dofetilide may be used as well. For patients without structural heart disease, propafenone and flecainide can be used in addition to other therapies. These agents should not be used in patients with CAD. Catheter ablation should only be used as first line for paroxysmal atrial fibrillation (class IIa indication). Catheter ablation can be used as second-line therapy. AV nodal ablation should only be used when a rate control or rhythm control strategy cannot maintain stability of the patient with persistent fast heart rates or in patients who are not candidates for other traditional therapies.

8. A. Given the prior MI, this patient is at risk for scar formation, and ventricular tachycardia is the most likely cause of syncope. Syncope is a common presentation caused by diverse problems. The patient's history can be helpful in understanding likely causes of syncope. Cardiac syncope is manifested by rapid onset without aura, clear sensorium afterward, and a history of CAD and/or LV dysfunction. Bradyarrhythmias should be considered in patients with a history of conduction disease or heart transplant. Neurologic syncope is often preceded by aura and has a clouded sensorium with incontinence, tongue biting, and/or seizure activity. Hysterical fainting is not accompanied by change in pulse, BP, or skin color. These patients experience paresthesias of hands/face, hyperventilation, dyspnea, and signs of anxiety. Neurocardiogenic syncope is the underlying etiology of approximately 50% of cases. Precipitants include emotional distress, fear, decreased venous response, and pain.
9. D. This patient has a DVT that is likely provoked by his recent airplane travel. Despite the chest pain, there is no evidence of an acute PE, an often-fatal consequence of DVT progression. The clinical presentation can be variable. However, a properly conducted CT angiography has an excellent negative predictive value, and thus a V/Q scan is not necessary. The initial treatment for DVT typically requires unfractionated heparin, low-molecular-weight heparin, or a novel oral anticoagulant (NOAC), such as rivaroxaban (Jaff MR, McMurtry MS, Archer SL, et al. Management of massive and submassive pulmonary embolism, iliofemoral deep vein thrombosis, and chronic thromboembolic pulmonary hypertension: a scientific statement from the American Heart Association. *Circulation*. 2011;123:1788-1830). In the presence of heparin-induced thrombocytopenia, a direct thrombin inhibitor should be used initially. Chronic management requires warfarin that is overlapped with a minimum of 5 days of anticoagulation (excluding NOAC) and INR >2. If the initial treatment is an NOAC, then there is no bridge required; however, warfarin should not be used simultaneously.
10. D. This patient likely did not tolerate such a rapid up-titration of beta-blockade and likely had a decreased cardiac output. Beta-blockers are a recommended therapy for chronic heart failure patients and should be initiated in those who can tolerate them, even during a hospitalization, if there is no evidence of congestion; however, this class should be initiated at low doses and increased slowly. Cardiac output, and even LVEF, may decrease in the early course of treatment with beta-blockers. Other acute complications include bradycardia, fatigue, bronchospasm, fluid retention/decompensated heart failure, hypotension, and dizziness. Over the next 3 months, patients often have improved symptoms, less fatigue, improved LVEF, and better drug tolerance. There are no signs of fluid retention on physical examination. An isolated BNP is of limited clinical utility because many patients have persistently elevated BNP values, and this does not necessarily mean volume overload. If the BNP increased over 2 weeks from 80 to 700 pg/mL, this would support volume retention. There is no definitive data for the routine use of BNP-guided therapy. Digitalis should not be initiated until the patient remains symptomatic despite multiple classes of medicines with known survival benefit. Cardiac transplantation may be considered, but it is preferable to wait until therapy is optimized. The QRS duration is not prolonged enough to warrant cardiac resynchronization.
11. C. This is a question that discusses this strategy for hypertension control. In general, reducing the systolic BP to <140 mm Hg and diastolic BP <90 mm Hg with any antihypertensive agent is the appropriate target for pharmacologic intervention. In self-described African-American patients, the ALLHAT study demonstrated that a thiazide-type diuretic was more effective in improving composite cardiovascular outcome, heart failure, and stroke in comparison with an ACE inhibitor (Wright JT, Jr., Dunn JK, Cutler JA, et al. Outcomes in hypertensive black and nonblack patients treated with chlorthalidone, amlodipine, and lisinopril. *JAMA*. 2005;293:1595–1608). Calcium channel blockers had some benefit as well but were not listed as an answer. The Eighth Joint National Committee

guidelines published in 2014 recommended an anti-hypertensive regimen that included either a thiazide diuretic or a calcium channel blocker for African-American patients with hypertension (James PA, Oparil S, Carter BL, et al. 2014 evidence-based guideline for the management of high blood pressure in adults: report from the panel members appointed to the eighth joint national committee (JNC8). *JAMA*. 2014;311:507–520). ACE inhibitors can be used as first-line therapy for patients with chronic kidney disease, proteinuria, heart failure, and vascular disease. Spironolactone may be an option for patients with documented hypertension caused by hyperaldosteronism. Hydralazine is a great antihypertensive drug that has been used for hypertensive crisis in the past. Compliance with a three-times-a-day drug must be considered as well. For nonblack patients, the general approach for controlling hypertension has been recommended without specific recommendations on the class of antihypertensive.

12. D. Normal mental status can be present during a hypertensive crisis. Hypertensive encephalopathy can be associated with confusion, irritability, headaches, stupor, neurologic deficits, seizures, and coma. It is caused by a sudden rise in BP, which results in acute damage to blood vessels but is not always present with malignant hypertension. It could also be caused by failure of cerebral autoregulation causing excess cerebral blood flow and damage to the wall leading to increased vascular permeability.

Clinical features include renal insufficiency with proteinuria, hematuria, azotemia, microangiopathic hemolytic anemia, heart failure, nausea, and vomiting.

13. A. Pericarditis is typically idiopathic in 85% of patients (Dudzinski DM, Mak GS, Hung JW. Pericardial diseases. *Curr Prob Cardiol*. 2012;37:75–118). The most common clinical scenario is acute MI in 5% to 20% of cases and advanced renal disease in 5% to 13% caused by uremia or dialysis. Autoimmune processes including lupus, rheumatic fever, and scleroderma are not uncommon. The treatment of acute pericarditis usually requires nonsteroidal antiinflammatory medicines for 1 to 3 days, and this can include ibuprofen 800 mg every 8 hours, aspirin 2 to 4 g/d, and indomethacin 75 to 225 mg/d. Colchicine has been used for chronic or recurrent pericarditis with or without NSAIDs or aspirin. The colchicine dose typically is 1 to 2 mg on day one followed by 0.5 to 1 mg/d for up to 3 months. Treating the underlying cause is important as well. Prednisone may be used for some autoimmune processes, but it would not be first-line therapy for acute pericarditis. In the absence of cardiac tamponade, pericardiocentesis should not be performed and may be risky. If there is a concern for infectious (bacterial) pericarditis, a diagnostic pericardiocentesis may be performed.

14. A. Acute kidney injury and chronic kidney disease are common post heart transplantation. Dialysis occurs in approximately 6% of patients, and the most common risk factor is the use of a calcineurin inhibitor, such as tacrolimus. Additional predictors of chronic kidney disease after heart transplantation include older recipient age, pretransplant renal disease, DM, and human leukocyte antigen hypersensitization. Contrast nephropathy typically occurs within a few days after exposure and thus is unlikely in this case. The dose of ACE inhibitor has remained stable, and it is unlikely that it is the cause of the acute kidney injury. Mycophenolate mofetil and azathioprine do not typically cause renal failure; they are more commonly associated with leukopenia. In addition, mycophenolate mofetil has been associated with diarrhea caused by drug-induced colitis, which can be confirmed by colonoscopy and biopsy.
15. A. This patient has acute bacterial endocarditis, likely in the setting of intravenous drug use. The presence of new heart block is suggestive of perivalvular extension of the endocarditis and is one of the many indications for potential urgent surgical intervention. This would be the best answer among the choices. Additional indications include persistent vegetation after systemic embolization, vegetation of the anterior mitral leaflet is >10 mm in size, >1 embolic event during the first 2 weeks of antibacterial therapy, and increased vegetation size despite appropriate antimicrobial therapy. Acute aortic or mitral insufficiency with signs of ventricular failure, heart failure unresponsive to medical therapy, valve perforation or rupture, valvular dehiscence rupture or fistula, and large abscess or extension of the abscess despite appropriate therapy are additional reasons for surgical intervention. The best approach is careful monitoring with initiation of antibiotics in most cases of endocarditis without these concerning findings.
16. E. Fondaparinux should not be used as anticoagulation in patients who undergo primary coronary intervention in the setting of an ST elevation MI (Levine GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on clinical practice guidelines: an update of the 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention, 2011 ACCF/AHA guideline for coronary artery bypass graft surgery, 2012 ACC/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease, 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction, 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes, and 2014 ACC/AHA guideline on perioperative cardiovascular

evaluation and management of patients undergoing noncardiac surgery. *Circulation*. 2016;134:e123–155). Unfractionated heparin or bivalirudin can be used with or without a IIb/IIIa receptor antagonist. A high-dose statin is beneficial post-MI, and patients should be started on either clopidogrel, prasugrel, or ticagrelor for at least 1 year due to the placement of a drug-eluting stent. Given the presence of a low ejection fraction in the setting of an acute MI, the patient should be on a mineralocorticoid receptor antagonist, ACE inhibitor or angiotensin-receptor blocker, and a beta-blocker.

17. C. The pleural findings and differential BP suggest a proximal dissection of the thoracic aorta. Surgical repair for proximal dissection is the best option given the high mortality rate with this condition. Stabilization and pain relief can be done as a bridge to surgery but should not be the sole option. The combination of sodium nitroprusside and beta-blockers is good to reduce BP and wall stress, but sodium nitroprusside should not be used in isolation. Distal dissections are often seen in older patients with CAD and do not require urgent surgery. A loop diuretic should not be used because the patients may be preload dependent if there is pericardial effusion from the dissection.
18. D. Cigarette smoking is a recognized risk factor for vascular disease. Inhalation causes an acute rise in systemic BP and can cause vasoconstriction. However, it is not a contributor to chronic hypertension. Four major contributors to essential hypertension include obesity, excessive salt intake, excessive alcohol intake, and lack of exercise.
19. B. Natriuretic peptides are released from the ventricle and respond to increased wall stress. Anything that affects the left or right ventricular wall stress could result in increased levels of NT-proBNP or BNP (Yancy CW, Jessup M, Bozkurt B, et al. 2013 ACCF/AHA guideline for the management of heart failure: a report of the American College of Cardiology Foundation/American Heart Association Task Force on practice guidelines. *J Am Coll Cardiol*. 2013;62:e147–239). Elevation of these biomarkers is associated with worse prognosis and a variety of syndromes beyond heart failure. Obesity is associated with a low BNP, even in the presence of acute heart failure, and therefore the BMI that exceeds 35 is the best answer. Cardiac causes of elevated natriuretic peptides include acute coronary syndrome, infiltrative and pericardial processes, valvular heart disease, myocarditis, cardiac surgery, and cardioversion. Noncardiac causes include advancing age, renal failure, chronic obstructive pulmonary disease, pneumonia, pulmonary hypertension, sepsis and critical illness, toxic-metabolic insults, and anemia.
20. B. This is a common scenario on board examinations. Given the patient's excellent exercise capacity and asymptomatic status, there is no need for further risk stratification. Treatment of single vessel disease with angioplasty/stents is not indicated in an asymptomatic patient; thus repeat angiography is not necessary. Pharmacologic stress tests should be performed in patients who are unable to exercise, and imaging is not required for patients with interpretable EKGs.

# 91

## Cardiology: Summary

BRADLEY A. MARON

Despite advances in the diagnosis, treatment, and prevention of cardiovascular disease (CVD), the World Health Organization (2014) estimates that CVD accounts for 17.3 million deaths worldwide and is responsible for 2150 deaths in the United States each day. Diseases that affect coronary artery, heart muscle, or valve function comprise the major CVD phenotypes, but the exclusive involvement of any single structure in isolation is rare. Updated population data from Mozaffarian et al. (2015) indicate that acute myocardial infarction (MI), which is the principal complication of thrombotic atherosclerotic plaque rupture, accounts for one in seven deaths in the United States per year, which in 2013 totaled ~370,200 fatalities. It is estimated that recurrent MI occurs in 305,000 Americans annually. The CVD death rate increases sharply with increasing age and disease burden and is greater in men compared with women, as well as in black patients versus white/Hispanic patients.

Importantly, incident CVD in the absence of comorbidities is uncommon. Diseases such as obesity, diabetes mellitus and depression, which are not primary diseases of the cardiovascular system per se, are often key contributors to the development and clinical expression of CVD. In addition, increased overlap in prevalence between CVD and primary parenchymal lung disease, particularly chronic obstructive pulmonary disease, is recognized increasingly. Together, these trends illustrate the importance of maintaining a high index of clinical suspicion for occult CVD in patients encountered commonly in general medical practice. Therefore, it is important for internal medicine practitioners to recognize risk factors for the development of CVD, as well as options available for treatment, which often include behavior modification and pharmacotherapy, but may also involve an expanding range of minimally invasive or surgical procedures.

### Primary Prevention

Conventional paradigm(s) for determining the probability of developing CVD in an individual patient rely upon epidemiologic data identifying risk factors associated with disease expression in large patient populations. This remains the mainstay strategy by which to risk stratify patients at the point of care and longitudinally, although as medicine

sojourns further into the genomic era, it is anticipated that integrating patient-specific genetic data will in the future yield personalized approaches to predicting disease onset and treatment response patterns.

Effective risk stratification hinges on accurately defining the extent to which a particular factor (e.g., tobacco use) influences the likelihood of developing CVD. Two important terms that establish the framework of this concept are *absolute risk* of CVD, which is the risk of developing CVD during a given period of time (e.g., 10 years), and *attributable risk*, which refers to the difference in the incidence of CVD between persons who have (or have not) been exposed to a cardiovascular risk factor. Because ischemic heart disease (IHD) resulting from atherosclerosis of the epicardial coronary arteries is the most common form of CVD, accounting for about one-half of the deaths caused by CVD, primary prevention strategies have focused largely on the identification of risk factors for IHD and development of algorithms for IHD risk prediction (Table 91.1). However, risk-prediction tools are also a central element to the clinical management of patients with other forms of CVD, including genetic cardiomyopathies, arrhythmias, and aortic dissection, among others.

Investigators from the Framingham heart study developed the Framingham cardiovascular risk score, which incorporates demographic information (gender, age), the systolic blood pressure, cholesterol data, cigarette smoking history, and diabetes mellitus status to establish a patient's 10-year risk of developing coronary heart disease (CHD). Comparable algorithms have been developed in Europe and published as the European Society of Cardiology coronary risk chart. Recent guidelines informing on patient candidacy for lipid-lowering therapy focus the initiation of HMG-coA-reductase (statin) drug treatment according to patient risk. However, treatment to a particular target cholesterol level has been deemphasized. Specifically, the recommendations suggest statin treatment for an adult with known atherosclerotic CHD, low-density lipoprotein-C (LDL-C) level >190 mg/dL, diabetes (age 40–75 years) and LDL-C 70 to 189 mg/dL, or 10-year risk of cardiac event or stroke  $\geq 7.5\%$  when analyzed using the pooled cohort risk calculator (Fig. 91.1). High-dose statin therapy is indicated in patients without a contraindication and meeting the following three groups: known atherosclerotic coronary artery

TABLE  
91.1

## Guide to Cardiovascular Disease Risk Reduction

Risk Factor	Apparently Healthy Patients	Secondary Prevention
Smoking cessation	Complete cessation	Complete cessation
Hypertension	<140/90 mm Hg	<130/80 mm Hg for patients with diabetes or chronic kidney disease
High cholesterol	LDL-C <160 mg/dL if patient has 0–1 other risk factors, <sup>a</sup> <130 mg/dL if 2 or more risk factors; also HDL-C >40 mg/dL and TG <200 mg/dL	Primary goal: LDL-C ≤100 and preferably ≤70 mg/dL Secondary goal: HDL-C >40 mg/dL and TG <200 mg/dL
Physical inactivity	30 min of moderate physical activity on most, if not all, days of the week	30 min of moderate physical activity on most, if not all, days of the week
Weight	BMI <25 kg/m <sup>2</sup> , waist circumference <40 inches for men and <35 inches for women; at a minimum, no increase in weight	BMI <25 kg/m <sup>2</sup> , waist circumference <40 inches for men and <35 inches for women; at a minimum, no increase in weight
Glucose control		Goal: HbA1c <7% First-step therapy: weight reduction and exercise Second-step therapy: oral hypoglycemic agents Third-step therapy: insulin
Menopause	Combined estrogen plus progestin should not be used to prevent CVD in postmenopausal women	Combined estrogen plus progestin should not be used to prevent CVD in postmenopausal women
Antioxidants	Antioxidant supplements should not be used to prevent CVD	Antioxidant supplements should not be used to prevent CVD
Psychosocial	Evaluate for depression/anxiety disorders Assess structural/functional support	Evaluate for depression/anxiety disorders Assess structural/functional support
Antiplatelet agents		Aspirin, 75–162 mg/d; clopidogrel, 75 mg/d for at least 1 month after BMS and at least 1 year after DES; long-term therapy (e.g., 1 year) after UA/NSTEMI and STEMI
RAAS inhibition		ACE inhibitors or ARBs for patients with LVEF ≤40% and those with hypertension, diabetes, chronic kidney disease
Beta-blockers		For all patients who have had an ACS or LV dysfunction with or without HF symptoms
Influenza vaccination		All patients with CVD should have an annual influenza vaccination
NSAIDs		Avoid if possible but use stepped care approach <sup>b</sup> if required to control musculoskeletal symptoms

<sup>a</sup>Risk factors include age (men ≥45 years, women ≥55 years or postmenopausal), smoking, hypertension, diabetes, family history of congestive heart disease in first-degree relative, and HDL-C <40 mg/dL. If HDL-C ≥60 mg/dL, subtract one risk factor.

<sup>b</sup>For further details on the stepped approach to control musculoskeletal symptoms, please refer to Antman EM, Bennett JS, Daugherty A, et al. Use of nonsteroidal antiinflammatory drugs: an update for clinicians: a scientific statement from the American Heart Association. *Circulation*. 2007;115:1634–1642.

ACE, Angiotensin-converting enzyme; ACS, acute coronary syndrome; ARBs, angiotensin receptor blockers; BMI, body mass index; BMS, bare metal stent; BP, blood pressure; CVD, cardiovascular disease; DES, drug-eluting stent; HbA1c, hemoglobin A1c; HDL-C, high-density lipoprotein cholesterol; HF, heart failure; LDL-C, low-density lipoprotein cholesterol; LV, left ventricular; LVEF, left ventricular ejection fraction; NSAIDs, nonsteroidal antiinflammatory drugs; NSTEMI, non-ST-elevation myocardial infarction; RAAS, renin-angiotensin-aldosterone-sympathetic axis; TG, triglycerides; UA, unstable angina.

• **Fig. 91.1** The Framingham 10-year cardiovascular disease (CVD) risk calculator. Point of care assessment for CVD risk may be performed using various validated risk models. In the Framingham risk calculator, the 10-year probability of developing a myocardial infarction is based on age, cholesterol levels, systolic blood pressure, cigarette smoking history, and diabetes mellitus status. *ASCVD*, Atherosclerotic cardiovascular disease; *HDL*, high-density lipoprotein. (Modified from Wilson PW, D'Agostino RB, Levy D, et al. Prediction of coronary heart disease using risk factor categories. *Circulation*. 1998;97:1837–1847.)

### • BOX 91.1 Summary of the ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Disease

- Persons age  $\geq 21$  years who fall into any of the following four at-risk groups are to be considered for statin therapy to reduce ASCVD risk:
  - Known ASCVD
  - LDL-C level  $> 190$  mg/dL
  - Diabetes, aged 40–75 years, with LDL-C levels of 70–189 mg/dL
  - 10-year risk of cardiac event or stroke  $\geq 7.5\%$  (by the pooled cohort risk calculator)
- Lipid-lowering statin therapy should be based on the degree of ASCVD risk and the intensity of the statin. High-intensity statin therapy<sup>a</sup> is recommended for patients with known ASCVD, LDL-C levels  $> 190$  mg/dL, and DM, with 10-year risk  $> 7.5\%$ . Moderate-dose statin therapy<sup>b</sup> is recommended for the other treatment groups (patients with DM but with 10-year risk  $< 7.5\%$  and those without DM who have a 10-year risk  $> 7.5\%$ ).
- The expert panel did not recommend for or against LDL-C goals or targets but rather recommends that lipids be checked at baseline and then 4–12 weeks after initiating statin therapy to assess adherence and response to therapy. Individuals receiving high-dose statin therapy would be expected to lower their LDL-C level by  $> 50\%$  from their baseline level, and those receiving moderate-dose statin therapy would be expected to lower their LDL-C level by 30%–49%.
- Consider rechecking lipid levels every 3–12 months as clinically indicated. Reassess lifestyle therapy on a regular basis.
- Shared decision making should be performed between providers and patients when considering the use of statin therapy for ASCVD risk reduction (see the section on shared decision making).
- The expert panel notes that these clinical guidelines, although based on evidence, should not replace clinical judgment, particularly in patients who fall outside of the four categories listed in item 1 but who still may be at elevated ASCVD risk (e.g., patients with a family history of early ASCVD).
- These guidelines are not meant to be inclusive of all types of hyperlipidemia. Patients with complex hyperlipidemias should be referred to a lipid specialist for evaluation and treatment recommendations.

<sup>a</sup>High-intensity therapy ( $\geq 50\%$  LDL-C reduction): atorvastatin, 40–80 mg; rosuvastatin, 20–40 mg.

<sup>b</sup>Moderate-intensity therapy (30%–49% LDL-C reduction): atorvastatin, 10–20 mg; rosuvastatin, 5–10 mg; simvastatin, 20–40 mg; pravastatin, 40–80 mg; lovastatin, 40 mg; fluvastatin XL, 80 mg; fluvastatin, 40 mg twice daily; pitavastatin, 2–4 mg.

health care professionals or clinical judgment when considering lipid treatment for a particular patient.

## Atherosclerotic Vascular Disease

Atherosclerosis describes a process in which various maladaptive cellular and molecular events within the blood vessel wall promote an arteriopathy that is characterized by luminal occlusion, abnormal vascular reactivity, and a predilection for thrombosis (i.e., atherosclerotic plaque rupture). Atherosclerosis may affect any vascular bed, although the most common (and often most critical) clinical presentation of atherosclerotic disease involves the coronary, cerebrovascular, and peripheral arterial circulation in which impaired blood flow results in clinically as myocardial ischemia (angina pectoris/acute coronary syndrome [ACS]), ischemic stroke, and claudication/critical limb ischemia, respectively.

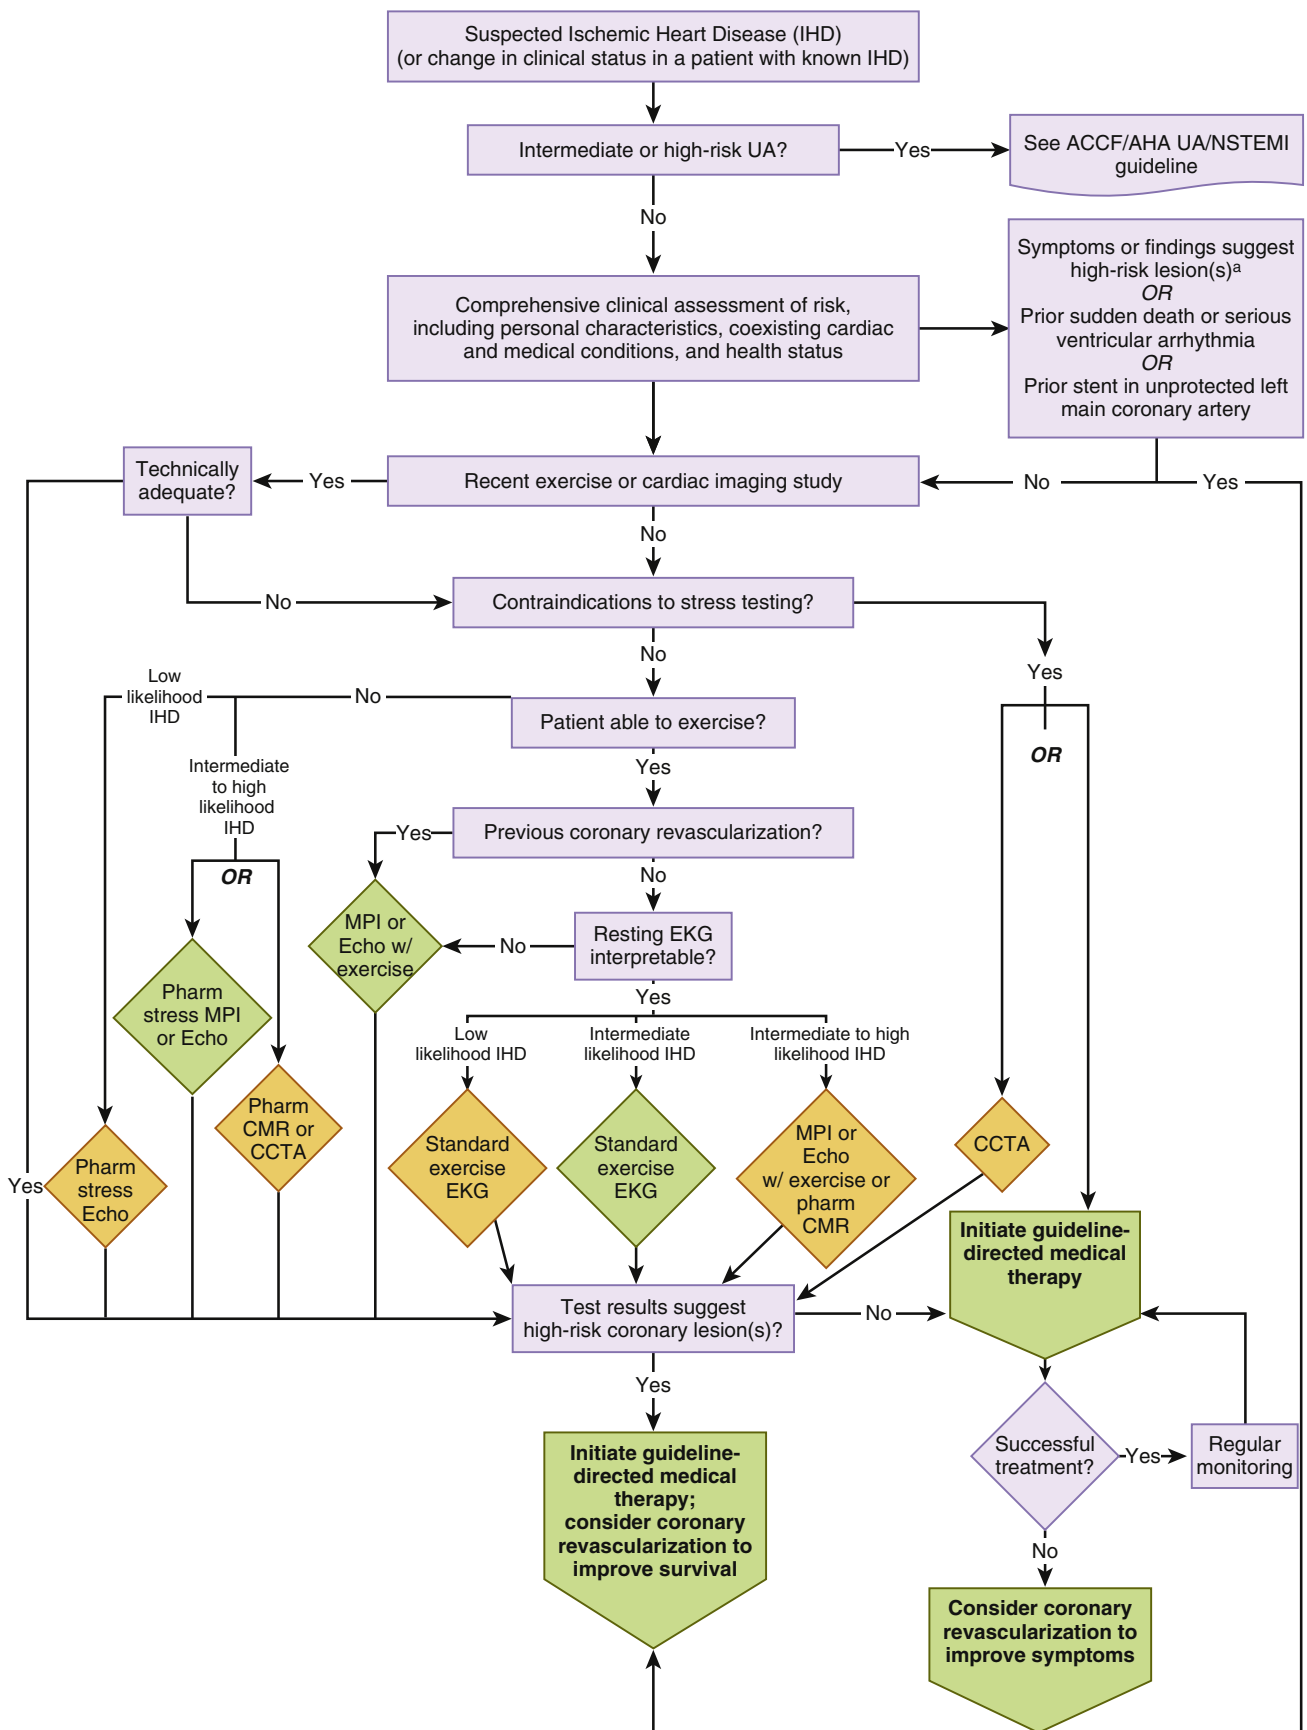

In general, atherosclerotic disease causes symptoms when blood vessel narrowing limits perfusion to a target organ. In the case of IHD, changes to myocardial oxygen demand as a result of increased heart rate, myocardial contractility, or myocardial wall stress that are not met with a proportional increase in coronary artery perfusion because of atherosclerosis-mediated narrowing of epicardial coronary arteries result in myocardial ischemia. Changes to left ventricular (LV) thickness or LV afterload may occur in the setting of aortic valvular disease and systemic hypertension, which increases myocardial oxygen demand and can decrease the threshold for developing myocardial ischemia. This may present clinically as exertional angina pectoris or an angina equivalent such as dyspnea at varying degrees of exercise intensity (Fig. 91.2). Cardiac angina caused by a myocardial supply-demand mismatch is a distinct pathophysiologic process from acute MI, in which sudden rupture of an atherosclerotic plaque triggers thrombosis and, subsequently, total or subtotal occlusion

of coronary blood flow and myocardial injury or necrosis (see Acute Myocardial Infarction section).

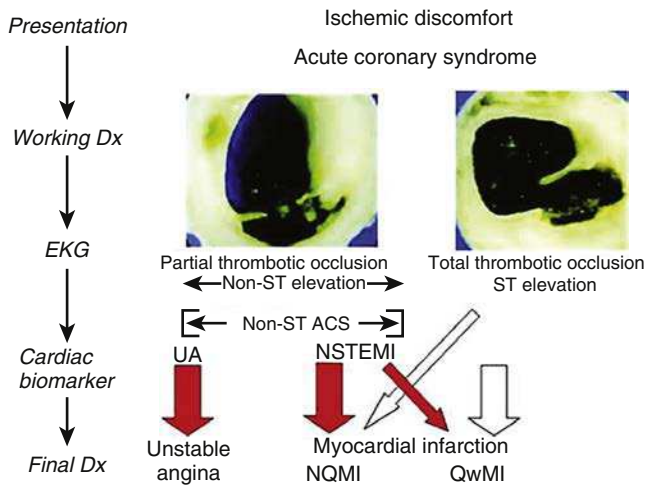

Once the diagnosis of IHD is established through history, physical examination, stress testing, nuclear perfusion or cardiac MRI, and/or cardiac angiography, the clinical management involves a combination of pharmacotherapeutic interventions to decrease demand ischemia and minimize risk factors for developing an acute MI. In patients for whom symptoms of cardiac angina persist despite optimal medical therapy or progress to include high-risk features, such as rest or crescendo angina, percutaneous coronary intervention with balloon angioplasty/coronary stent placement or coronary artery bypass surgery may be indicated. In patients with stable IHD without high-risk features, such as low LV ejection fraction (LVEF) or a high ischemic burden, optimal medical therapy is preferred to percutaneous coronary intervention with stent placement. A guide to the diagnosis of patients with suspected IHD is provided in Fig. 91.3.

## Acute Coronary Syndrome

Disruption of a lipid-laden plaque in an epicardial coronary artery exposes tissue factor and oxidized LDL to the passing bloodstream, setting in motion platelet adhesion, activation, and aggregation, as well as initiation of the coagulation cascade. Under these circumstances, the patient may present with a range of symptoms including ischemic chest discomfort; nausea; dizziness; arm, abdominal, or jaw pain; syncope; and other angina equivalent symptoms. The 12-lead electrocardiogram (EKG) and assessment of cardiac enzymes (i.e., cardiomyocyte injury-specific troponin I and troponin T) from the peripheral blood assist in establishing a diagnosis of ACS. The term ACS refers to a spectrum of conditions including unstable angina (UA), non-ST-elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI) (Fig. 91.4). In UA, history

• **Fig. 91.3** Diagnosis of patients with suspected ischemic heart disease (IHD). Colors correspond to the class of recommendations in the American College of Cardiology Foundation/American Heart Association. <sup>a</sup>Computed coronary tomography angiography (CCTA) is reasonable only for patients with intermediate probability of IHD. *CMR*, Cardiac magnetic resonance; *Echo*, echocardiography; *EKG*, electrocardiogram; *MI*, myocardial infarction; *MPI*, myocardial perfusion imaging; *Pharm*, pharmacologic; *UA*, unstable angina; *UA/NSTEMI*, unstable angina/non-ST-elevation myocardial infarction. (From Fihn SD, Gardin JM, Abrams J, et al. 2012 ACCF/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association of Thoracic Surgery, Preventative Cardiovascular Nurses Association, Society of Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol*. 2012;60:e44–e164.)

• **Fig. 91.4** Acute coronary syndrome (ACS). After disruption of a vulnerable or high-risk plaque, patients experience ischemic discomfort resulting from a reduction of flow through the affected epicardial coronary artery. The flow reduction may be caused by a completely occlusive thrombus (right side) or subtotally occlusive thrombus (left side). Patients with ischemic discomfort may present with or without ST-segment elevation on the electrocardiogram (EKG). Among patients with ST-segment elevation, most (*thick white arrow* in bottom panel) ultimately develop a transmural myocardial infarction (QwMI), although a few (*thin white arrow*) develop a non-Q-wave (nontransmural) MI (NQMI). Patients who present without ST-segment elevation are suffering from either unstable angina (UA) or a non-ST-elevation MI (NSTEMI) (*thick red arrows*), a distinction that is ultimately made based on the presence or absence of a serum cardiac marker such as CK-MB or a cardiac troponin detected in the blood. Most patients presenting with NSTEMI ultimately develop an NQMI on the EKG; a few may develop a QwMI. The spectrum of clinical presentations ranging from UA through NSTEMI and STEMI is referred to as the acute coronary syndromes. Dx, Diagnosis. (Modified from Anderson JL, Adams CD, Antman EM, et al. American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. 2011 ACCF/AHA focused update incorporated into the ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines developed in collaboration with the American Academy of Family Physicians, Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons. *J Am Coll Cardiol.* 2011;10(19):e215–e367.)

and physical examination findings suggest intermittently impaired coronary blood flow caused by an unstable but as yet unruptured atherosclerotic plaque. Electrocardiographic findings of myocardial ischemia, such as ST-segment depression on EKG, may also be observed in UA. By contrast, biomarkers of myocyte necrosis, which is indicative of MI, is not part of UA. Thus overall, UA is a clinical diagnosis. This differs from NSTEMI and STEMI, which are defined as forms of MI that may be subendocardial or transmural.

Prognosis in ACS is dependent upon various factors, including patient demographics, duration of ischemia, the presence of heart failure at initial medical contact, and pharmacologic or mechanical reperfusion. For example, antiplatelet therapies (aspirin, thienopyridines [clopidogrel, ticagrelor, prasugrel, cangrelor]) and anticoagulant therapies (unfractionated or low-molecular-weight heparin,

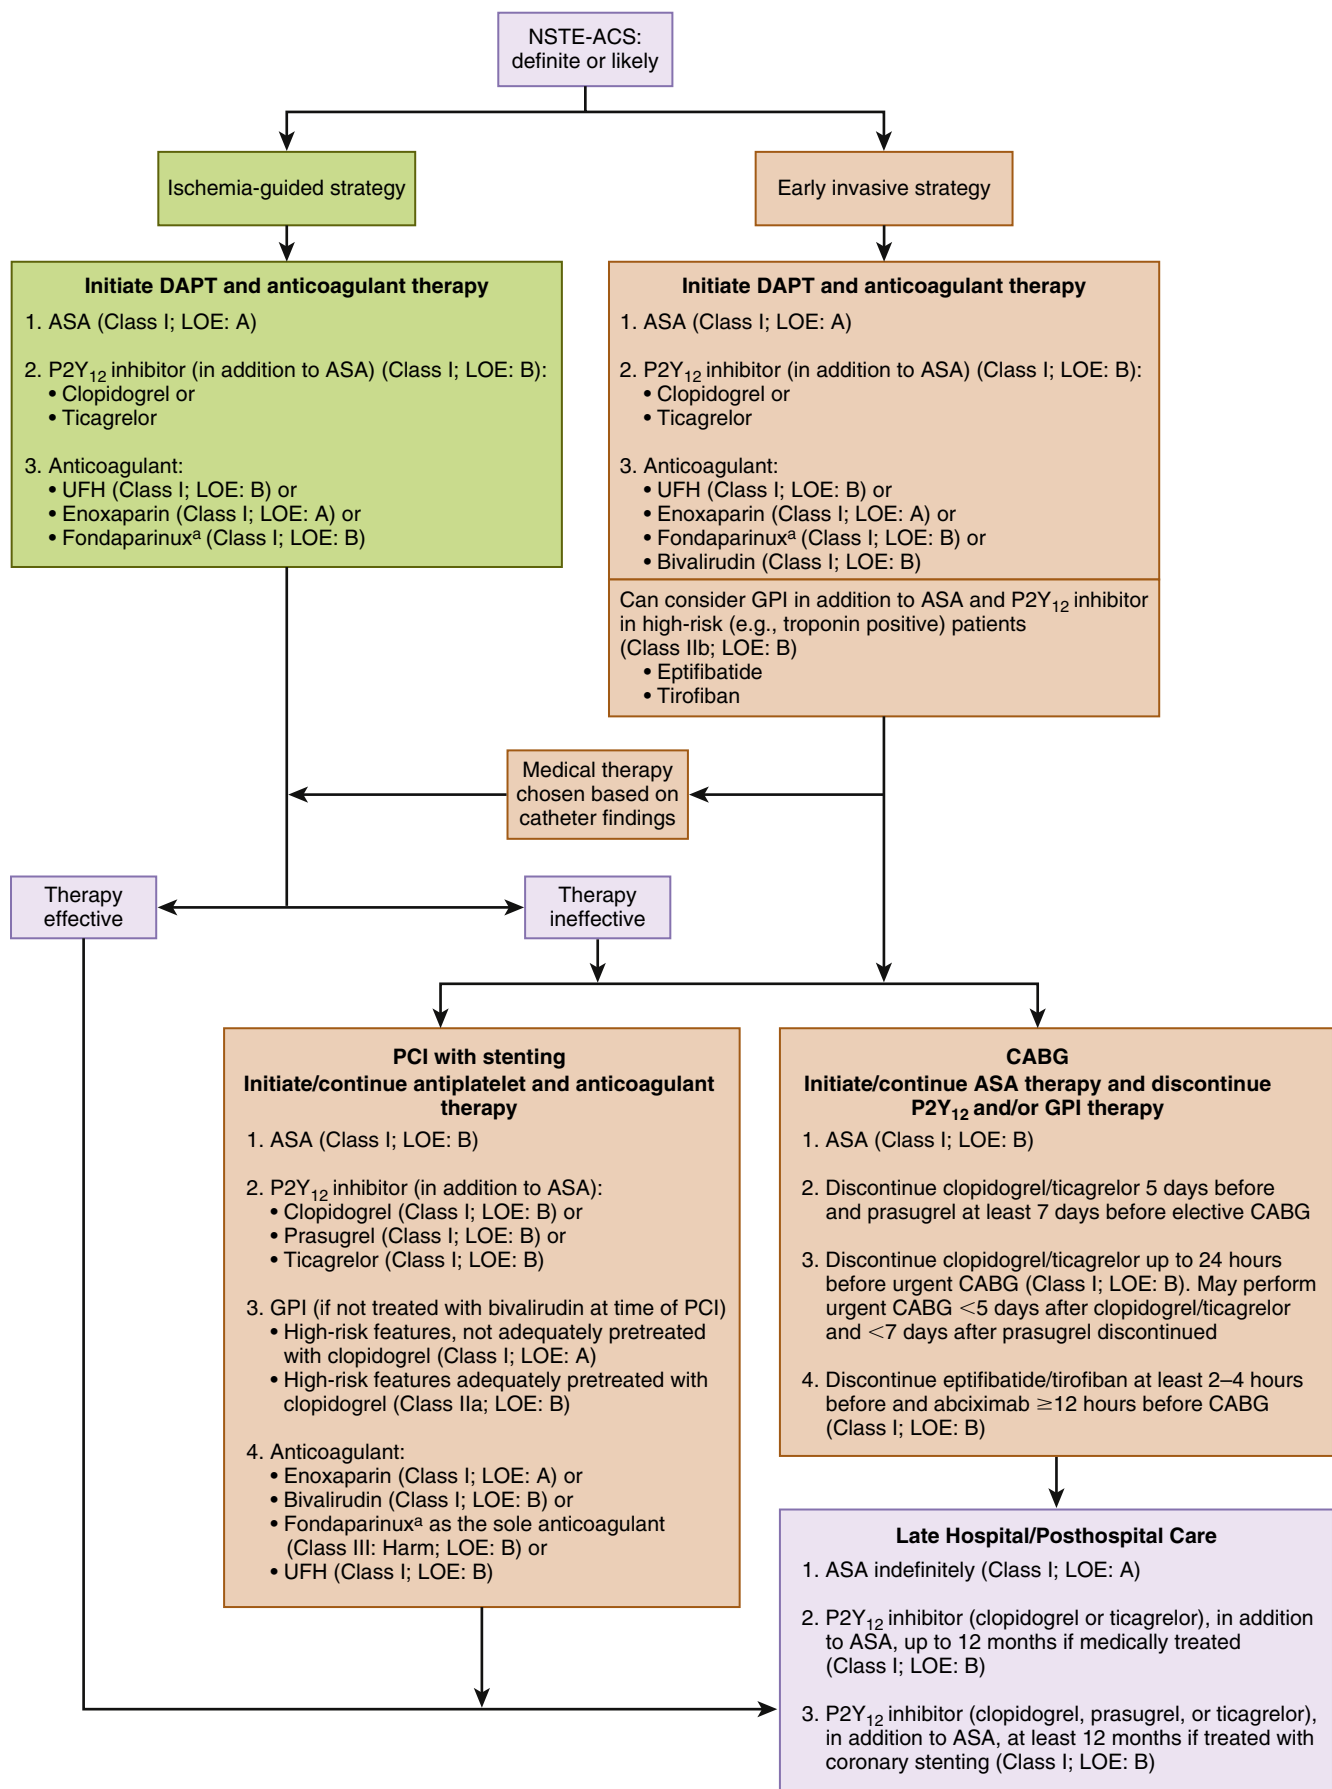

direct thrombin inhibitors [fondaparinux], factor Xa inhibitors [bivalirudin]) are used in ACS patients. Percutaneous coronary interventions involving balloon angioplasty and deployment of coronary stents (bare metal and drug-eluting) are available for use in patients with stable angina refractory to optimal medical management, UA, NSTEMI, and STEMI. Left main CAD, three-vessel disease with decreased LVEF, and two-vessel CAD in diabetic patients remain indications for coronary artery bypass graft surgery. However, multivessel and/or left main coronary artery stent placement may be a treatment option in patients with suitable coronary anatomy or high operative risk.

Algorithms for the management of patients presenting with NSTEMI and STEMI are shown in Figs. 91.5 and 91.6. Post-ACS patients should be treated in accordance with standard measure for the secondary prevention of ACS (see Table 91.1), including evaluation of vascular disease in other circulatory beds with particular attention to cerebrovascular (carotid disease) and peripheral vascular disease (PVD).

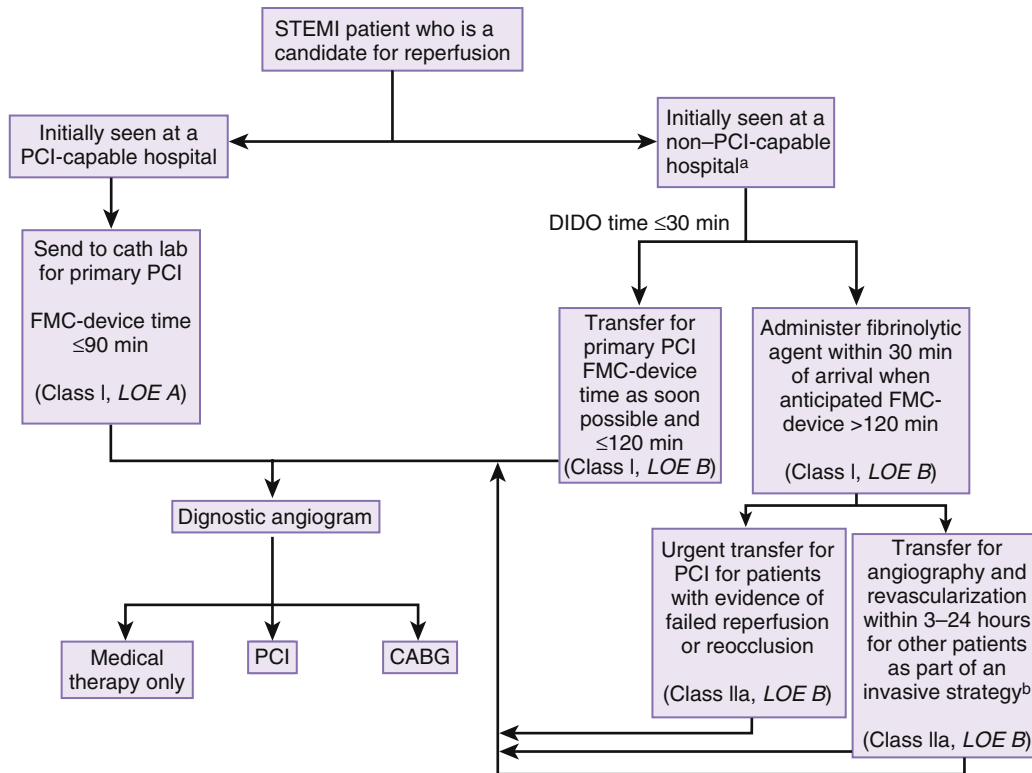

## Valvular Heart Disease

Diseases of the tricuspid, pulmonic, mitral, and aortic valves are generally divided into stenotic (failure to achieve normal valve opening) or regurgitant (failure to achieve normal valve closure) lesions and may be either congenital or acquired. Whereas rheumatic heart disease arising from un(der) treated *streptococcus* infection remains an important etiology of mitral valve abnormalities worldwide, affecting approximately 15 million children each year, the contribution of this to the broader universe of valvular disease patients in the United States continues to dwindle in the antibiotic era. Conversely, the aging general population provides a robust substrate for encountering in internal medicine practice clinically meaningful mitral regurgitation, which is often associated with congestive heart failure caused by IHD, as well as calcific aortic stenosis, which increases in prevalence significantly age >75 years.

Surgical or percutaneous correction of valvular disease is indicated in most symptomatic patients. Treatment of severe aortic stenosis in intermediate- or high-risk surgical patients now includes the option of transcatheter aortic valve replacement (TAVR), which involves the insertion of a bioprosthetic valve via the femoral artery or using a transapical approach (Fig. 91.7). The utility of prophylactic valve replacement in asymptomatic patients depends on the individual patient's clinical profile, the specific valve lesion, and the presence of maladaptive remodeling of the heart muscle from the valve disease. Currently, there is no approved role for TAVR in asymptomatic patients with aortic stenosis. Medical treatment strategies for regurgitant valve lesions are often implemented before consideration of surgery. For example, in patients with asymptomatic chronic mitral regurgitation, after-load reduction to attenuate the regurgitant blood volume and thereby lessen the chance of developing LV cavity dilation and systolic dysfunction is an acceptable initial

• **Fig. 91.5** Algorithm for management of patients with definite or likely non-ST-elevation acute coronary syndrome (NSTE-ACS). <sup>a</sup>In patients who have been treated with fondaparinux (as upfront therapy) who are undergoing percutaneous coronary intervention (PCI), an additional anticoagulant with anti-IIa activity should be administered at the time of PCI because of the risk of catheter thrombosis. ASA, Aspirin; CABG, coronary artery bypass graft; COR, Class of Recommendation; DAPT, dual antiplatelet therapy; GPI, glycoprotein IIb/IIIa inhibitor; LOE, Level of Evidence; UFH, unfractionated heparin. (From Amsterdam EA, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association task force on practice guidelines. *J Am Coll Cardiol.* 2014;64(24):e139–e228.)

• **Fig. 91.6** Reperfusion therapy for patients with ST-segment elevation myocardial infarction (STEMI). The *bold arrows and boxes* are the preferred strategies. Performance of percutaneous coronary intervention (PCI) is dictated by an anatomically appropriate culprit stenosis. For a review of LOE and class recommendation definitions, refer to source document. <sup>a</sup>Patients with cardiogenic shock or severe heart failure initially seen at a non-PCI-capable hospital should be transferred for cardiac catheterization (*cath*) and revascularization as soon as possible, irrespective of time delay from myocardial infarction (*MI*) onset (Class I, Level of Evidence [LOE]: B). <sup>b</sup>Angiography and revascularization should not be performed within the first 2 to 3 hours after administration of fibrinolytic therapy. CABG, Coronary artery bypass graft; DIDO, door-in–door-out; FMC, first medical contact. (From O’Gara, PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association task force on practice guidelines. *Circulation*. 2013;127:e362–e425.)

treatment strategy. Recommendations for the timing of valve repair or replacement in the setting of chronic mitral regurgitation continues to evolve; recent expert consensus guideline statements suggest that surgery is reasonable in asymptomatic patients with low-normal LVEF (<60%), mild LV cavitory dilation, new onset atrial fibrillation (AF), or severe pulmonary hypertension. Although chronic aortic regurgitation is usually well tolerated, valve replacement may be indicated in asymptomatic patients with progressive, severe LV dilation.

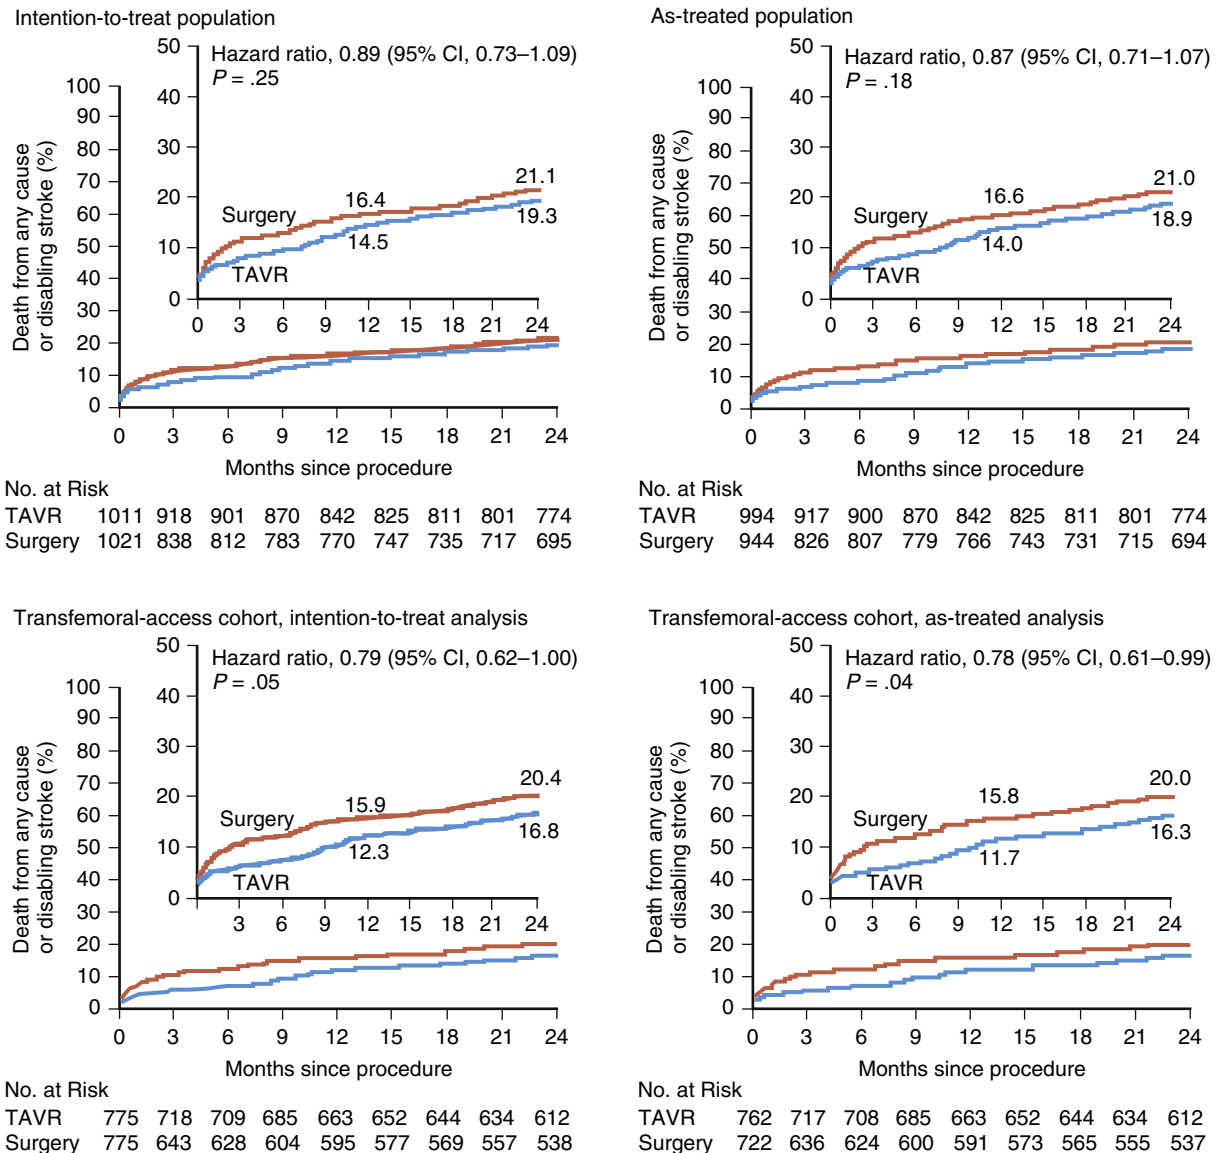

Valve replacement options include a bioprosthesis (e.g., pig pericardium) or mechanical prosthesis (bileaflet mechanical valve). The bioprosthesis has a short life span (~15 years) relative to mechanical prosthetic valves and therefore is preferred in elderly patients owing to (1) a lack of need for long-term anticoagulation and (2) a decrease in the probability that these patients will require a repeat valve replacement. On the other hand, a mechanical prosthesis is preferred in younger patients but requires anticoagulation to prevent thrombosis. Therefore for patients with a separate indication for

anticoagulation (e.g., AF), a mechanical valve may be preferred. Patients with a prosthetic heart valve should receive antibiotic prophylaxis against endocarditis when they undergo dental procedures. In the case of women of childbearing potential, special consideration to valve and anticoagulation options is advised.

## Cardiac Arrhythmias

Commonly encountered cardiac dysrhythmias in the practice of internal medicine include AF and atrial flutter (which are forms of supraventricular tachycardia), bradyarrhythmia caused by polypharmacy or primary conduction disease, and ventricular rhythm disturbances such as premature ventricular contractions and ventricular tachycardia. Cardiac arrhythmias should be suspected in patients for whom dizziness, (pre-)syncope, unexplained weakness, shortness of breath, or palpitations are reported. Outside of ventricular tachycardia resulting in sudden cardiac death, an initial medical strategy to maintain sinus rhythm is preferred for most cardiac

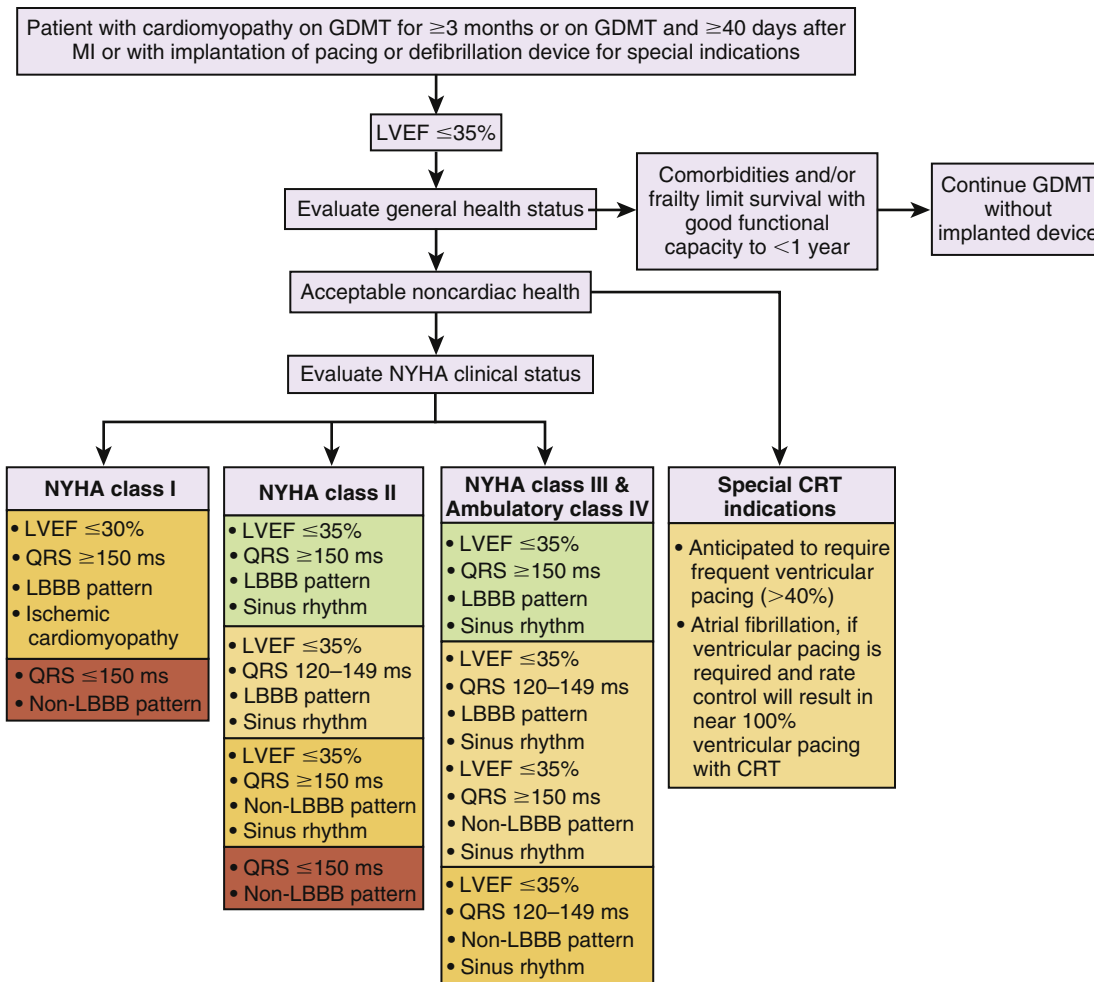

• **Fig. 91.7** Transcatheter aortic valve replacement (TAVR) or surgical aortic valve replacement in intermediate-risk patients. Time to event curves for patients enrolled in a randomized clinical trial investigating differences in outcome according to treatment of severe aortic stenosis with TAVR or standard of care with open surgical replacement. (From Leon MB, Smith CR, Mack MJ, et al. Transcatheter or surgical aortic valve replacement in intermediate-risk patients. *N Engl J Med*. 2016;374:1609–1620.)

dysrhythmias. However, the clinical indications continue to evolve for radiofrequency ablation of ventricular tachycardias and atrial arrhythmias (e.g., AF and atrial flutter), as well as device therapy to treat conduction delay in patients with heart failure. Leadless and MRI-safe pacemakers are increasingly available. Moreover, an increasing number of patients are eligible for implantable cardioverter-defibrillator (ICD) therapy as a primary-prevention or secondary-prevention strategy to abort potentially fatal ventricular arrhythmia events in IHD and select cardiomyopathies (Fig. 91.8). Therefore internists must remain familiar with the guidelines for general device maintenance (performed by an electrophysiologist), including battery life evaluations, as well as the importance of surveying on physical examination for the

presence of pocket infection or hematoma. In patients with severely diminished quality of life and limited life expectancy, a contraindication to ICD placement, primary care physicians often play a critical role in multidisciplinary approaches to consider device capability downgrading.

Despite expanding indications for device therapy, most patients will undergo a trial antiarrhythmic drug therapy in the management of cardiac arrhythmias. Thus, it is important for internists and cardiologists alike to be familiar with the complex (and off-target) effects of these therapies on the cardiovascular system and extracardiac tissues. Another issue encountered commonly in the management of patients with cardiac rhythm disorders involves the need for anticoagulation therapy for prevention of thrombotic stroke, which

• **Fig. 91.8** Indications for cardiac resynchronization therapy (CRT) (biventricular pacing). CRT-D, Cardiac resynchronization therapy defibrillator; GDMT, guideline-directed medical therapy; ICD, implantable cardioverter-defibrillator; IV, intravenous; LV, left ventricular; LVEF, left ventricular ejection fraction; LBBB, left bundle branch block; MI, myocardial infarction; NYHA, New York Heart Association. (From Tracy CM, Epstein AE, Darbar D, et al. 2012 ACCF/AHA/HRS focused update incorporated into the ACCF/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol.* 2013;61:e6–e75.)

must be considered in all patients with AF or atrial flutter. Compared with classical methods, contemporary risk stratification schemes, such as the CHADS<sub>2</sub>-VASc risk score, expand the potential pool of patients for whom anticoagulation is necessary (Fig. 91.9). Along these lines, novel anticoagulation strategies for the prevention of stroke in AF include the direct thrombin inhibitor dabigatran and the direct factor Xa inhibitors rivaroxaban and apixaban that are also approved for prevention of venothromboembolism following knee or hip surgery (Fig. 91.10). The antibody fragment idarucizumab has been shown to reverse the anticoagulant effect of dabigatran. However, concerns regarding the inability to monitor circulating markers of anticoagulation must be considered before use. Overall, the selection of an anticoagulation agent hinges on (1) stroke risk; (2) the potential for major bleeding; (3) practical concerns regarding anticoagulation drug monitoring; and (4) and the need to reverse drug therapy (i.e., elective surgery).

Beyond anticoagulation, the central objective in the management of AF/flutter is rhythm control (where efforts are made to suppress recurrences of AF) and rate control (where AF is accepted as the underlying rhythm, and efforts are made to slow the ventricular rate). A common problem encountered in clinical practice is the decision to initiate anticoagulation in patients for whom cardioversion is planned as part of a rhythm control strategy. Therefore joint decision making between the internist and cardiologist/electrophysiologist is recommended in this clinical scenario.

### Congenital Heart Disease in Adults

Owing to improvements in the early detection and treatment of congenital anatomic catastrophes of the heart, the population of adults living with structural heart disease discovered initially during the embryonic, infant, or childhood stages of life is increasing. The most common congenital

Risk factors	Score	CHADS <sub>2</sub> -VASc annual stroke risk score (%)
Congestive heart failure	1	1 = 1.3
Hypertension	1	2 = 2.2
Age >75 years	2	3 = 3.2
Diabetes mellitus	1	4 = 4.0
Stroke/transient ischemic attack/systemic embolism	2	5 = 6.7
Peripheral vascular disease	1	6 = 9.8 7 = 9.6
Age 65–74 years	1	8 = 6.7
Female sex	1	9 = 15.2

• **Fig. 91.9** The CHADS<sub>2</sub>-VASc score and annual stroke risk. In patients with atrial fibrillation or atrial flutter, the determination of annual thrombotic stroke risk may be calculated by assessing for the presence of individualized risk factors. In the CHADS<sub>2</sub>-VASc risk assessment tool, these include history of congestive heart failure, peripheral vascular disease, systemic hypertension, age >65 years, diabetes mellitus status, prior stroke/transient ischemic attack/thrombotic event, and female gender. (Modified from Lip GYH, Nieuwlaet R, Pisters R, et al. Refining the clinical risk stratification for predicting stroke and thromboembolism in atrial fibrillation using a novel risk factor-based approach. *Chest*. 2010;137:263–272.)

heart defects internists are likely to encounter in practice are septal defects (atrial septal defect [ASD], ventricular septal defect), tetralogy of Fallot, transposition of the great arteries, and coarctation of the aorta. Patients with congenital heart disease frequently will have undergone one or more cardiac surgical procedures, either palliative or for repair of a defect. Advances in catheter-based techniques have led to the percutaneous placement of devices (e.g., clamshell occluder for ASD) in many patients with congenital heart disease.

Vascular communications between the systemic and pulmonary circulations may result in left-to-right and/or right-to-left shunting of blood. Patients with right-to-left shunting may develop cyanosis of the skin and mucous membranes with clubbing of the nailbeds, an increase in erythrocyte mass/blood volume, renal dysfunction, diminished exercise capacity, and increased risk of cerebrovascular accidents as well as cognitive impairment. Because of the risk of paradoxical embolism, filters should be placed in any intravenous lines necessary for patients with intracardiac shunt, although closure of intracardiac shunt for the sole purpose of reducing stroke risk is not supported by currently available clinical data. Patients with unrepaired cyanotic congenital heart disease, those within 6 months of a completely repaired defect with prosthetic material or devices (surgically or percutaneously placed), and those with repaired defects but who have a residual defect at the site of or adjacent to a prosthetic patch or device are at risk for endocarditis and should receive antibiotic prophylaxis at

the time of dental procedures. In the case of coarctation of the aorta, it is important to recognize that successful defect repair either surgically or by percutaneous intervention does not mitigate the future risk of developing clinically meaningful systemic hypertension.

For these collective reasons, congenital heart disease is an important cause of hospital admission and readmission; thus closely coordinated care between the internist, general cardiologist, and congenital disease expert is required for optimal care. In fact, when possible, patients with unrepaired cardiac shunt, cyanosis, or pulmonary hypertension (see later) under consideration for any surgery should be evaluated by a congenital heart disease expert before operating.

## Pulmonary Hypertension

Pulmonary hypertension is defined by a mean pulmonary artery pressure (mPAP)  $\geq 25$  mm Hg, although recent data suggest that the clinical risk associated with pulmonary hypertension is evident at mPAP  $>19$  mm Hg (Fig. 91.11). Early diagnosis of pulmonary hypertension is important because of the adverse effects of increased pulmonary arterial blood pressure on right ventricular (RV) function and the substantially increased rates of morbidity and mortality in patients with right-sided heart failure. Pulmonary arterial hypertension (PAH) (formerly known as *primary pulmonary hypertension*) is a rare disorder caused by the interplay between genetic and molecular factors resulting in a plexogenic vasculopathy of small pulmonary arterioles.

Pharmacologic properties of new anticoagulants			
Drug	Dabigatran (Pradaxa)	Rivaroxaban (Xarelto)	Apixaban (Eliquis)
Mechanism of action	Direct thrombin inhibitor	Direct factor Xa inhibitor	Direct factor Xa inhibitor

(From Madan S, Shah S, Partovi S, et al. Use of novel oral anticoagulant agents in atrial fibrillation: current evidence and future perspective. *Cardiovasc Diagn Ther.* 2014;4(4):314–323.)

Conditions associated with the development of PAH include scleroderma, congenital heart defects with large left-to-right shunts, and portopulmonary hypertension. Current treatment targets in PAH include endothelin-1, nitric oxide, and prostacyclin signaling pathways that result in abnormal pulmonary vascular function. This has led to the introduction of endothelin receptor antagonists, exogenous nitric oxide, phosphodiesterase type-V inhibitors, and prostacyclin derivatives as therapeutic approaches to PAH. Fresh clinical trial data from [Galiè et al. \(2015\)](#) support early, aggressive pharmacotherapy with an endothelin receptor antagonist and phosphodiesterase type-V inhibitor (e.g., ambrisentan + tadalafil) in treatment-naïve patients to decrease PAH-associated mortality and morbidity. Therefore a low index of clinical suspicion for PAH patients and early referral to a pulmonary hypertension specialist are imperative for improving outcome in this disease. Women of childbearing potential require extensive counseling on the serious

complications associated with child birth in the setting of pulmonary hypertension, and many therapies are contraindicated in pregnant women.

## Pericardial Disease

Acute pericarditis is characterized by chest pain, a friction rub, and diffuse PR-segment/ST-T-wave abnormalities on the EKG. It is important to distinguish the chest pain of pericarditis from that of myocardial ischemia. A major distinguishing feature is the fact that pericardial discomfort frequently radiates to the trapezius muscle(s), whereas this is not seen with ischemic discomfort. Pericarditis typically responds to treatment with nonsteroidal antiinflammatory drugs (NSAIDs). Colchicine may be useful as an adjunct therapy to NSAIDs to improve remission and decrease recurrence in acute or recurrent pericarditis compared with monotherapy with NSAIDs alone. Efforts should be made

• **Fig. 91.11** Continuous relationship between mean pulmonary artery pressure (*mPAP*) and mortality risk. Right heart catheterization data from a national referral cohort was assembled, and the relationship between *mPAP* and adjusted hazard for mortality was analyzed. An increase in the mortality hazard was observed beginning at 19 mm Hg. (From Maron BA, Hess E, Maddox TM, et al. Association of borderline pulmonary hypertension with mortality and hospitalization in a large patient cohort: insights from the Veterans Affairs clinical assessment, reporting, and tracking program. *Circulation*. 2016;133(13):1240–1248.)

to avoid corticosteroids in acute pericarditis because of the risk of precipitating a pattern of recurrent episodes of pericarditis over an extended period of time, and they are absolutely contraindicated in patients with pericarditis following acute MI (Dressler syndrome).

Pericardial effusions typically do not require drainage unless there is suspicion of tamponade, an underlying infection, or malignant invasion of the pericardium. However, as reviewed recently by Imazio (2015), temperature >100.4°F, subacute course, large effusion or tamponade, and failed NSAID therapy are indications for hospitalization. Pericardial drainage can be accomplished by percutaneous pericardiocentesis, subxiphoid or balloon pericardiectomy, or an open surgical procedure.

Constrictive pericarditis may develop following cardiac trauma/surgery, infection (e.g., tuberculosis), malignant invasion of the pericardium or myocardium (e.g., neoplasms of the lung and breast), or in patients with a history of prior cardiac surgery. Imaging studies such as echocardiography, CT, and MRI may be helpful in identifying the presence of a thickened, scarred pericardium. Pericardiectomy is the definitive treatment for hemodynamically compromising constrictive pericarditis; however, morbidity rates remain elevated for this procedure even at experienced centers because of the risk of major bleeding associated with “stripping” of the pericardium from the heart muscle wall. In addition, symptomatic relief and normalization of cardiac pressures may take several months. Thus confirmation

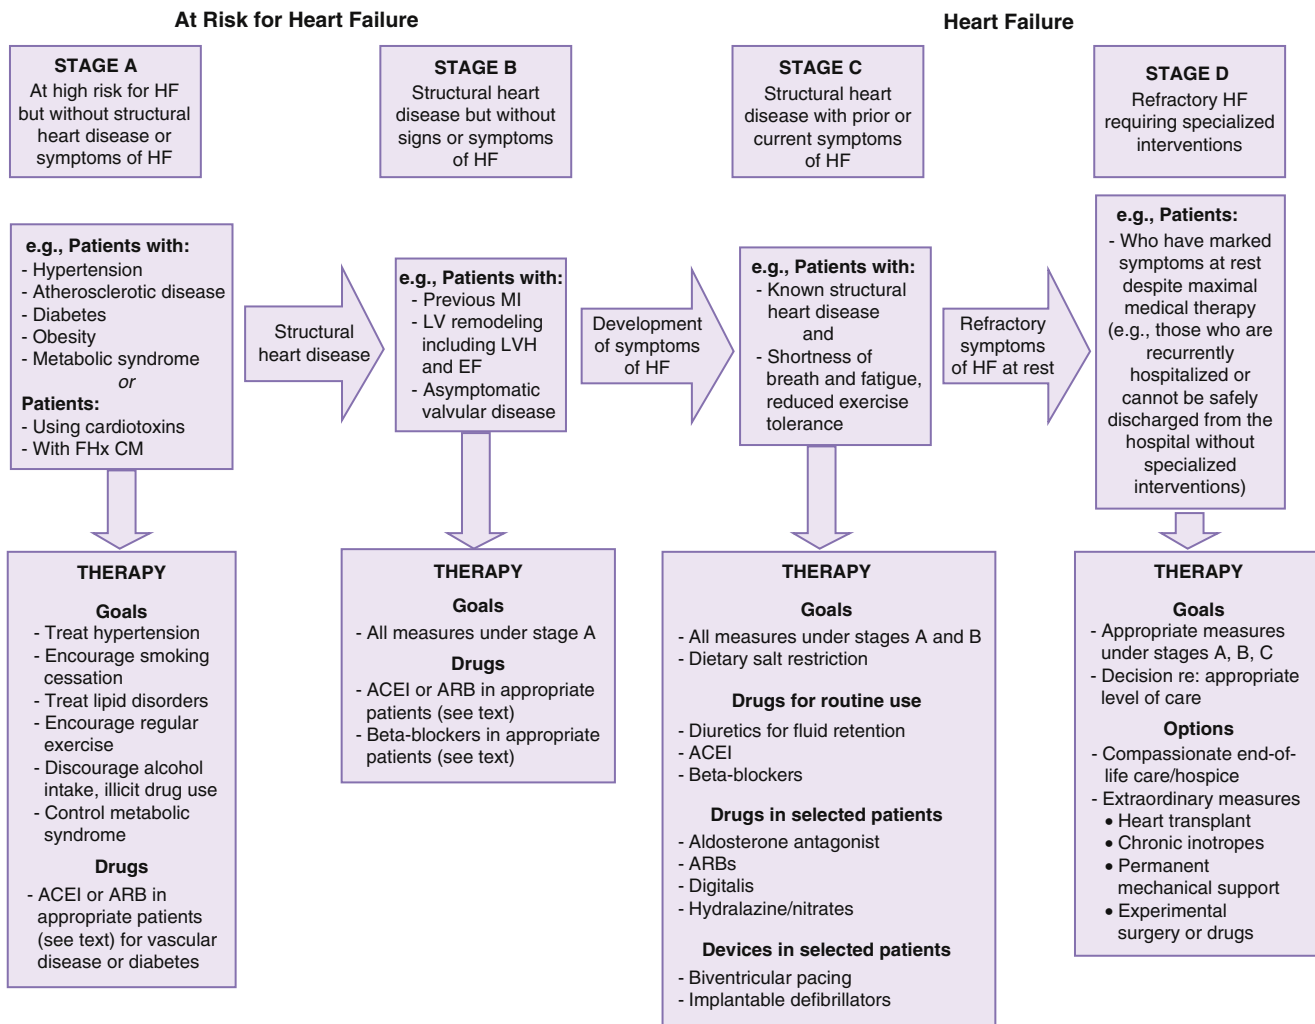

of the diagnosis of constrictive pericarditis often requires analysis of right- and left-sided intracardiac hemodynamics before committing patients to surgical intervention.

In addition to the conditions discussed earlier, internists should also be aware that pericardial disease may be observed in a variety of general medical conditions, including infections, myocardial infection, radiation treatment where the port involves the heart, renal failure, myxedema, connective-tissue disorders, and as a consequence of exposure to drugs and toxins.

## Cardiomyopathy and Congestive Heart Failure

Most diseases of the myocardium may be subdivided into hypertrophic, dilated, restrictive, and ischemic cardiomyopathy. Hypertrophic cardiomyopathy (HCM) is a genetically transmitted disease that affects 1:500 people in the general population. The HCM phenotype is heterogeneous, but thickening of the LV may achieve 5-fold above normal, and dynamic (rather than fixed) LV outflow tract obstruction may also be present. Patients with HCM require cardiology consultation to assess the risk for sudden cardiac death, which is perpetuated by pathologic arrangement of cardiomyocytes that predispose to ventricular arrhythmias. In addition, HCM is the most common form of sudden cardiac death on the athletic field, and patients need to be counseled by a cardiologist regarding acceptable levels of physical activity and guidelines pertaining to participation in organized athletic activity. Restrictive cardiomyopathy is distinguished from HCM by virtue of an infiltrative process of the myocardium, such as in cardiac amyloidosis. Dilated cardiomyopathy, in which thinning of the heart wall is associated with enlargement of the LV (and RV) cavity, may be infectious, genetic, or acquired, as is the case in patients with certain nutritional deficiencies, excessive alcohol consumption, or postpartum cardiomyopathy. Despite advances in the molecular and genetic basis of dilated cardiomyopathy, a substantial proportion of cases remain idiopathic. Takotsubo (or stress) cardiomyopathy describes a clinical syndrome characterized by sudden dilation of the LV apex that is associated with acute chest discomfort and heart failure in the absence of active epicardial CAD, which often occurs under conditions of extreme emotional stress. This form of cardiomyopathy is generally self-limited, responsive to conventional heart failure therapy, and associated with major adverse events in only very rare instances.

In all forms of cardiomyopathy, impaired diastolic or systolic function places patients at risk for developing the congestive heart failure syndrome. Under these conditions, impaired cardiac output results in the upregulation of various neurohumoral factors, including the adrenergic and renin-angiotensin-aldosterone axes, which promotes further maladaptive changes to cardiac (and blood vessel) structure and function. Mainstay strategies by which to treat congestive heart failure in the ambulatory

• **Fig. 91.12** Stages in the development of heart failure (HF): recommended therapy by stage. ACEI, Angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; EF, ejection fraction; FHx CM, family history of cardiomyopathy; LV, left ventricular; LVH, left ventricular hypertension; MI, myocardial infarction. (From Hunt SA, Abraham WT, Chin MH, et al. ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Update the 2001 Guidelines for the Evaluation and Management of Heart Failure] *J Am Coll Cardiol.* 2005;46:1–82.)

setting include afterload reduction therapy (e.g., angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists),  $\beta_1$ -adrenergic-receptor antagonism, loop and thiazide diuretics, digoxin, and aldosterone receptor antagonists although the timing, dosing, and combination of these therapies require detailed and patient-specific consideration. Nephilysin is a neutral endopeptidase that degrades endogenous vasoactive peptides, such as bradykinin, and therefore in heart failure augments the functional effects of neurohumoral overactivation. McMurray et al. (2014) recently demonstrated that combination therapy with nephilysin inhibition plus angiotensin inhibition improved survival and hospitalization in patients with systolic heart failure. On the other hand, there has been little progress in the development of effective therapies in patients with heart failure and preserved LVEF. Clinical

trials recently established that no benefit on symptom burden or outcome was observed for this patient subgroup when treated with long-acting nitrate and phosphodiesterase type-V inhibition therapies. The stages of heart failure and attendant treatment recommendations are outlined in Fig. 91.12.

### Acknowledgment

The author and editors gratefully acknowledge the contributions and great creativity of Dr. Elliot Antman, who authored an earlier edition of this chapter. This work was supported in part by the NIH (1K08HL11207-01A1, 1R56HL131787-01A1 to B.A.M.), American Heart Association (15GRNT25080016 to B.A.M.), Pulmonary Hypertension Association, and Scleroderma Foundation.

## Chapter Review

### Questions

- According to the most recent American Heart Association/American College of Cardiology guideline statement on lipid management, each of the following are indications for the initiation of statin therapy except:
  - Known CHD
  - LDL-C level >140 mg/dL
  - Diabetic age 55 years with LDL-C level 129 mg/dL
  - 10-year cardiac event or stroke rate 7.9%
- Transaortic valve replacement is a reasonable treatment consideration in each of the following patients except:
  - A 71-year-old man with aortic valve area 0.8 cm<sup>2</sup>, exertional angina, history of prior stroke, and glomerular filtration rate 14 mL/min/1.73 m<sup>2</sup>
  - An 82-year-old woman with severe aortic stenosis, forced expiratory volume-1 second of 0.8 L, diabetes mellitus, and history of prior bypass surgery
  - A 64-year-old man with aortic valve area 0.9 cm<sup>2</sup>, Canadian class III cardiac angina, and 70% occlusion in the left main coronary artery
  - A 74-year-old man with aortic valve area 0.6 cm<sup>2</sup>, recent syncope, LVEF 30%, and history of pericardial stripping for constrictive pericarditis caused by remote mantle radiation therapy for lymphoma
- What is the annual stroke risk for a 77-year-old woman with treated type II diabetes mellitus?
  - 2%
  - 4%
  - 6%
  - 10%

# SECTION 9

## Neurology

# The Neurologic Examination

KATHLEEN E. MCKEE AND ANEESH B. SINGHAL

The neurologic examination is an essential component of the physical examination. Indeed, in a study of 200 patients with neurologic disease, the physical examination helped establish the diagnosis in nearly one-third of cases (Simpson, 1977). However, the examination findings were misleading in 10% of cases; this emphasizes the need to interpret the examination in light of the history and other diagnostic studies, and it underscores the need for more rigorous study of examination techniques themselves. Experienced neurologists will have at their disposal an infinite number of variations on the standard neurologic examination that are tailored to each patient based on the patient's history and current mental state. A thorough history remains the cornerstone of a neurologic evaluation and should entirely guide the subsequent examination. For the nonneurologist or those early in training it is suggested to have at one's disposal at least two neurologic examinations: one for awake and interactive patients and one for the less-awake or less-cooperative patients. These two examinations are summarized in Tables 92.1 and 92.2 and further elaborated upon in the remainder of the chapter. We present each examination in an order that reflects how the examination is commonly documented, but each clinician can decide for him- or herself what order to use. With experience, the examination can be performed in a fascicle and fluid manner guided in large part by the patient's history, but while first learning the examination we suggest executing it in the same self-selected order each time.

## Functional Neurologic Disorders

Before turning to the physical examination itself we want to briefly address the topic of functional neurologic disorders (also often referred to as nonorganic, psychogenic, or conversion disorders), which may be suspected when the neurologic examination does not make sense. These disorders are common, widely misunderstood, and can cause both patient and physician great suffering. Scottish neurologist John Stone, an expert in the field of functional neurologic disorders, defines functional neurologic disorders as characterized by "real" (not imagined) neurologic symptoms such as weakness, numbness, or blackouts that are caused by a problem with the functioning of the nervous system and not caused by neurologic disease. Functional disorders represent

a distinct entity from malingering, which is the exaggeration or feigning of illness for secondary gain, although it can be difficult to distinguish malingering versus functional disorders versus true organic neurologic disease.

Functional neurologic disorders were previously thought to be a diagnosis of exclusion but are now considered a "rule-in" diagnosis. If signs and symptoms characteristic of a functional disorder are present, then this diagnosis should be considered at first presentation along with other conditions on the differential diagnosis. Treatment is accomplished jointly by physicians from both neurology and psychiatry and revolves around helping the patient develop insight into his or her condition. With appropriate treatment, most functional neurologic disorders have a good prognosis. In general, because of the difficulty in distinguishing functional disorders from neurologic disease it is recommended to seek neurologic consultation for these patients. There are many neurologic disorders, in particular movement disorders, which may seem to have a psychogenic etiology but in fact represent neurologic disease. One example is Parkinson disease, in which patients are often profoundly bradykinetic but can catch a thrown ball with great speed and accuracy; they can hardly walk but can ride a bicycle with ease. Just because a neurologic disorder is bizarre and defies classification does not mean it is functional or psychogenic. And just because a disorder is thought to be functional or psychogenic does not mean it falls outside the scope of neurology. The brain works in mysterious ways. The examinations that follow are our best attempt as a medical community to unravel and interrogate this complex organ.

## Neurologic Examination of the Awake/Interactive Patient

### Mental Status

The mental status examination (MSE) is useful in differentiating neurologic and psychiatric disease as well as focal from diffuse cerebral impairment. As such it should begin with an assessment of attention, followed by an abbreviated psychiatric examination. In addition to the bedside examination described here, tools such as the mini-mental state examination and the

TABLE  
92.1

## General Neurologic Examination in Awake and Interactive Patients

Mental Status	<p>Psychiatric examination (abbreviated)</p> <p>Affect: outward appearance of feelings</p> <p>Mood: actual feelings</p> <p>Thought: content and process</p> <p>Neurologic examination</p> <p>Level of consciousness</p> <p>Orientation: person/place/time/situation</p> <p>Attention: Say days of the week or spell words both forwards/backwards. Note: If patient is inattentive, the remainder of the mental status exam cannot be used to draw definitive conclusions.</p> <p>Language</p> <p>Fluency</p> <p>Naming</p> <p>Repetition</p> <p>Comprehension</p> <p>Reading and writing</p> <p>Memory: delayed recall of 4 words, remote memories</p> <p>Calculations: serial 7s</p> <p>Abstractions: "Don't judge a book by its cover" or "How are a train and a bicycle alike?"</p>	
Cranial Nerves	<p>I: olfactory</p> <p>II: visual acuity, visual fields, funduscopy</p> <p>III, IV, VI: pupil size/shape, direct/consensual response to light and accommodation, extraocular movements</p> <p>V: facial sensation, jaw strength</p> <p>VII: facial motor strength—forehead raise, tight eye closure, smile, cheek puff</p> <p>VIII: hearing</p> <p>IX, X: dysarthria, swallowing, palate elevation, uvula position</p> <p>XI: shoulder shrug, head turn</p> <p>XII: tongue position, strength, atrophy, fasciculations</p>	
Motor	<p>Appearance</p> <p>Tone</p> <p>Strength: confrontational and pronator drift</p> <p>Rapid finger tap</p>	<p><i>Scale for grading confrontational strength testing<sup>a</sup></i></p> <p>5: Full power</p> <p>4: Movement against resistance but can be broken</p> <p>3: Movement against gravity but not resistance</p> <p>2: Movement only with gravity eliminated</p> <p>1: Flicker of contraction but no movement</p> <p>0: No visible muscle contraction</p>
Sensory	<p>Primary sensory modalities</p> <p>Light touch</p> <p>Temperature</p> <p>Pain</p> <p>Vibration</p> <p>Joint position</p>	<p>Secondary (cortical) sensory modalities</p> <p>Tactile discrimination (double simultaneous stimuli)</p> <p>Two-point discrimination</p> <p>Stereognosis</p> <p>Graphesthesia</p>
Reflexes	<p>Biceps: C5,6 musculocutaneous</p> <p>Brachioradialis: C5,6 radial</p> <p>Triceps: C7,8 radial</p> <p>Patellar L3,4 femoral</p> <p>Achilles S1,2 tibial</p> <p>Babinski</p>	<p><i>Scale for grading reflexes</i></p> <p>0: Absent; unable to elicit even with augmentation</p> <p>1+: Present but diminished, may need augmentation to elicit</p> <p>2+: Normal</p> <p>3+: Increased but not to a pathologic degree</p> <p>4+: Markedly hyperactive, pathologic, often with clonus</p>
Coordination	<p>Finger-nose-finger</p> <p>Heel-knee-shin</p> <p>Rapid alternating movements</p>	
Gait	<p>Natural gait and turns</p> <p>Toe walk</p> <p>Heel walk</p> <p>Heel to toe</p> <p>Romberg</p>	

<sup>a</sup>*Italics* indicate that scales are not part of the examination.

**TABLE 92.2** Neurologic Examination in Less-Awake or Comatose Patients

Mental Status	Attempt arousal to increasing level of stimuli: voice → cotton swab in nare Note any purposeful movement as well as regarding/tracking with eyes Attempt simple axial and appendicular commands		
	<b>Characterization of Varying Levels of Consciousness</b>		
	<b>Term</b>	<b>Eyes</b>	<b>Arousability</b>
	Awake	Open	Spontaneously alert
	Lethargy	Closed	Arousable with mild stimuli (e.g., to voice)
	Stupor	Closed	Arousable with effort
	Coma	Closed	Unarousable
	<b>Thought Content</b>		
			Appropriate
			Mildly impaired
			Markedly impaired
			N/A
Cranial Nerves	II and III: pupil size/shape and direct/consensual response to light II and VII: response to visual threat III, IV, VI: eye position and tracking movements III, VI, VIII: oculoccephalic maneuver V and VII: corneal reflex VII: observe for any gross facial asymmetry or asymmetry during grimace IX and X: cough, gag reflex		
Motor	Observe for spontaneous movement, posturing, tremor Bulk/tone Noxious stimuli to each extremity: observe for withdrawal, extension, triple flexion		
Sensation	Withdraw to pain as tested during motor examination		
Reflexes	Biceps: C5,6 musculocutaneous Brachioradialis: C5,6 radial Triceps: C7,8 radial Patellar L3,4 femoral Achilles S1,2 tibial Babinski sign		

Montreal cognitive assessment can be used as a more standardized method of tracking cognitive status over time.

### Psychiatric Examination

Much of this examination can be performed while obtaining a history. The examiner should make note of the patient's affect; that is, the outward appearance of feelings. Does he or she appear happy, sad, anxious, angry, etc.? Mood, a self-reported experience of feelings, should be assessed by direct questioning such as, "How is your mood?" Thought content (topics or themes that recur, concern or lack of concern with acute illness, etc.) and thought process (perseverative, tangential, linear, circumferential, etc.) should be documented. A more formal and thorough psychiatric MSE can be pursued if, after complete neurologic examination and consultation, there is strong suspicion for comorbid or primary psychiatric disorder.

### Neurologic Mental Status Examination

Level of consciousness (LOC) is the patient's relative state of awareness of the self and the environment. In order of decreasing level of alertness, LOC ranges from fully awake to lethargic, stuporous, and finally comatose. These states are further detailed in [Table 92.2](#) and discussed later as part of the neurologic examination of less-alert patients.

For the awake patient, LOC should be assessed by questions regarding orientation: Ask the patient to state name, location, time, and describe the current situation ("Why are you in the hospital?"; "What is the plan?"). Attention, which is sustained through working memory housed in the prefrontal cortex, can be assessed by asking the patient to say the days of the week backwards or spell "world" backwards. Of note, if the patient is inattentive, the remainder of the MSE should be interpreted with caution. Inattention could reflect an underlying neurologic illness, but, especially in hospitalized patients, inattention often simply reflects delirium. Delirium is the acute onset of disturbed attention, awareness, and cognition, has a fluctuating and variable course, and is secondary to an underlying medical cause. Only after delirium has resolved can a reliable MSE be obtained; sometimes this must even wait until the outpatient setting.

Language is assessed in part simply from talking with the patient during history taking. From this you should get a sense of whether he or she is speaking fluently without hesitation or interruption. And is he or she making paraphasic errors—that is, producing any unintended syllables, words, or phrases during the effort to speak? More formal language testing includes asking the patient to name high and low frequency objects and repeat a sentence of moderate length.

Comprehension is tested by ability to follow simple and complex commands. This can be made more challenging by also testing the ability to comprehend grammatical construction (e.g., point to the ceiling after you point to the floor). Also ask him or her to write a sentence and read and respond to a written command. Impaired language often arises from lesions of the left inferior frontal lobe (Broca's area) and left superior temporal lobe (Wernicke's area). Note that dysarthria (difficult or unclear articulation of speech) is caused by cortical or cranial nerve (CN) abnormalities affecting the muscles of speaking or swallowing. Dysarthric speech may be difficult to understand but is otherwise linguistically normal.

Memory should be analyzed according to three main processes for encoding memory: (1) immediate or working memory—the ability to hold information across an undistracted delay—has already been assessed during tests of attention; (2) episodic or short-term memory is assessed by asking the patient to recall the same four items 5 minutes later; and (3) somatic or long-term memory is evaluated by determining how well the patient is able to provide a coherent chronological history of his or her illness or personal events.

Calculations can be tested with simple arithmetic, subtracting serial 7s, and converting change to a dollar amount (e.g., "How many dollars is 9 quarters?"). Dyscalculia often localizes to lesions of the dominant parietal lobe.

Abstractions can be tested by asking the patient to interpret proverbs such as "don't judge a book by its cover" or "a rolling stone gathers no moss." Impaired abstraction can occur in many conditions but is common in disorders of the frontal lobe.

## Cranial Nerves

### I: Olfactory

Although often not tested, anosmia can be an early sign of dementia, Parkinson disease, or a frontal lobe tumor. To test: Ask the patient to close the eyes and sniff in alternating nostrils a mild stimulus such as deodorant or coffee.

### II: Optic

Check visual acuity (with eyeglasses or contact lens correction in place) using a Snellen chart or even a newspaper with varying sizes of print. Test the visual fields by facing the patient at a distance of approximately 2 to 3 feet and placing your hands at the periphery of your visual field in the plane that is equidistant between you and the patient. Instruct the patient to look directly at your nose and to indicate when and where he or she sees one of your fingers moving. Test each eye and all four quadrants individually: A bitemporal hemianopia can be missed if eyes are tested simultaneously. Visual field abnormalities can localize anywhere along the optic tracts and to the visual cortex of the occipital lobes. Extinction, which is a form of neglect often caused by lesions to the cortex of the nondominant hemisphere, can be tested

by using double simultaneous stimuli (i.e., waving your fingers in the right lower and left lower quadrant at the same time). If the patient previously saw stimuli in each quadrant individually but does not see them both with double simultaneous stimuli, then he or she is said to have visual extinction. The interpretation of this is further discussed in the sensory examination. Optic fundi should be examined with an ophthalmoscope. Note the color, size, and degree of swelling or elevation of the optic disc, as well as the color and texture of the retina and the character of the retinal vessels.

### III, IV, VI: Oculomotor, Trochlear, Abducens

Describe the size and shape of pupils. If the pupils are asymmetric in shape, inquire as to whether the patient has had ocular surgery; often an irregular pupil is simply a postsurgical pupil. If the pupils are different sizes, examine them in both a light and dark room and attempt to determine in which setting the difference between the two is largest. Test for direct pupillary response to light by shining a light in one eye from the side and observing that pupil constrict. Note that if light is shined directly in front of the eye, the accommodative constriction response is also likely to be activated thus clouding interpretation of the pupillary response to light. Test for consensual pupillary response to light by shining a light in one eye from the side and observing constriction of the contralateral pupil. Test for pupillary response to accommodation by asking the patient to focus on your finger as you bring it toward his or her nose; the pupils should converge and constrict. Note that an intact CN II is necessary for normal direct pupillary function.

To check extraocular movements, ask the patient to keep his or her head still while tracking the movement of the tip of your finger. Move your finger slowly in the horizontal and vertical planes; observe any paresis, nystagmus, or abnormalities of smooth pursuit. If the patient complains of diplopia, find the direction of gaze in which the deficit is most pronounced. Also ask the patient to close each eye in turn. If the diplopia persists monocularly, the lesion is most likely ocular; if the diplopia resolves with one eye closed, it is likely neurologic in origin.

### V: Trigeminal

Examine sensation to light touch, temperature, and pinprick within the three territories of the branches of the trigeminal nerve (V1, ophthalmic; V2, maxillary; and V3, mandibular) on each side of the face. The motor component of CN V is often not examined but can be tested by asking the patient to clench his or her jaw tightly while the examiner palpates for any asymmetry in masseter and pterygoid muscle contraction.

### VII: Facial

Look for facial asymmetry, especially subtle flattening of the nasolabial fold, at rest and with spontaneous movements.

Test forehead wrinkling, tight eye closure, smiling, and cheek puff. Look in particular for differences in the lower versus upper facial muscles; weakness of the lower two-thirds of the face with preservation of the upper third suggests an upper motor neuron lesion, whereas weakness of an entire side suggests a lower motor neuron lesion.

### VIII: Vestibulocochlear

Whisper into one ear while rubbing your fingers next to the contralateral ear. This masks the ear closest to the finger rub and allows more precise testing of one ear at a time. To determine whether hearing loss is sensorineural or conductive, the Rinne and Webber tests can be done.

### IX, X: Glossopharyngeal, Vagus

Listen for dysarthria (difficult or unclear articulation of speech that is otherwise linguistically normal). Dysarthria is caused by weakness of the muscles of speaking and swallowing, many of which are innervated by CNs IX and X. Inquire about difficulty swallowing. Observe the position and symmetry of the palate and uvula at rest and with activation (“say aah”). Gag reflex is usually only tested in comatose patients as mentioned later.

### XI: Spinal Accessory

Check shoulder shrug (trapezius) and head turn to each side (sternocleidomastoid) against resistance.

### XII: Hypoglossal

Observe the tongue’s position with protrusion and strength when extended against the inner surface of the cheeks on each side. If there is weakness, the tongue will deviate to the side of muscle weakness. Also inspect the tongue for atrophy or fasciculations.

## Motor

### Appearance

For a screening or emergent examination, it is often not practical to have the patient undress. But in a patient with a neuromuscular chief complaint, the patient must change into a gown to facilitate prolonged and direct visualization of the muscles. Muscles should be inspected and palpated for fasciculations, atrophy, and tenderness. Also observe any involuntary hyperkinetic movements. Rather than name the movement on initial examination, it is best to simply describe what you see, or, with the patient’s permission, record a video. Also ask the patient and caregivers if the movements disappear in sleep. Apart from restless leg syndrome, myokymia, and some forms of myoclonus, all involuntary movements cease during sleep. [Table 92.3](#) defines several hyperkinetic involuntary movements.

## Tone

Muscle tone is tested by measuring resistance to passive movement of a relaxed limb. Measurement is subjective and prone to interexaminer variability. Accurate assessment comes only with clinical experience and even then, it can be difficult to separate slightly increased tone from an incompletely relaxed patient. In all limbs, tone is assessed through passive range of motion around joints—first slowly and then with increasing speed. If the patient is lying on a stretcher, lower limb tone can be assessed by placing the examiner’s hands behind the knees and pulling up; with normal tone, the heels remain in contact with the bed as the knee passively flexes, but increased tone results in an immediate lift of the heel off the surface along with the rest of the leg. Decreased tone is most commonly caused by lower motor neuron or peripheral nerve disorders.

Increased tone often reflects upper motor neuron lesions and may be further described as spastic, rigid, or paratonic. Spasticity is increased tone elicited only when the joint is moved at fast velocity; with slow movement of the joint, the tone is near normal. Rigidity is characterized by a steady increased resistance to passive movement regardless of velocity. Paratonia (also called *gegenhalten*) is characterized by an involuntary, variable increase in tone that may or may not be velocity dependent. Unlike spasticity, if the patient with paratonia is distracted or asked repeatedly to relax, the tone might temporarily decrease, although this is usually short-lived. In patients with paratonia, it can (frustratingly) feel to the examiner as if the patient is purposefully resisting movement about his or her joint, but ultimately the mechanism is involuntary.

Distinguishing between these three different kinds of increased tone can provide a clue to the location of the lesion. Spasticity and paratonia reflect upper motor neuron injury within the pyramidal tracts. Paratonia is often found in older patients and can reflect early dementia or frontal lobe injury. Spasticity commonly results after upper motor neuron injury from diseases such as multiple sclerosis or stroke. Spasticity is always an abnormal finding that should prompt further workup. Rigidity is caused by extrapyramidal lesions such as in Parkinson disease.

## Strength

Confrontational strength testing is performed by having the patient activate muscle groups in their strongest (i.e., most fully contracted) position while the examiner tests his or her strength against the patient’s. Isolate each muscle group to avoid confounding results. A thorough neuromuscular examination will test numerous muscle groups, but for screening purposes, it is sufficient to test shoulder abduction and flexion and extension at the following joints: elbow, wrist, fingers, hips, knees, ankles. Gross weakness will be easy to elicit, but subtle weakness can only be elicited when the examiner puts his or her full strength into the assessment trying in earnest to “break” each muscle group. Muscle strength is traditionally graded using the scale depicted

**TABLE 92.3** Involuntary Hyperkinetic Movements

Dyskinesia	Technically a term for all hyperkinetic involuntary movements but often used to describe involuntary movements that do not fit into one of the later categories, especially drug-induced movements
Tremor	Involuntary rhythmic oscillation of a body part caused by alternating contractions of agonist and antagonist muscles
Chorea	Irregular purposeless nonrhythmic multijoint activity, usually large amplitude and can flow from one body part to another
Athetosis	Very slow, writhing chorea
Akathisia	Sense of inner restlessness and urge to move that compels almost constant motion
Dystonia	Involuntary sustained muscle contraction usually forcing the affected body part into abnormal posture
Hemiballismus	Wild flinging movements of one side of the body
Clonus	Involuntary rhythmic contractions and relaxations of a single muscle caused by its passive stretch
Myoclonus	Abrupt rapid jerking of part or all of a muscle, or groups of muscle; may occur once or repetitively
Asterixis	Brief loss and recovery of normal muscle tone (e.g., with wrists extended like stopping traffic); the brief loss of tone may cause the hands to flow downward, then quickly recover repeatedly
Tic	Quick, irregular but repetitive and stereotyped movements that may be seemingly purposeful; despite awareness of the compulsion to complete the movement, they are not completely under voluntary control
Stereotypy	Repetitive movement similar to a tic but consisting of a more patterned motor activity that is purposeless but may seem purposeful (e.g., foot shaking, ritualistic behavior, hand-wringing)
Fasciculations	Fine, rapid, flickering twitching movements caused by contraction of a bundle (or fasciculus) of muscle fibers; too small to cause movement of a joint and easily missed if patient is not undressed
Myokymia	Involuntary quivering movements that affect a few muscle bundles within a single muscle but are still not large enough to cause movement of a joint; compared with tics they are coarser, slower, more prolonged, and undulating or worm-like under the skin; typically of eyelid, lip, or finger; mistakenly colloquially called a <i>tic</i> or <i>tremor</i>
Spasms	Involuntary contractions of a muscle or group of muscles

in Table 92.1. Sometimes the scale is further expanded by adding plus (+) or minus (–) signs to levels 4 and 5 to indicate a range within these categories.

With a completely normal confrontational strength examination, subtle weakness may be elicited through pronator drift testing. The patient is asked to hold both arms fully extended with palms up and eyes closed. This position should be maintained for approximately 10 seconds; any flexion at the elbow or fingers, pronation of the forearm, or downward drift of the arm, especially if asymmetric, is a sign of potential weakness.

The pattern of weakness is as important as assessing the magnitude of weakness. Weakness secondary to upper motor neuron lesions often causes extensor more than flexor muscle weakness in the upper extremities and flexor more than extensor weakness in the lower extremities.

### Finger Tap

Ask the patient to tap the index finger on the thumb with high amplitude and fast taps. Observe any abnormalities in speed, rhythm, amplitude.

### Sensation

The sensory examination is difficult and at times unreliable. Its sequence within the neurologic examination should be adjusted based on the chief complaint and the cooperation of the patient. With patients who are uncooperative or lack an understanding of the tests, the sensory examination may be less valuable and should be postponed until the end of the examination and deferred if it becomes clear the information is unreliable. For a cooperative and discerning patient with a chief sensory complaint, it may be best to start with the sensory examination before the patient and the examiner become fatigued.

The sensory examination is divided into interrogation of primary (touch, pain, temperature, joint position sense, vibration) and secondary modalities. Secondary modalities such as perception of double simultaneous stimuli require higher cortical association. The examination should focus on the suspected lesion. For example, in spinal cord, spinal root, or peripheral nerve abnormalities, all major primary sensory modalities should be tested while looking for a pattern consistent with a spinal level and dermatomal or nerve

distribution. In patients with lesions at or above the brainstem, screening the primary sensory modalities in the distal extremities along with tests of secondary cortical sensation is usually sufficient.

The five primary sensory modalities—light touch, pain, temperature, vibration, and joint position—are tested in each limb and the trunk. Two general screening patterns can be used: side-to-side when comparing major dermatomes and peripheral nerves and distal-to-proximal when interrogating for a peripheral neuropathy. Light touch is assessed by stimulating the skin with single, very gentle touches of the examiner's finger or a wisp of cotton. Pain is tested using single light touches of a new pin, and temperature is assessed using a metal object (e.g., tuning fork) that has been immersed in cold and warm water. Vibration is tested using a 128-Hz tuning fork applied to bony surfaces such as the distal phalanx of the great toe or index finger just below the nail bed. For joint position testing, the examiner grasps the digit or limb laterally and distal to the joint being assessed and, with the patient's eyes closed, moves the digit up and down; small 1- to 2-mm excursions can usually be sensed.

The sensory association area of the parietal lobe synthesizes and interprets the primary sensory input, thereby giving rise to cortical or secondary sensory modalities, which include tactile localization, two-point discrimination, stereognosis, graphesthesia, and others. Testing cortical sensation is meaningful only when primary sensation is intact. Double simultaneous stimulation is a useful screening test for parietal sensory abnormality. Having confirmed primary sensation to light touch is intact bilaterally, the patient is asked to close his or her eyes while the examiner lightly touches one or both sides of the patient's body (hands, legs, trunk) and asks the patient to identify the stimuli. With a parietal lobe lesion, the patient will be able to identify single stimuli on each side but may be unable to identify the stimulus on the contralateral side of the lesion when both sides of the body are touched simultaneously. Extinction to visual double simultaneous stimuli also localizes to the parietal lobe and is discussed earlier under the CN portion of the examination. Other modalities relying on the parietal cortex include two-point discrimination (the discrimination of two closely placed stimuli as separate), stereognosis (identification of an object by touch and manipulation alone), and graphesthesia (the identification of numbers or letters written on the skin surface).

## Reflexes

Reflexes are the most objective part of the neurologic examination because they are less dependent on cooperation of the patient. The deep tendon reflexes normally examined include the biceps (C5, C6), brachioradialis (C5, C6), triceps (C7, C8), patellar or quadriceps (L3, L4) and Achilles (S1, S2). The patient should be relaxed and the muscle positioned midway between full contraction and extension.

Reflexes may be enhanced by asking the patient to voluntarily contract other, distant muscle groups (Jendrassik maneuver); for example, the patellar reflex is enhanced by asking the patient to simultaneously hook the flexed fingers of the two hands together and attempt to pull them apart. For each reflex tested, the two sides should be tested sequentially, and it is important to determine the smallest stimulus required to elicit a reflex rather than the maximum response. Reflexes are graded according to the scale presented in Table 92.1. Note that the "+" after the number is traditional rather than informative and is sometimes omitted.

Aside from the deep tendon reflexes, there are myriad other reflexes. Probably the most widely known is the Babinski sign, which is a pathologic reflex reflecting disease of the corticospinal system at any level from the motor cortex through the descending pathways. To elicit the reflex, stimulate the lateral plantar surface of the foot with a blunt point (key, handle of reflex hammer, tongue blade, etc.) starting near the heel and progressing up the side of the foot and then along the metatarsal pad from the little toe medially. A normal response is plantar flexion of the toes. An abnormal response is dorsiflexion of the great toe with variable separation or fanning of the lateral four toes. Of note, fanning of the lateral toes without the accompanying great toe dorsiflexion is of little clinical significance and should not be considered abnormal.

## Coordination

The cerebellum is responsible for coordination of muscle movements. It modulates input and output from the corticospinal tract by telling agonist and antagonist muscles precisely when to contract and relax, thus allowing humans to move the way we do. Without a cerebellum, we would still be able to contract all our muscles, but we would lack proper sequencing and be rendered unable to walk, jump, or perform dexterous movements with our hands. As such, lesions of the cerebellum do not cause weakness but rather incoordination and inability to gauge and regulate.

Cerebellar function is interrogated through three main screening tests. Finger-nose-finger is performed by asking the patient to touch his or her index finger repetitively to his or her own nose and then to the examiner's outstretched finger. The test is abnormal if the patient points past the plane of the examiner's finger or has multiple corrections in his or her path of approach to the examiner's finger. Heel-knee-shin is tested by asking the patient to drag his or her heel up and down the length of the contralateral tibia. The test is abnormal if the heel frequently falls off the shin or cannot stay in a smooth line up and down the tibia. Rapid alternating movements can be tested in many ways, including asking the patient to rapidly pronate and then supinate each hand individually against the thigh. The test is abnormal if the patient is not able to achieve a consistent, fast, smooth rhythm.

## Gait

Because of the tremendous amount of information obtained from observation of gait, this part of the neurologic examination should never be omitted as long as the patient is physically able to walk. Normal gait requires that multiple systems (including strength, sensation, and coordination) function in a highly integrated fashion. Unexpected abnormalities may be detected, prompting the examiner to return, in more detail, to other aspects of the examination. The patient should be observed while walking and turning normally, walking on the heels, walking on the toes, and walking heel-to-toe along a straight line. The examination may reveal decreased arm swing on one side (corticospinal tract disease), a stooped posture and short-stepped gait (parkinsonism), a broad-based unstable gait (ataxia), scissoring (spasticity), or a high-stepped, slapping gait (posterior column or peripheral nerve disease), or the patient may appear to be stuck in place (apraxia with frontal lobe disease or freezing of gait as in parkinsonism).

The Romberg test should be performed by asking the patient to stand with the feet as close together as possible to still maintain balance while the eyes are open; the eyes are then closed. When visual input is eliminated the patient must rely on proprioception to maintain balance. Significant swaying or a loss of balance with the eyes closed is an abnormal response usually indicating abnormal proprioception. The Romberg sign is positive only if there is a clear worsening of balance with eyes closed. A patient who cannot maintain balance with feet together and eyes open does not have a positive Romberg sign, and the eyes-closed portion of the test should not be pursued in these patients. This test is designed in particular to detect abnormalities in proprioception that could be caused by lesions in the dorsal column; however, it can be confounded by patients with cerebellar disease. Patients with cerebellar lesions may sway with eyes closed but usually not to the same degree as those with proprioceptive difficulty.

## Neurologic Examination of the Less-Awake/Interactive Patient

Although it is not possible to perform the full traditional neurologic examination as just detailed in less-awake or less-cooperative patients, nearly as complete an interrogation of the nervous system can be obtained via a slightly modified examination, even in comatose patients. The examination described below assumes the patient is mostly unresponsive or comatose. For the patient somewhere in between (e.g., awake but delirious and unable to follow instructions), elements of both examinations can be used. Clinical judgment should be used regarding what is appropriate for each patient; for example, we generally do not test gag reflex in awake patients unless there is specific concern about CNs IX and X. Finally, a reliable neurologic examination can only be obtained if the patient is off sedative medications.

Infusions such as propofol should be held for at least 10 minutes before the examination. [Table 92.2](#) provides a summary of the examination described below.

## Mental Status

In order of decreasing level of alertness, LOC ranges from fully awake to lethargic, stuporous, and finally comatose. These states are further detailed in [Table 92.2](#). Delirium is not addressed in this table but is characterized by fluctuating level of consciousness and thought content. The first step in examining a patient who is not awake is to determine his or her level of consciousness. This should be achieved first with verbal stimuli, then with physical stimuli starting with a light shoulder squeeze and progressing to more noxious stimuli such as inserting a cotton swab into the nare, shaking of shoulders, firm squeeze of trapezius muscle, or sternal rub. If the patient is at all arousable, it may be necessary to repeatedly stimulate him or her throughout the examination to obtain the best examination possible. If the patient is arousable, note any purposeful movement such as reaching for the endotracheal tube. Also note “regarding” or “tracking” with the eyes. Ask the patient to follow simple commands. Midline/axial commands such as “stick out your tongue” are easier than appendicular commands such as “show me two fingers.”

## Cranial Nerves

Almost all CNs can still be interrogated in the comatose patient.

- If the patient’s eyes are not already open, pull up the eyelids and examine the pupils as described previously for size, shape, and direct and consensual response to light.
- Visual acuity can be tested by assessing response to visual threat: rapidly bring your hand or another object close to the patient’s eye from the side, and observe for any attempt to blink. This test is easier if the patient’s eyes open spontaneously, but the patient’s eyelids can also be pulled open gently with enough slack that an attempted blink could still be observed. If a blink is present, this confirms intact CN II and also CN VII, which mediates eye closure.
- Next observe eye position for conjugate or disconjugate gaze, and attempt to elicit extraocular movements by moving stimuli such as your face or a mirror in front of the patient’s face.
- If the patient does not track, the oculoccephalic maneuver can be attempted, which will test both the vestibuloocular reflex mediated by CN VIII as well as CNs III and VI, which move the eyes laterally, medially, and up. To perform this maneuver, hold the patient’s eyelids open with one hand while quickly moving the patient’s head side to side (as if shaking the head “no”). Next let go of the eyelids and bend the patient’s head forward (as if shaking the head “yes”). The reflex is present and normal if the eyes move in the opposite direction of the head movements, similar to the eye movements observed in a toy

doll (hence the alternate name *doll's eyes*). The absence of the vestibuloocular reflex suggests brainstem dysfunction in the comatose patient but can be normally absent in the awake patient because voluntary eye movements may mask the reflex. Cold water caloric testing is a more sensitive test to interrogate the same reflexes and is performed by neurologists as part of the brain death examination.

- CN V can be tested by checking corneal sensation with a wisp of cotton (more sensitive) or a drop of saline applied to each cornea individually. A blink response indicates intact CNs V and VII.
- CN VII can be further examined by simple observation for any facial asymmetry as well as asymmetry during any grimacing.
- CNs IX and X can be interrogated by checking cough and gag reflexes; in the intubated patient, deep suctioning should produce a cough, and manipulation of the endotracheal tube should produce a gag. Often the nurse will already be aware if these reflexes are present.

## Motor

Observe the patient for any purposeful or spontaneous movement including reaching for the endotracheal tube, posturing,

or tremor. Assess bulk, and assess tone in the neck and all four extremities. If the patient has no spontaneous movement in a limb, attempt a noxious stimulus such as stroking the plantar aspect of the foot or compressing the nailbed with a hard instrument such as a reflex hammer. Consistent withdrawal away from stimuli applied in different directions is an encouraging response. Other possible responses include extension into the stimulus, and in the lower extremity triple flexion, which is a spinal reflex characterized by flexion at the hip and knee and dorsiflexion at the ankle.

## Sensation

A very limited sensory examination has already been performed with noxious stimuli. Of note, failure to move in response to noxious stimuli to a limb may indicate either impaired sensation or impaired motor function.

## Reflexes

Reflexes should be tested in an identical manner as in the awake patient. It is usually easier to elicit reflexes in the comatose patient because he or she is likely to be relaxed without any volitional muscle tone.

## Chapter Review

### Questions

1. A 73-year-old man with hypertension and hyperlipidemia is hospitalized for community-acquired pneumonia. On admission, the core temperature is 101.7°F, heart rate is 115 beats per minute, blood pressure is 97/83 mm Hg, peripheral oxygen saturation is 96% on 2 L nasal oxygen, and respiratory rate is 15 breaths per minute. He is awake and interactive. On neurologic examination he appears fatigued and is oriented to the hospital and his admission for pneumonia but states the wrong month and year. He cannot state the days of the week backwards. His speech is fluent without paraphasic errors, he is able to name a pen and a watch, but he has difficulty naming low frequency objects such as the lapel of the examiner's coat and knuckles. When asked to repeat "today is a sunny day in Boston," he says "today was a sunny day." He registers four words but cannot recall any of them even with cues after 5 minutes. He can subtract 7 from 100 correctly until 86, but cannot continue the sequence. When asked the meaning of "don't judge a book by its cover," he responds that it means exactly that and will not elaborate further. He requires frequent stimulation to enable completion of the neurologic examination. The CN, motor, and sensory examinations show no abnormalities. What can you conclude based on his MSE?
  - A. Based on his poor memory, impaired calculations, and inability to interpret abstractions, he is likely suffering from undiagnosed dementia.
  - B. His mild language impairment is concerning for small L hemispheric lesion for which he should undergo urgent MRI of his brain.
  - C. His inability to perform calculations likely indicates a parietal lobe lesion.
  - D. None of the above
2. A 65-year-old woman with obesity, hypertension, hyperlipidemia, and poorly controlled diabetes presents for evaluation of burning pain in her toes that has progressed slowly over approximately 6 months. The neurologic examination is notable for reduced sensation to pinprick, light touch, temperature below her knees, absent vibratory sense in her great toes but preserved at the malleoli and knees, and an inability to sense 2 to 3 mm up and down excursions of her great toe. Finger-nose-finger testing shows no dysmetria. Her gait is wide based and slightly lumbering with moderate sway. When she brings her feet together to perform Romberg testing, she loses balance. Upon closing her eyes, she falls to the left. Where is the lesion?
  - A. Cerebellum
  - B. Dorsal column
  - C. Peripheral nerves
  - D. Parietal lobe
3. A 27-year-old man with a history of idiopathic generalized epilepsy presented to an outside hospital after three generalized tonic-clonic seizures occurring within 30 minutes. He was intubated for airway protection, loaded with phenobarbital, and transferred to your institution

for continuous electroencephalogram (EEG) monitoring in the neurologic intensive care unit. Upon arrival at the bedside, you note that he is on intravenous propofol but no other sedatives. It is now approximately 2 hours since the onset of seizures. You ask his nurse to stop the propofol infusion. Twenty minutes later, on neurologic examination he is unarousable to noxious stimuli. His face is symmetric, and his pupils are fixed and dilated. With eyelids held loosely open, he does not blink when you rapidly approach his eye with your other hand. His eyes remain midline with doll's eye maneuver, and the corneal, cough, and gag reflexes are absent. To nail bed compression, he has no movement in his upper or lower extremities. Muscle tone is decreased, the joint reflexes

are depressed, and there is no response to the plantar reflex. There are no significant abnormalities on brain MRI. The EEG shows flat waveforms indicating the absence of any surface-detectable electrical brain activity. What is the next best step in management?

- A. Supportive care and serial reexamination
- B. Activate brain death examination protocol
- C. Restart propofol
- D. Load with additional phenobarbital

### Answers

1. D
2. C
3. A

## Stroke Prevention

GALEN V. HENDERSON

Approximately 795,000 people in the United States have a stroke each year,  $\approx$ 610,000 of whom have had first attacks, resulting in 6.8 million stroke survivors age >19 years. Stroke ranks as the fourth leading cause of death in the United States. Globally, over the past four decades, stroke incidence rates have fallen by 42% in high-income countries and increased by >100% in low-income and middle-income countries. Stroke incidence rates in low- and middle-income countries now exceed those in high-income countries.

Stroke is a leading cause of functional impairment. For patients who are age  $\geq$ 65 years, 6 months after stroke, 26% are dependent in their activities of daily living, and 46% have cognitive deficits. Stroke changes the lives not only of those who experience one but also of their family and other caregivers. A major stroke is viewed by more than half of those at risk as being worse than death. Despite the advent of reperfusion therapies for selected patients with acute ischemic stroke, effective prevention remains the best approach for reducing the burden of stroke. Primary prevention is particularly important because >76% of strokes are first events. Fortunately, there are enormous opportunities for preventing stroke. An international case-control study of 6000 individuals found that 10 potentially modifiable risk factors explained 90% of the risk of stroke. As detailed in the sections that follow, stroke-prone individuals can readily be identified and targeted for effective interventions.

### Assessing the Risk of First Stroke: Recommendations

The use of a risk assessment tool such as the American Heart Association (AHA)/American College of Cardiology (ACC) CV Risk Calculator (<http://my.americanheart.org/cvriskcalculator>) is reasonable because these tools can help identify individuals who could benefit from therapeutic interventions and who may not be treated on the basis of any single risk factor. These calculators are useful to alert clinicians and patients of possible risk, but basing treatment decisions on the results needs to be considered in the context of the overall risk profile of the patient.

### Generally Nonmodifiable Risk Factors and Risk Assessment

#### Age

The cumulative effects of aging on the cardiovascular system and the progressive nature of stroke risk factors over a prolonged period substantially increase the risk of ischemic stroke and intracerebral hemorrhage (ICH). An analysis of data from eight European countries found that the combined risk of fatal and nonfatal stroke increased by 9% per year in men and 10% per year in women. The incidence of ICH increases with from age <45 years to age >85 years, and the incidence rates did not decrease between 1980 and 2006. Disturbing trends have been observed in the risk of stroke in younger individuals.

#### Low Birth Weight

Low birth weight has been associated in several populations with risk of stroke in later life. Stroke mortality rates among adults in England and Wales are higher among people with lower birth weights. The mothers of these low-birth-weight babies were typically poor, were malnourished, had poor overall health, and were generally socially disadvantaged. A similar study compared a group of South Carolina Medicaid beneficiaries age <50 years who had stroke with population control subjects. The odds of stroke were more than double for those with birth weights <2500 g compared with those weighing 4000 g (with a significant linear trend for intermediate birth weights).

#### Race/Ethnicity

Epidemiologic studies support racial and ethnic differences in the risk of stroke. Blacks and some Hispanic/Latino Americans have a higher incidence of all stroke types and higher mortality rates compared with whites. This is particularly true for young and middle-aged blacks, who have a substantially higher risk of subarachnoid hemorrhage (SAH) and ICH than whites of the same age. In the Atherosclerosis Risk in Communities (ARIC) study, blacks had an incidence of all stroke types that was 38% (95% confidence

interval [CI], 1.01–1.89) higher than that of whites. American Indians have an incidence rate for stroke of 679 per 100,000 person-years, which is high relative to non-Hispanic whites. It remains unclear whether these racial differences are genetic, environmental, or an interaction between the two.

### Genetic Factors

A metaanalysis of cohort studies showed that a positive family history of stroke increases the risk of stroke by  $\approx 30\%$  (odds ratio [OR], 1.3; 95% CI, 1.2–1.5;  $P < .00001$ ). The Framingham study showed that a documented parental history of stroke before age 65 years was associated with a 3-fold increase in the risk of stroke in offspring. The odds of both monozygotic twins having strokes are 1.65-fold higher than for dizygotic twins. Stroke heritability estimates vary with age, sex, and stroke subtype. Younger stroke patients are more likely to have a first-degree relative with stroke. Women with stroke are more likely than men to have a parental history of stroke.

Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy is characterized by subcortical infarcts, dementia, migraine headaches, and white matter changes that are readily apparent on brain MRI. Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy is caused by any one of a series of mutations in the *NOTCH3* gene. Genetic testing for *NOTCH3* mutations is available. Retinal vasculopathy with cerebral leukodystrophy is caused by mutation in the *TREX1* gene, a DNA exonuclease involved in the response to oxidative DNA damage. Mutations in the *COL4A1* gene can cause leukoaraiosis and microbleeds and can present with ischemic or hemorrhagic stroke or as the hereditary angiopathy with nephropathy, aneurysm, and muscle cramps syndrome.

Fabry disease is a rare inherited disorder that can also lead to ischemic stroke. It is caused by lysosomal  $\alpha$ -galactosidase A deficiency, which causes a progressive accumulation of globotriaosylceramide and related glycosphingolipids. Deposition affects mostly small vessels in the brain and other organs, although involvement of the larger vessels has been reported. Enzyme replacement therapy appears to improve cerebral vessel function. Two prospective, randomized studies using human recombinant lysosomal  $\alpha$ -galactosidase A found a reduction in microvascular deposits and reduced plasma levels of globotriaosylceramide. These studies had short follow-up periods, and no reduction in stroke incidence was found. Agalsidase- $\alpha$  and agalsidase- $\beta$  given at the same dose of 0.2 mg/kg have similar short-term effects in reducing left ventricular mass.

Many coagulopathies are inherited as autosomal-dominant traits. These disorders, including protein C and S deficiencies, the factor V Leiden mutation, and various other factor deficiencies, can lead to an increased risk of cerebral venous thrombosis. As discussed later, there has not been a strong association between several of these disorders and

arterial events such as myocardial infarction (MI) and ischemic stroke. Some apparently acquired coagulopathies such as the presence of a lupus anticoagulant or anticardiolipin antibody (aCL) can be familial in  $\approx 10\%$  of cases. Inherited disorders of various clotting factors (i.e., factors V, VII, X, XI, and XIII) are autosomal-recessive traits and can lead to cerebral hemorrhage in infancy and childhood. Arterial dissections, Moyamoya syndrome, and fibromuscular dysplasia have a familial component in 10% to 20% of cases.

Intracranial aneurysms are a feature of certain mendelian disorders, including autosomal-dominant polycystic kidney disease and Ehlers-Danlos type IV syndrome (so-called vascular Ehlers-Danlos). Intracranial aneurysms occur in  $\approx 8\%$  of individuals with autosomal-dominant polycystic kidney disease and 7% with cervical fibromuscular dysplasia. Ehlers-Danlos type IV is associated with dissection of vertebral and carotid arteries, carotid-cavernous fistulas, and intracranial aneurysms.

Loss-of-function mutations in *KRIT1*, malcavernin, and *PDCD10* genes cause cerebral cavernous malformation syndromes CCM1, CCM2, and CCM3, respectively. Mutations in the amyloid precursor protein gene, cystatin C, gelsolin, and *BRI2* can cause inherited cerebral amyloid angiopathy syndromes.

### Genetic Factors: Recommendations

1. Obtaining a family history can be useful in identifying people who may have increased stroke risk.
2. Referral for genetic counseling may be considered for patients with rare genetic causes of stroke.
3. Treatment of Fabry disease with enzyme replacement therapy might be considered but has not been shown to reduce the risk of stroke, and its effectiveness is unknown.
4. Noninvasive screening for unruptured intracranial aneurysms in patients with two or more first-degree relatives with SAH or intracranial aneurysms might be reasonable.
5. Noninvasive screening may be considered for unruptured intracranial aneurysms in patients with autosomal-dominant polycystic kidney disease and one or more relatives with autosomal-dominant polycystic kidney disease and SAH or one or more relatives with autosomal-dominant polycystic kidney disease and intracranial aneurysm.
6. Noninvasive screening for unruptured intracranial aneurysms in patients with cervical fibromuscular dysplasia may be considered.
7. Pharmacogenetic dosing of vitamin K antagonists may be considered when therapy is initiated.
8. Noninvasive screening for unruptured intracranial aneurysms in patients with no more than one relative with SAH or intracranial aneurysms is not recommended.
9. Screening for intracranial aneurysms in every carrier of autosomal-dominant polycystic kidney disease or Ehlers-Danlos type IV mutations is not recommended.

10. Genetic screening of the general population for the prevention of a first stroke is not recommended.
11. Genetic screening to determine risk for myopathy is not recommended when initiation of statin therapy is being considered.

## Well-Documented and Modifiable Risk Factors

### Physical Inactivity

Physical inactivity is associated with numerous adverse health effects, including an increased risk of total mortality, cardiovascular morbidity and mortality, and stroke. The 2008 physical activity guidelines for Americans provide an extensive review and conclude that physically active men and women generally have a 25% to 30% lower risk of stroke or mortality than the least active. Two metaanalyses of physical activity reached the same conclusion. The benefits appear to occur from a variety of activities, including leisure-time physical activity, occupational activity, and walking. Overall, the relationship between activity and stroke is not influenced by age or sex, but some data suggest linkages between these factors and activity levels.

The relationship between the amount or intensity of physical activity and stroke risk remains unsettled and includes the possibility of a sex interaction. One study suggested an increasing benefit with greater intensity in women (median relative risk [RR], 0.82 for all strokes for moderate intensity vs. no or light activity; RR, 0.72 for high intensity vs. no or light activity). In men, there was no apparent benefit of higher intensity (median RR, 0.65 for moderate intensity vs. no or light activity; RR, 0.72 for high intensity vs. no or light activity). In contrast, the prospective Northern Manhattan Study (NOMAS) suggested that moderate- to high-intensity physical activity was protective against risk of ischemic stroke in men (hazard ratio [HR], 0.37; 95% CI, 0.18–0.78) but not women (HR, 0.93; 95% CI, 0.57–1.50). Increased physical activity has also been associated with a lower prevalence of brain infarcts. Vigorous physical activity, regardless of sex, was associated with a decreased incidence of stroke in the National Runners' Health Study.

The protective effect of physical activity may be partly mediated through its role in reducing blood pressure (BP) and controlling other risk factors for cardiovascular disease (CVD), including diabetes mellitus and excess body weight. Physical activity also reduces plasma fibrinogen and platelet activity and elevates plasma tissue plasminogen activator activity and high-density lipoprotein (HDL) cholesterol concentration. Physical activity may also exert positive health effects by increasing circulating antiinflammatory cytokines, including interleukin-1 receptor antagonist and interleukin-10, and modulating immune function in additional ways.

### Physical Inactivity: Recommendations

1. Physical activity is recommended because it is associated with a reduction in the risk of stroke.
2. Healthy adults should perform at least moderate- to vigorous-intensity aerobic physical activity at least 40 minutes per day, 3 to 4 days per week.

### Dyslipidemia

#### Total Cholesterol

Most studies have found high total cholesterol to be a risk factor for ischemic stroke. In the Multiple Risk Factor Intervention Trial (MRFIT), comprising >350,000 men, the RR of death resulting from nonhemorrhagic stroke increased progressively with each higher level of cholesterol. In the Alpha-Tocopherol Beta-Carotene Cancer Prevention (ATBC) study, which included >28,000 cigarette-smoking men, the risk of cerebral infarction was increased among those with total cholesterol levels of  $\geq 7$  mmol/L ( $\geq 271$  mg/dL). In the Asia Pacific Cohort Studies Collaboration (APCSC), which included 352,033 individuals, there was a 25% (95% CI, 13–40) increase in ischemic stroke rates for every 1-mmol/L (38.7 mg/dL) increase in total cholesterol. In the Women's Pooling Project, which included 24,343 US women age <55 years with no previous CVD, and in the Women's Health Study (WHS), a prospective cohort study of 27,937 US women age  $\geq 45$  years, higher cholesterol levels were also associated with increased risk of ischemic stroke. In other studies, the association between cholesterol and stroke was less clear. In the ARIC study, including 14,175 middle-aged men and women free of clinical CVD, the relationships between lipid values and incident ischemic stroke were weak.

Given the complex relationship between total cholesterol and stroke, it is noteworthy that there appears to be no positive association between total cholesterol and stroke mortality.

#### High-Density Lipoprotein Cholesterol

Some epidemiologic studies have shown an inverse relationship between HDL cholesterol and risk of stroke, whereas others have not. The Emerging Risk Factors Collaboration performed a metaanalysis involving individual records on 302,430 people without vascular disease from 68 long-term prospective studies. Collectively, there were 2.79 million person-years of follow-up. The aggregated data set included 2534 ischemic strokes, 513 hemorrhagic strokes, and 2536 unclassified strokes. The analysis adjusted for risk factors other than lipid levels and corrected for regression dilution. The adjusted HRs were 0.93 (95% CI, 0.84–1.02) for ischemic stroke, 1.09 (95% CI, 0.92–1.29) for hemorrhagic stroke, and 0.87 (95% CI, 0.80–0.94) for unclassified stroke. There was modest heterogeneity among studies of ischemic stroke ( $I^2 = 27\%$ ). The absence of an association between HDL and ischemic stroke and between HDL and hemorrhagic stroke contrasts with the clear inverse association between HDL cholesterol and coronary heart disease observed in the same metaanalysis.

## Triglycerides

Epidemiologic studies that have evaluated the relationship between triglycerides and ischemic stroke have been inconsistent, in part because some have used fasting and others used nonfasting levels. Fasting triglyceride levels were not associated with ischemic stroke in ARIC. Triglycerides did not predict the risk of ischemic stroke among healthy men enrolled in the Physicians' Health Study. Similarly, in the Oslo study of healthy men, triglycerides were not related to the risk of stroke. In contrast, a metaanalysis of prospective studies conducted in the Asia-Pacific region found a 50% increased risk of ischemic stroke among those in the highest quintile of fasting triglycerides compared with those in the lowest quintile. The Copenhagen City Heart Study, a prospective, population-based cohort study comprising  $\approx 14,000$  people, found that elevated nonfasting triglyceride levels increased the risk of ischemic stroke in both men and women. After multivariate adjustment, there was a 15% (95% CI, 9–22) increase in the risk of ischemic stroke for each 89-mg/dL increase in nonfasting triglycerides. HRs for ischemic stroke among men and women with the highest ( $\geq 443$  mg/dL) compared with the lowest ( $< 89$  mg/dL) nonfasting triglyceride levels were 2.5 (95% CI, 1.3–4.8) and 3.8 (95% CI, 1.3–11), respectively. The 10-year risks of ischemic stroke were 16.7% and 12.2%, respectively, in men and women age  $\geq 55$  years with triglyceride levels of  $\geq 443$  mg/dL. Similarly, the WHS found that in models adjusted for total and HDL cholesterol and measures of insulin resistance, nonfasting triglycerides, but not fasting triglycerides, were associated with cardiovascular events, including ischemic stroke. A metaanalysis of 64 randomized clinical trials that tested lipid-modifying drugs found an adjusted RR of stroke of 1.05 (95% CI, 1.03–1.07) for each 10-mg/dL increase in baseline triglycerides, although fasting status is not specified. In the Emerging Risk Factors Collaboration metaanalysis, triglyceride levels were not associated with either ischemic or hemorrhagic stroke risk, and determination of fasting status did not appear to change the lack of association.

## Treatment of Dyslipidemia

Treatment with statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors) reduces the risk of stroke in patients with or at high risk for atherosclerosis. One metaanalysis of 26 trials that included  $> 90,000$  patients found that statins reduced the risk of all strokes by  $\approx 21\%$  (95% CI, 15–27). Baseline mean low-density lipoprotein (LDL) cholesterol in the studies ranged from 124 to 188 mg/dL and averaged 149 mg/dL. The risk of all strokes was estimated to decrease by 15.6% (95% CI, 6.7–23.6) for each 10% reduction in LDL cholesterol. Another metaanalysis of randomized trials of statins in combination with other preventive strategies that included 165,792 individuals showed that each 1-mmol/L (39-mg/dL) decrease in LDL cholesterol was associated with a 21.1% (95% CI, 6.3–33.5;  $P = .009$ ) reduction in stroke. Several metaanalyses also found that beneficial effects are greater with greater lipid lowering.

One metaanalysis of seven randomized, controlled trials of primary and secondary prevention reported that more-intensive statin therapy that achieved an LDL cholesterol of 55 to 80 mg/dL resulted in a lower risk of stroke than less-intensive therapy that achieved an LDL cholesterol of 81 to 135 mg/dL (OR, 0.80; 95% CI, 0.71–0.89). Another metaanalysis of 10 randomized, controlled trials of patients with atherosclerosis and coronary artery disease reported a significant reduction in the composite of fatal and nonfatal strokes with higher versus lower statin doses (RR, 0.86; 95% CI, 0.77–0.96).

In addition, in Justification for the Use of statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER), statin treatment reduced the incidence of fatal and nonfatal stroke compared with placebo (HR, 0.52; 95% CI, 0.34–0.79) in healthy men and women with LDL cholesterol levels  $< 130$  mg/dL and high-sensitivity C-reactive protein (hs-CRP) levels  $\geq 2$  mg/L.

Concerns about lowering of LDL cholesterol by statin therapy increasing the risk of hemorrhagic stroke are not supported. One metaanalysis of 31 trials comparing statin therapy with a control reported that statin therapy decreased total stroke (OR, 0.84; 95% CI, 0.78–0.91) and found no difference in the incidence of ICH (OR, 1.08; 95% CI, 0.88–1.32). These findings are consistent with another metaanalysis that included 23 randomized trials and found that statins were not associated with an increased risk of ICH (RR, 1.10; 95% CI, 0.86–1.41). The intensity of cholesterol lowering did not correlate with risk of ICH.

The beneficial effect of statins on ischemic stroke is most likely related to their capacity to reduce progression or to induce regression of atherosclerosis. Metaanalyses of statin trials found that statin therapy slows the progression of carotid intima-media thickness (IMT) and that the magnitude of LDL cholesterol reduction correlates inversely with the progression of carotid IMT.

Statins should be prescribed in accordance with the 2013 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults. These guidelines represent a dramatic shift away from specific LDL cholesterol targets. Instead, the guidelines call for estimating the 10-year risk for atherosclerotic CVD and, based on the estimated risk, prescribing a statin at low, moderate, or high intensity. The intensity of statin therapy depends on the drug and the dose. For example, lovastatin at 20 mg/day is considered low-intensity therapy, and lovastatin at 40 mg/day is considered moderate-intensity therapy. Atorvastatin at 10 mg/day is considered moderate-intensity therapy, and atorvastatin at 80 mg/day is considered high-intensity therapy. A cardiovascular risk calculator to assist in estimating 10-year risk can be found online at <http://my.americanheart.org/cvriskcalculator>. Although the new guidelines shift focus away from specific lipid targets, values for total cholesterol and HDL are incorporated into the cardiovascular risk calculator, along with age, sex, race, systolic blood pressure (SBP), hypertension treatment, diabetes mellitus, and cigarette smoking.

The benefits of lipid-modifying therapies other than statins on the risk of ischemic stroke are not established. A metaanalysis of 78 lipid-lowering trials involving 266,973 patients reported that statins decreased the risk of total stroke (OR, 0.85; 95% CI, 0.78–0.92), whereas the benefits of other lipid-lowering interventions were not significant, including diet (OR, 0.92; 95% CI, 0.69–1.23), fibrates (OR, 0.98; 95% CI, 0.86–1.12), and other treatments (OR, 0.81; 95% CI, 0.61–1.08). Reduction in the risk of stroke is proportional to the reduction in total and LDL cholesterol; each 1% reduction in total cholesterol is associated with a 0.8% reduction in the risk of stroke. Similarly, another metaanalysis of 64 randomized, controlled trials reported that treatment-related decreases in LDL cholesterol were associated with decreases in all strokes (RR reduction, 4.5% per 10-mg/dL reduction; 95% CI, 1.7–7.2); however, there was no relationship between triglycerides and stroke.

Niacin increases HDL cholesterol and decreases plasma levels of lipoprotein(a) [Lp(a)]. The Coronary Drug Project found that treatment with niacin reduced mortality in men with prior MI. In the Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) study of patients with established CVD, the addition of extended-release niacin to intensive simvastatin therapy did not reduce the risk of a composite of cardiovascular events, which included ischemic stroke. In a metaanalysis of 11 studies comprising 9959 subjects, niacin use was associated with a significant reduction in cardiovascular events, including a composite of cardiac death, nonfatal MI, hospitalization for acute coronary syndrome, stroke, or revascularization procedure (OR, 0.66; 95% CI, 0.49–0.89). There was an association between niacin therapy and coronary heart disease event (OR, 0.75; 95% CI, 0.59–0.96) but not with the incidence of stroke (OR, 0.88; 95% CI, 0.5–1.54). However, there are serious safety concerns about niacin therapy. The Heart Protection Study 2—Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) trial involving 25,693 patients at high risk for vascular disease showed that extended-release niacin with laropiprant (a prostaglandin D2 signal blocker) caused a significant 4-fold increase in the risk of myopathy in patients taking simvastatin.

Fibric acid derivatives such as gemfibrozil, fenofibrate, and bezafibrate lower triglyceride levels and increase HDL cholesterol. The Bezafibrate Infarction Prevention study, which included patients with prior MI or stable angina and HDL cholesterol  $\leq 45$  mg/dL, found that bezafibrate did not significantly decrease either the risk of MI or sudden death (primary endpoint) or stroke (secondary endpoint). The Veterans Administration HDL Intervention Trial of men with coronary artery disease and low HDL cholesterol found that gemfibrozil reduced the risk of all strokes, primarily ischemic strokes. In the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, fenofibrate neither decreased the composite primary endpoint of coronary heart disease death or nonfatal MI nor decreased the risk

of stroke. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study of patients with type 2 diabetes mellitus, adding fenofibrate to simvastatin did not reduce fatal cardiovascular events, nonfatal MI, or nonfatal stroke compared with simvastatin alone. A metaanalysis of 18 trials found that fibrate therapy produced a 10% (95% CI, 0–18) relative reduction in the risk for major cardiovascular events but no benefit on the risk of stroke (RR reduction, –3%; 95% CI, –16 to 9).

Ezetimibe lowers blood cholesterol by reducing intestinal absorption of cholesterol. In a study of familial hypercholesterolemia, adding ezetimibe to simvastatin did not affect the progression of carotid IMT more than simvastatin alone. In another trial of subjects receiving a statin, niacin led to greater reductions in mean carotid IMT than ezetimibe over 14 months ( $P = .003$ ). Counterintuitively, patients receiving ezetimibe who had greater reductions in the LDL cholesterol had an increase in the carotid IMT ( $r = -0.31$ ;  $P < .001$ ). The rate of major cardiovascular events was lower in those randomized to niacin (1% vs. 5%;  $P = .04$ ). Stroke events were not reported. A clinical outcome trial comparing ezetimibe and simvastatin with simvastatin alone on cardiovascular outcomes is in progress. Ezetimibe has not been shown to decrease cardiovascular events or stroke.

### Dyslipidemia: Recommendations

1. In addition to therapeutic lifestyle changes, treatment with a hydroxymethylglutaryl coenzyme-A reductase inhibitor (statin) medication is recommended for the primary prevention of ischemic stroke in patients estimated to have a high 10-year risk for cardiovascular events as recommended in the 2013 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults.
2. Niacin may be considered for patients with low HDL cholesterol or elevated Lp(a), but its efficacy in preventing ischemic stroke in patients with these conditions is not established. Caution should be used with niacin because it increases the risk of myopathy.
3. Fibric acid derivatives may be considered for patients with hypertriglyceridemia, but their efficacy in preventing ischemic stroke is not established.
4. Treatment with nonstatin lipid-lowering therapies such as fibric acid derivatives, bile acid sequestrants, niacin, and ezetimibe may be considered in patients who cannot tolerate statins, but their efficacy in preventing stroke is not established.

### Diet and Nutrition

A large and diverse body of evidence has implicated several aspects of diet in the pathogenesis of high BP, the major modifiable risk factor for ischemic stroke. A scientific statement from the AHA concluded that several aspects of diet lead to elevated BP. Specifically, dietary risk factors that are causally related to elevated BP include excessive salt intake, low potassium intake, excessive weight, high alcohol

consumption, and suboptimal dietary pattern. Blacks are especially sensitive to the BP-raising effects of high salt intake, low potassium intake, and suboptimal diet. In this setting, dietary changes have the potential to substantially reduce racial disparities in BP and stroke.

Nutrition science is generally limited because randomized trials involving long-term follow-up are challenging to conduct. Nutritional epidemiology faces challenges of measurement error, confounders, variable effects of food items, variable reference groups, interactions, and multiple testing. Keeping these limitations in mind, it is worth noting that several aspects of diet have been associated with stroke risk. A metaanalysis found a strong inverse relationship between servings of fruits and vegetables and subsequent stroke. Compared with individuals who consumed <3 servings per day, the RR of ischemic stroke was less in those who consumed 3 to 5 servings per day (RR, 0.88; 95% CI, 0.79–0.98) and in those who consumed >5 servings per day (RR, 0.72; 95% CI, 0.66–0.79). The dose-response relationship extends into the higher ranges of intake. Specifically, in analyses of the Nurses' Health Study and the Health Professionals' Follow-Up Study, the RR of incident stroke was 0.69 (95% CI, 0.52–0.92) for people in the highest versus lowest quintile of fruit and vegetable intake. Median intake in the highest quintile was 10.2 servings of fruits and vegetables in men and 9.2 in women. For each serving-per-day increase in fruit and vegetable intake, the risk of stroke was reduced by 6% (95% CI, 1–10). A subsequent analysis of the Nurses' Health Study showed that increased intake of flavonoids, primarily from citrus fruits, was associated with a reduced risk of ischemic stroke (RR, 0.81; 95% CI, 0.66–0.99;  $P = .04$ ). As highlighted in the 2010 US Dietary Guidelines, most Americans obtain only 64% and 50% of the recommended daily consumption of vegetables and fruits, respectively.

A randomized, controlled trial of the Mediterranean diet performed in 7447 individuals at high cardiovascular risk showed that those on an energy-unrestricted Mediterranean diet supplemented by nuts (walnuts, hazelnuts, and almonds) had a lower risk of stroke than people on a control diet (3.1 vs. 5.9 strokes per 1000 person-years;  $P = .003$ ) and that those on an energy-unrestricted Mediterranean diet supplemented by extra virgin olive oil had a lower risk of stroke than people on a control diet (4.1 strokes per 1000 person-years;  $P = .03$ ).

In ecologic studies, prospective studies, and metaanalyses, a higher level of sodium intake was associated with an increased risk of stroke. In prospective studies, a higher level of potassium intake was also associated with a reduced risk of stroke. It should be emphasized that a plethora of methodologic limitations, particularly difficulties in estimating dietary electrolyte intake, hinder risk assessment and may lead to false-negative or even paradoxical results in observational studies.

One trial tested the effects of replacing regular salt (sodium chloride) with a potassium-enriched salt in elderly Taiwanese men. In addition to increased overall survivorship

and reduced costs, the potassium-enriched salt reduced the risk of mortality from cerebrovascular disease (RR, 0.50). This trial did not present follow-up BP measurements; hence, it is unclear whether BP reduction accounted for the beneficial effects of the intervention. In contrast, in the Women's Health Initiative, a low-fat diet that emphasized consumption of whole grains, fruits, and vegetables did not reduce stroke incidence; however, the intervention did not achieve a substantial increase in fruit and vegetable consumption (mean difference, only 1.1 servings per day) or decrease in BP (mean difference, <0.5 mm Hg for both SBP and diastolic blood pressure [DBP]).

The effects of sodium and potassium on stroke risk are likely mediated through direct effects on BP and effects independent of BP. In clinical trials, particularly dose-response studies, the relationship between sodium intake and BP is direct and progressive, without an apparent threshold. Blacks, hypertensives, and middle-aged and older adults are especially sensitive to the BP-lowering effects of a reduced sodium intake. In other trials, an increased intake of potassium was shown to lower BP and to blunt the pressor effects of sodium. Diets rich in fruits and vegetables, including those based on the dietary approaches to stop hypertension (DASH) diet (rich in fruits, vegetables, and low-fat dairy products and reduced in saturated and total fat), lower BP. As documented in a study by the Institute of Medicine, sodium intake remains high and potassium intake quite low in the United States.

Other dietary factors may affect the risk of stroke, but the evidence is insufficient to make specific recommendations. In Asian countries, a low intake of animal protein, saturated fat, and cholesterol has been associated with a decreased risk of stroke, but such relationships have been less apparent in Western countries. A recent prospective study showed that higher intake of red meat was associated with a higher risk of stroke, but a higher intake of poultry was associated with a lower risk of stroke. In addition, a metaanalysis of prospective studies concluded that intake of fresh, processed, and total red meat is associated with an increased risk of ischemic stroke. Potentially, the source of dietary protein may affect stroke risk. In the absence of a clinical syndrome of a specific vitamin or nutrient deficiency, there is no conclusive evidence that vitamins or other supplements prevent incident stroke.

### **Diet and Nutrition: Recommendations**

1. Reduced intake of sodium and increased intake of potassium as indicated in the US Dietary Guidelines for Americans are recommended to lower BP.
2. A DASH-style diet, which emphasizes fruits, vegetables, and low-fat dairy products and reduced saturated fat, is recommended to lower BP.
3. A diet that is rich in fruits and vegetables and thereby high in potassium is beneficial and may lower the risk of stroke.
4. A Mediterranean diet supplemented with nuts may be considered in lowering the risk of stroke.

## Hypertension

The Seventh Joint National Committee defined hypertension as SBP >140 mm Hg and DBP >90 mm Hg. The most recent panel appointed by the National Heart, Lung, and Blood Institute to review hypertension management guidelines was silent on the issue of defining hypertension but chose instead to focus on defining BP thresholds for initiating or modifying therapy. Hypertension is a major risk factor for both cerebral infarction and ICH. The relationship between BP and stroke risk is strong, continuous, graded, consistent, independent, predictive, and etiologically significant. Throughout the usual range of BPs, including the nonhypertensive range, the higher the BP, the greater the risk of stroke.

The prevalence of hypertension has plateaued over the past decade. On the basis of national survey data from 1999 to 2000 and 2007 to 2008, the prevalence of hypertension in the United States remained stable at 29%. Control has also improved over the past 25 years, with control rates of 27.3% measured in 1988 to 1994 and 50.1% measured in 2007 to 2008. The improved control is likely attributable to heightened awareness and treatment. Awareness of hypertension among US residents significantly increased from 69% in 1988 to 1994 to 81% in 2007 to 2008, and treatment improved from 54% to 73% over the same period. Despite the improvements, however, rates of control were lower among Hispanics compared with whites and among those age 18 to 39 years compared with older individuals.

BP, particularly SBP, rises with increasing age in both children and adults. Individuals who are normotensive at age 55 years have a 90% lifetime risk for developing hypertension. More than two-thirds of people age  $\geq 65$  years are hypertensive.

Because the risk of stroke increases progressively with increasing BP and because many individuals have a BP level below current drug treatment thresholds, nondrug or lifestyle approaches are recommended as a means of reducing BP in nonhypertensive individuals with an elevated BP (i.e., prehypertension: 120–139 mm Hg SBP or 80–89 mm Hg DBP). Pharmacologic treatment of prehypertension appears to reduce the risk of stroke. In a metaanalysis of 16 trials involving 70,664 prehypertensive patients, prehypertensive patients randomized to active antihypertensive treatment had a consistent and statistically significant 22% reduction in the risk of stroke compared with those taking placebo ( $P < .000001$ ).

Behavioral lifestyle changes are recommended by the Seventh Joint National Committee as part of a comprehensive treatment strategy for hypertension. Compelling evidence from >40 years of clinical trials has documented that drug treatment of hypertension prevents stroke and other BP-related target-organ damage, including heart failure, coronary heart disease, and renal failure. A metaanalysis of 23 randomized trials showed that antihypertensive drug treatment reduced the risk of stroke by 32% (95% CI, 24–39;  $P = .004$ ) compared with no drug treatment. The

use of antihypertensive therapies among those with mild hypertension (SBP, 140–159 mm Hg; DBP, 90–99 mm Hg; or both), however, was not clearly shown to reduce the risk of first stroke in a Cochrane Database Systematic Review, although a trend of clinically important magnitude was present (RR, 0.51; 95% CI, 0.24–1.08). Because 9% of patients stopped therapy as a result of side effects, the authors recommended further trials be conducted.

Several trials have addressed the potential role of antihypertensive treatment among patients with prevalent CVD but without hypertension. In a metaanalysis of 25 trials of antihypertensive therapy for patients with prevalent CVD (including stroke) but without hypertension, patients receiving antihypertensive medications had a pooled RR for stroke of 0.77 (95% CI, 0.61–0.98) compared with control subjects. The magnitude of the RR reduction was greater for stroke than for most other cardiovascular outcomes, although the absolute risk reductions were greater for other outcomes because of their greater relative frequency.

In a separate metaanalysis of 13 trials involving 80,594 individuals, among those either with prevalent atherosclerotic disease or at high risk for developing it, angiotensin-converting enzyme (ACE) inhibitors (ACEIs) or angiotensin receptor blocker (ARB) therapy reduced the risk of a composite primary outcome including stroke by 11%, without variability by baseline BP. There was also a significant reduction in fatal and nonfatal strokes (OR, 0.91; 95% CI, 0.86–0.97). Non-ACEI/ARB therapies were allowed, but metaregression analyses provided evidence that the benefits were not solely because of BP reductions during the trial. Several other metaanalyses have evaluated whether specific classes of antihypertensive agents offer protection against stroke beyond their BP-lowering effects. In one of these metaanalyses evaluating different classes of agents used as first-line therapy in subjects with a baseline BP >140/90 mm Hg, thiazide diuretics (RR, 0.63; 95% CI, 0.57–0.71),  $\beta$ -blockers (RR, 0.83; 95% CI, 0.72–0.97), ACEIs (RR, 0.65; 95% CI, 0.52–0.82), and calcium channel blockers (CCBs) (RR, 0.58; 95% CI, 0.41–0.84) each reduced the risk of stroke compared with placebo or no treatment. Compared with thiazides,  $\beta$ -blockers, ACEIs, and ARBs, CCBs appear to have a slightly greater effect on reducing the risk of stroke, although the effect is not seen for other cardiovascular outcomes and was of small magnitude (8% relative reduction in risk). One metaanalysis found that diuretic therapy was superior to ACEI therapy, and another found that CCBs were superior to ACEIs. Another found that  $\beta$ -blockers were less effective in reducing stroke risk than CCBs (RR, 1.24; 95% CI, 1.11–1.40) or inhibitors of the renin-angiotensin system (RR, 1.30; 95% CI, 1.11–1.53). Subgroup analyses from one major trial suggest that the benefit of diuretic therapy over ACEI therapy is especially prominent in blacks, and subgroup analysis from another large trial found that  $\beta$ -blockers were significantly less effective than thiazide diuretics and ARBs at preventing stroke in those age  $\geq 65$  years than in younger patients. The results of a recent trial of the direct renin inhibitor aliskiren

in patients with type 2 diabetes mellitus plus chronic kidney disease or prevalent CVD did not find evidence that aliskiren reduced cardiovascular endpoints, including stroke. In general, therefore, although the benefits of lowering BP as a means to prevent stroke are undisputed, there is no definitive evidence that any particular class of antihypertensive agents offers special protection against stroke in all patients. Further hypothesis-driven trials are warranted, however, to test differences in efficacy of individual agents in specific subgroups of patients.

BP control can be achieved in most patients, but most patients require therapy with two or more drugs. In one open-label trial conducted in Japan, among patients taking a CCB who had not yet achieved a target BP, the addition of a thiazide diuretic significantly reduced the risk of stroke compared with the addition of either a  $\beta$ -blocker ( $P = .0109$ ) or an ARB ( $P = .0770$ ). The advantage of the combination of a CCB and thiazide was not seen, however, for other cardiovascular endpoints.

Metaanalyses support that more intensive control of BP (SBP  $<130$  mm Hg) reduces risk of stroke more than less intensive control (SBP, 130–139 mm Hg), although the effects on other outcomes and in all subgroups of patients remain unclear. Among 11 trials with 42,572 participants, the RR of stroke for those whose SBP was  $<130$  mm Hg was 0.80 (95% CI, 0.70–0.92). The effect was greater among those with cardiovascular risk factors but without established CVD. This benefit of intensive BP lowering may be more specific to stroke than to other cardiovascular outcomes, at least among certain subgroups of patients. Among patients with diabetes mellitus at high cardiovascular risk enrolled in the ACCORD Blood Pressure Trial, more intensive BP control (SBP  $<120$  mm Hg) compared with standard control ( $<140$  mm Hg) led to a significant reduction in risk of stroke, a prespecified secondary outcome (HR, 0.59; 95% CI, 0.39–0.89). However, there was no effect on either the primary composite outcome or overall mortality. This absence of benefit on nonstroke outcomes was not attributable to obesity because effects were similar across levels of obesity. A metaanalysis of 31 trials with 73,913 individuals with diabetes mellitus demonstrated that more intensive BP reduction significantly reduced the risk of stroke but not MI. For every 5-mm Hg reduction in SBP, the risk of stroke decreased by 13% (95% CI, 5–20). In a secondary analysis of the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) trial, however, among 9193 hypertensive patients with left ventricular hypertrophy by electrocardiogram (EKG) criteria, achieving intensive BP control to  $<130$  mm Hg was not associated with a reduction in stroke after multivariable adjustment, and there was a significant increase in all-cause mortality (HR, 1.37; 95% CI, 1.10–1.71). The target for BP reduction, therefore, may differ by patient characteristics and comorbidities.

Pharmacogenomics may contribute to improving individualized selection of antihypertensive medications for stroke prevention. For example, in genetic studies ancillary to the Antihypertensive and Lipid Lowering to Prevent

Heart Attack Trial (ALLHAT), individuals with the stromelysin (matrix metalloproteinase-3) genotype 6A/6A had higher stroke rates on lisinopril than on chlorthalidone, and those with the 5A/6A genotype had lower stroke rates on lisinopril. The 5A/5A homozygotes had the lowest stroke rates compared with those taking chlorthalidone (HR for interaction = 0.51; 95% CI, 0.31–0.85). The effect was not seen for other medications. Carriers of mutations of the fibrinogen- $\beta$  gene also had a lower risk of stroke on lisinopril compared with amlodipine than those who were homozygous for the usual allele, potentially because ACEIs lower fibrinogen levels, and this effect is more clinically important among those with mutations associated with higher fibrinogen levels. The role of genetic testing in hypertension management remains undefined at present, however.

Recent evidence suggests that intraindividual variability in BP may confer risk beyond that caused by mean elevations in BP alone. There is further observational evidence that CCBs may have benefits in reducing BP variability that are not present with  $\beta$ -blockers and that these benefits may provide additional benefits in stroke risk reduction. Twenty-four-hour ambulatory BP monitoring provides additional insight into risk of stroke and cardiovascular events. Measurements of nocturnal BP changes (“reverse dipping” or “extreme dipping”) and the ratio of nocturnal to daytime BPs may provide data about risk beyond that provided by mean 24-hour SBP. Further study of the benefits on stroke risk reduction of treatments focused on reducing intraindividual variability in BP and nocturnal BP changes seems warranted.

Controlling isolated systolic hypertension (SBP  $\geq 160$  mm Hg and DBP  $<90$  mm Hg) in the elderly is also important. The Systolic Hypertension in Europe (Syst-Eur) trial randomized 4695 patients with isolated systolic hypertension to active treatment with a CCB or placebo and found a 42% (95% CI, 18–60;  $P = .02$ ) risk reduction in the actively treated group. The Systolic Hypertension in the Elderly Program (SHEP) trial found a 36% reduction (95% CI, 18–50;  $P = .003$ ) in the incidence of stroke from a diuretic-based regimen. In the Hypertension in the Very Elderly (HYVET) trial, investigators randomized 3845 patients age  $\geq 80$  years with SBP  $\geq 160$  mm Hg to placebo or indapamide, with perindopril or placebo added as needed to target a BP  $<150/80$  mm Hg. After 2 years, there was a reduction in SBP of 15 mm Hg, associated with a 30% reduction in risk of stroke ( $P = .06$ ), a 39% reduction in fatal stroke ( $P = .046$ ), and a 21% reduction in overall mortality ( $P = .02$ ). No trial has focused on individuals with lesser degrees of isolated systolic hypertension (SBP = 140–159 mm Hg; DBP  $<90$  mm Hg).

The most recent National Heart, Lung, and Blood Institute-appointed panel provides an evidence-based approach to pharmacologic treatment of hypertension. The report focuses on age as a guide for therapeutic targets, with recommendations to lower BP pharmacologically to a target of  $<150/90$  mm Hg for patients age  $>60$  years and target a BP of  $<140/90$  mm Hg for younger patients. However, these recommendations differ from the 2014 science advisory on

high BP control endorsed by the AHA, ACC, and Centers for Disease Control and Prevention in which more aggressive BP targets are recommended (<140/90 mm Hg) regardless of age. There is concern that raising the SBP threshold from 140 to 150 mm Hg might reverse some of the gains that have been achieved in reducing stroke by tighter BP control. For patients with diabetes mellitus who are age  $\geq 18$  years, the panel originally appointed by the National Heart, Lung, and Blood Institute to review the evidence on treatment of hypertension recommends initiating pharmacologic treatment to lower BP at SBP of  $\geq 140$  mm Hg or DBP of  $\geq 90$  mm Hg and to treat to a goal SBP of <140 mm Hg and a goal DBP <90 mm Hg.

The International Society on Hypertension in Blacks revised its recommendations for managing BP in this at-risk population in 2010. In the absence of target-organ damage, the target should be <135/85 mm Hg; in the presence of target-organ damage, the target should be <130/80 mm Hg. For patients who are within 10 mm Hg above target, monotherapy with diuretic or CCB is preferred, and for patients >15/10 mm Hg above target, two-drug therapy is preferred either with a CCB plus renin-angiotensin system blocker or, in edematous or volume-overloaded states, with a thiazide diuretic plus a renin-angiotensin system blocker. Largely on the basis of a prespecified subgroup analysis of the ALLHAT trial, the National Heart, Lung, and Blood Institute panel originally appointed to address hypertension management recommends that in the general black population, including those with diabetes mellitus, initial antihypertensive therapy should include a thiazide-type diuretic or a CCB.

Population-wide approaches to reducing BP have also been advocated as more effective than approaches focused on screening individual patients for the presence of hypertension and treating them. Because the benefits of BP reduction can be seen across the range of measurements in the population, with and without preexisting CVD, it may be reasonable to provide BP-lowering medications to all patients above a certain age (e.g., age 60 years). Similarly, on the basis of observational data from 19 cohorts with 177,025 participants showing lower salt intake to be associated with a lower risk of stroke and other cardiovascular outcomes, population-wide reductions in salt intake may be advocated as a way to reduce stroke risk. Self-measured BP monitoring is recommended because with or without additional support such monitoring lowers BP compared with usual care.

### Hypertension: Recommendations

1. Regular BP screening and appropriate treatment of patients with hypertension, including lifestyle modification and pharmacologic therapy, are recommended.
2. Annual screening for high BP and health-promoting lifestyle modification are recommended for patients with prehypertension (SBP of 120 to 139 mm Hg or DBP of 80 to 89 mm Hg).
3. Patients who have hypertension should be treated with antihypertensive drugs to a target BP of <140/90 mm Hg.
4. Successful reduction of BP is more important in reducing stroke risk than the choice of a specific agent, and treatment should be individualized on the basis of other patient characteristics and medication tolerance.
5. Self-measured BP monitoring is recommended to improve BP control.

### Obesity and Body Fat Distribution

Stroke, along with hypertension, heart disease, and diabetes mellitus, is associated with being overweight or obese. The prevalence of obesity in the United States has tripled for children and doubled for adults since 1980. Only in the last 3 years has a leveling off been seen. Increasing public awareness and government initiatives have placed this public health issue in the forefront.

According to the National Center for Health Statistics data from the Department of Health and Human Services, in 2009 and 2010, the prevalence of obesity was 35.7% among adults and 16.9% among children, with a higher prevalence in adults age >60 years and adolescents. Among the race/ethnic groups surveyed in the United States, age-adjusted rates of obesity indicate the highest rates in non-Hispanic blacks (49.5%), followed by Mexican Americans (40.45%), and then all Hispanics (39.1%), with the lowest rate being among non-Hispanic whites (34.3%).

A patient's body mass index (BMI), defined as weight in kilograms divided by the square of the height in meters, is used to distinguish overweight (BMI, 25–29 kg/m<sup>2</sup>) from obesity (BMI >30 kg/m<sup>2</sup>) and morbid obesity (BMI >40 kg/m<sup>2</sup>). Men presenting with a waist circumference of >102 cm (40 in) and women with a waist circumference >88 cm (35 in) are categorized as having abdominal obesity. Abdominal obesity can also be measured as the waist-to-hip ratio. For every 0.01 increase in waist-to-hip ratio, there is a 5% increase in risk of CVD.

Abdominal body fat has proved to be a stronger predictor of stroke risk than BMI. In contrast, another study reported that in men only BMI was significantly associated with stroke, whereas for women it was waist-to-hip ratio. Adiposity, however, correlated with risk of ischemic heart disease for both sexes. When fat distribution measured by dual-energy x-ray absorptiometry in relation to incidence of stroke was studied, there was a significant association in both men and women between stroke and abdominal fat mass. This association, however, was not independent of diabetes mellitus, smoking, and hypertension.

Mounting evidence shows a graded positive relationship between stroke and obesity independent of age, lifestyle, or other cardiovascular risk factors. Prospective studies of the relationship between weight (or measures of adiposity) and incident stroke indicate that in the BMI range of 25 to 50 there was a 40% increased stroke mortality with each 5-kg/m<sup>2</sup> increase in BMI. However, in the BMI range of 15 to 24, there was no relationship between BMI and mortality.

A metaanalysis of data from 25 studies involving >2.2 million people and >30,000 events found an RR for

ischemic stroke of 1.22 (95% CI, 1.05–1.41) for overweight people and 1.64 (95% CI, 1.36–1.99) for obese people. For hemorrhagic stroke, the RR was 1.01 (95% CI, 0.88–1.17) for overweight people and 1.24 (95% CI, 0.99–1.54) for obese people. This metaanalysis showed an increased risk of ischemic stroke compared with normal-weight individuals of 22% in overweight individuals and 64% in obese individuals. When diabetes mellitus, hypertension, dyslipidemia, and other confounders were taken into account, there was no significant increase in the incidence of hemorrhagic stroke. These findings have been subsequently borne out in a Chinese study of 27,000 patients. In Japan, a metaanalysis of 44,000 patients found a positive correlation in both sexes of elevated BMI with both ischemic and hemorrhagic events. ARIC examined a population of 13,000 black and white participants and found that obesity was a risk factor for ischemic stroke independently of race. Adjustments for covariates in all these studies significantly reduced these associations.

The effects of stroke risk and weight reduction have not been studied extensively. A Swedish study that followed 4000 patients over 10 to 20 years, comparing individuals with weight loss through bariatric surgery and obese subjects receiving usual care, showed significant reductions in diabetes mellitus, MI, and stroke. Some 36,000 Swedish subjects followed for >13 years again showed a significant decrease in stroke incidence when more than three healthy lifestyle goals, including normal weight, were met. The Sibutramine Cardiovascular Outcomes (SCOUT) trial followed up 10,000 patients with CVD or type 2 diabetes mellitus and found that even modest weight loss reduced cardiovascular mortality in the following 4 to 5 years. Reduction in body weight improves control of hypertension. A metaanalysis of 25 trials showed mean SBP and DBP reductions of 4.4 and 3.6 mm Hg, respectively, with a 5.1-kg weight loss.

The US Preventive Services Task Force (USPSTF) currently recommends that all adults be screened for obesity and that patients with a BMI of  $\geq 30$  be referred for intensive multicomponent behavioral interventions for weight loss.

### Obesity and Body Fat Distribution: Recommendations

1. Among overweight (BMI = 25–29) and obese (BMI >30) individuals, weight reduction is recommended for lowering BP.
2. Among overweight (BMI = 25–29) and obese (BMI >30) individuals, weight reduction is recommended for reducing the risk of stroke.

### Diabetes Mellitus

People with diabetes mellitus have both an increased susceptibility to atherosclerosis and an increased prevalence of atherogenic risk factors, notably hypertension and abnormal blood lipids. In 2010 an estimated 20.7 million adults or 8.2% of adult Americans had diabetes mellitus. Moreover,

the prevalence of prediabetes among Americans age >65 years tested in 2005 through 2008 was estimated to be 50%.

Diabetes mellitus is an independent risk factor for stroke. Diabetes mellitus more than doubles the risk for stroke, and  $\approx 20\%$  of patients with diabetes mellitus will die of stroke. Duration of diabetes mellitus also increases the risk of non-hemorrhagic stroke (by 3% per year of diabetes duration). For those with prediabetes, fasting hyperglycemia is associated with stroke. In a study of 43,933 men (mean age,  $44.3 \pm 9.9$  years) free of known CVD and diabetes mellitus at baseline between 1971 and 2002, a total of 595 stroke events (156 fatal and 456 nonfatal strokes) occurred. Age-adjusted fatal, nonfatal, and total stroke event rates per 10,000 person-years for normal fasting plasma glucose (80–109 mg/dL), impaired fasting glucose (110–125 mg/dL), and undiagnosed diabetes mellitus ( $\geq 126$  mg/dL) were 2.1, 3.4, and 4.0 ( $P_{\text{trend}} = .002$ ); 10.3, 11.8, and 18.0 ( $P_{\text{trend}} = .008$ ); and 8.2, 9.6, and 12.4 ( $P_{\text{trend}} = .008$ ), respectively.

In the Greater Cincinnati/Northern Kentucky Stroke Study, ischemic stroke patients with diabetes mellitus were younger, more likely to be black, and more likely to have hypertension, MI, and high cholesterol than patients without diabetes mellitus. Age-specific incidence rates and rate ratios showed that diabetes mellitus increased ischemic stroke incidence for all ages but that the risk was most prominent before age 55 years in blacks and before age 65 years in whites. Although Mexican Americans had a substantially greater incidence rate for the combination of ischemic stroke and ICH than non-Hispanic whites, there is insufficient evidence that the presence of diabetes mellitus or other forms of glucose intolerance influenced this rate. In the Strong Heart Study (SHS), 6.8% of 4549 Native American participants age 45 to 74 years at baseline without prior stroke had a first stroke over 12 to 15 years, and diabetes mellitus and impaired glucose tolerance increased the HR to 2.05.

In NOMAS, which included 3298 stroke-free community residents, 572 reported a history of diabetes mellitus, and 59% ( $n = 338$ ) had elevated fasting blood glucose. Those subjects with an elevated fasting glucose had an increased stroke risk (HR, 2.7; 95% CI, 2.0–3.8), but those with a fasting blood glucose level of <126 mg/dL were not at increased risk.

Stroke risk can be reduced in patients with diabetes mellitus. In the Steno-2 Study, 160 patients with type 2 diabetes mellitus and persistent microalbuminuria were assigned to receive either intensive therapy, including behavioral risk factor modification and the use of a statin, an ACEI, an ARB, or an antiplatelet drug as appropriate, or conventional therapy with a mean treatment period of 7.8 years. Patients were subsequently followed up for an average of 5.5 years. The primary endpoint was time to death resulting from any cause. The risk of cardiovascular events was reduced by 60% (HR, 0.41; 95% CI, 0.25–0.67;  $P < .001$ ) with intensive versus conventional therapy, and strokes were reduced from 30 to 6. In addition, intensive therapy was associated with a 57% lower risk of death from cardiovascular causes (HR,

0.43; 95% CI, 0.19–0.94;  $P = .04$ ). Eighteen of the 30 strokes were fatal in the conventional group, and all 6 were fatal in the intensive group.

In the Euro Heart Survey on Diabetes and the Heart, 3488 patients were enrolled, 59% without and 41% with diabetes mellitus. Evidence-based medicine was defined as the combined use of renin-angiotensin-aldosterone system inhibitors,  $\beta$ -adrenergic receptor blockers, antiplatelet agents, and statins. In patients with diabetes mellitus, the use of evidence-based medicine (RR, 0.37; 95% CI, 0.20–0.67;  $P = .001$ ) had an independent protective effect on 1-year mortality and on cardiovascular events (RR, 0.61; 95% CI, 0.40–0.91;  $P = .015$ ) compared with those without diabetes mellitus. Although stroke rates were not changed, there was an  $\approx 50\%$  reduction in cerebrovascular revascularization procedures.

### Glycemic Control

The effect of previous randomization of the UK Prospective Diabetes Study (UKPDS) to either conventional therapy (dietary restriction) or intensive therapy (either sulfonylurea or insulin or, in overweight patients, metformin) for glucose control was assessed in an open-label extension study. In posttrial monitoring, 3277 patients were asked to attend UKPDS clinics annually for 5 years; however, there were no attempts to maintain their previously assigned therapies. A reduction in MI and all-cause mortality was found; however, stroke incidence was not affected by assignment to either sulfonylurea/insulin or metformin treatment.

Three major recent trials have evaluated the effects of reduced glycemia on CVD events in patients with type 2 diabetes mellitus. The ACCORD recruited 10,251 patients (mean age, 62 years) with a mean glycosylated hemoglobin of 8.1%. Participants were then randomized to receive intensive (glycosylated hemoglobin goal,  $<6.0\%$ ) or standard (goal, 7.0%–7.9%) therapy. The study was stopped earlier than planned because of an increase in all-cause mortality in the intensive therapy group with no difference in the numbers of fatal and nonfatal strokes. The Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) trial included 11,140 patients (mean age, 66.6 years) with type 2 diabetes mellitus and used a number of strategies to reduce glycemia in an intensive treatment group. Mean glycosylated hemoglobin levels were 6.5% versus 7.4% at 5 years, with no effect of more intensive therapy on the risk of CVD events or on the risk of nonfatal strokes between groups. In another study, 1791 US veterans (Veterans Affairs Diabetes Trial) with an average duration of diabetes mellitus of  $>10$  years (mean age, 60.4 years) were randomized to a regimen to decrease glycosylated hemoglobin by 1.5% or standard care. After 5.6 years, the mean levels of glycosylated hemoglobin were 6.9% versus 8.4%, with no difference in the number of macrovascular events, including stroke, between the two groups. From the available clinical trial results, there is no evidence that reduced glycemia decreases the short-term risk of macrovascular events, including stroke, in patients with type

2 diabetes mellitus. A glycosylated hemoglobin goal of  $<7\%$  has been recommended by the American Diabetes Association to prevent long-term microangiopathic complications in patients with type 2 diabetes mellitus. Whether or not control to this level also reduces the long-term risk of stroke requires further study. In patients with recent-onset type 1 diabetes mellitus, intensive diabetes therapy aimed at achieving near-normal glycemia can be accomplished with good adherence but with more frequent episodes of severe hypoglycemia. Although glycemia was similar between the groups over a mean 17 years of follow-up in the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) study, intensive treatment reduced the risk of any CVD event by 42% (95% CI, 9–63;  $P = .02$ ) and the combined risk nonfatal MI, stroke, or death from CVD events by 57% (95% CI, 12–79;  $P = .02$ ). The decrease in glycosylated hemoglobin was associated with the positive effects of intensive treatment on the overall risk of CVD. There were too few strokes, however, to evaluate the effect of improved glycemia during the trial, and, as with type 2 diabetes mellitus, there remains no evidence that tight glycemic control reduces risk of stroke.

Despite the lack of convincing support from any individual clinical trial for intensified glycemic control to reduce stroke incidence in patients with diabetes mellitus, a recent metaanalysis provided some supportive evidence in a subgroup of patients with diabetes mellitus. From 649 identified studies, the authors identified nine relevant trials, which provided data for 59,197 patients and 2037 stroke events. Overall, intensive control of glucose compared with usual care had no effect on incident stroke (RR, 0.96; 95% CI, 0.88–1.06;  $P = .445$ ); however, in a stratified analysis, a beneficial effect was seen in patients with diabetes mellitus and a BMI  $>30$  (RR, 0.86; 95% CI, 0.75–0.99;  $P = .041$ ).

### Diabetes Mellitus and Hypertension

More aggressive lowering of BP in patients with diabetes mellitus and hypertension reduces stroke incidence. In addition to comparing the effects of more intensive glycemic control and standard care on the complications of type 2 diabetes mellitus, the UKPDS found that tight BP control (mean BP, 144/82 mm Hg) resulted in a 44% reduction (95% CI, 11–65;  $P = .013$ ) in the risk of stroke compared with more liberal control (mean BP, 154/87 mm Hg). There was also a nonstatistically significant 22% (RR, 0.78; 95% CI, 0.45–1.34) risk reduction with antihypertensive treatment in subjects with diabetes mellitus in SHEP. In UKPDS, 884 patients with type 2 diabetes mellitus who attended annual UKPDS clinics for 5 years after study completion were evaluated. Differences in BP between the two groups, standard of care and more aggressive BP lowering, disappeared within 2 years. There was a nonsignificant trend toward reduction in stroke with more intensive BP control (RR, 0.77; 95% CI, 0.55–1.07;  $P = .12$ ). Continued efforts to maintain BP targets might have led to maintenance of the benefit.

The Heart Outcomes Prevention Evaluation (HOPE) study compared the addition of an ACEI to the current medical regimen in high-risk patients. The substudy of 3577 patients with diabetes mellitus with a previous cardiovascular event or an additional cardiovascular risk factor (total population, 9541 participants) showed a reduction in the ACEI group in the primary combined outcome of MI, stroke, and cardiovascular death by 25% (95% CI, 12–36;  $P = .0004$ ) and stroke by 33% (95% CI, 10–50;  $P = .0074$ ). Whether or not these benefits represent a specific effect of the ACEI or were simply the result of BP lowering remains unclear. The LIFE study compared the effects of an ARB with a  $\beta$ -adrenergic receptor blocker in 9193 people with essential hypertension (160–200/95–115 mm Hg) and electrocardiographically determined left ventricular hypertrophy over 4 years. BP reductions were similar for each group. The two regimens were compared among the subgroup of 1195 people who also had diabetes mellitus in a prespecified analysis. There was a 24% reduction (RR, 0.76; 95% CI, 0.58–0.98) in major vascular events and a nonsignificant 21% reduction (RR, 0.79; 95% CI, 0.55–1.14) in stroke among those treated with the ARB.

The ADVANCE trial also determined whether a fixed combination of perindopril and indapamide or matching placebo in 11,140 patients with type 2 diabetes mellitus would decrease major macrovascular and microvascular events. After 4.3 years of follow-up, subjects assigned to the combination had a mean reduction in BP of 5.6/2.2 mm Hg. The risk of a composite of major macrovascular and microvascular events was reduced by 9% (HR, 0.91; 95% CI, 0.83–1;  $P = .04$ ), but there was no reduction in the incidence of major macrovascular events, including stroke.

In the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT), the effects of two antihypertensive treatment strategies (amlodipine with the addition of perindopril as required [amlodipine-based] or atenolol with addition of thiazide as required [atenolol-based]) for the prevention of major cardiovascular events were compared in 5137 patients with diabetes mellitus. The target BP was <130/80 mm Hg. The trial was terminated early because of reductions in mortality and stroke with the amlodipine-based regimen. In patients with diabetes mellitus, the amlodipine-based therapy reduced the incidence of total cardiovascular events and procedures compared with the atenolol-based regimen (HR, 0.86; 95% CI, 0.76–0.98;  $P = .026$ ), including a 25% reduction ( $P = .017$ ) in fatal and nonfatal strokes.

The open-label ACCORD trial randomized 4733 participants to one of two groups with different treatment goals: SBP <120 mm Hg as the more intensive goal and SBP <140 mm Hg as the less intensive goal. Randomization to the more intensive goal did not reduce the rate of the composite outcome of fatal and nonfatal major CVD events (HR, 0.88; 95% CI, 0.73–1.06;  $P = .20$ ). Stroke was a prespecified secondary endpoint occurring at annual rates of 0.32% (more intensive) and 0.53% (less intensive) treatment (HR, 0.59; 95% CI, 0.39–0.89;  $P = .01$ ).

In the Avoiding Cardiovascular Events in Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial, 11,506 patients (6746 with diabetes mellitus) with hypertension were randomized to treatment with benazepril plus amlodipine or benazepril plus hydrochlorothiazide. The primary endpoint was the composite of death resulting from CVD, nonfatal MI, nonfatal stroke, hospitalization for angina, resuscitated cardiac arrest, and coronary revascularization. The trial was terminated early after a mean follow-up of 36 months when there were 552 primary outcome events in the benazepril/amlodipine group (9.6%) and 679 in the benazepril/hydrochlorothiazide group (11.8%), an absolute risk reduction of 2.2% (HR, 0.80; 95% CI, 0.72–0.90;  $P < .001$ ). There was, however, no difference in stroke between the groups. Of the participants in the ACCOMPLISH trial with diabetes mellitus, the primary outcome results were similar.

Two recent metaanalyses investigated the effect of BP lowering in patients with type 2 diabetes mellitus. The first included 37,760 patients with type 2 diabetes mellitus or impaired fasting glucose/impaired glucose tolerance with achieved SBP of  $\leq 135$  versus  $\leq 140$  mm Hg, and the follow-up was at least 1 year. Intensive BP control was associated with a 10% reduction in all-cause mortality (OR, 0.90; 95% CI, 0.83–0.98) and a 17% reduction in stroke, but there was a 20% increase in serious adverse effects. Metaregression analysis showed continued risk reduction for stroke to a SBP of <120 mm Hg. However, at levels of <130 mm Hg, there was a 40% increase in serious adverse events with no benefit for other outcomes.

In the second metaanalysis, 73,913 patients with diabetes mellitus (295,652 patient-years of exposure) were randomized in 31 intervention trials. Overall, more aggressive treatment reduced stroke incidence by 9% ( $P = .006$ ), and lower versus less aggressive BP control reduced the risk of stroke by 31% (RR, 0.61; 95% CI, 0.48–0.79). In a metaregression analysis, the risk of stroke decreased by 13% (95% CI, 0.05–0.20;  $P = .002$ ) for each 5-mm Hg reduction in SBP and by 11.5% (95% CI, 0.05–0.17;  $P < .001$ ) for each 2-mm Hg reduction in DBP.

### Lipid-Altering Therapy and Diabetes Mellitus

Although secondary subgroup analyses of some studies did not find a benefit of statins in patients with diabetes mellitus, the Medical Research Council/British Heart Foundation Heart Protection Study (HPS) found that the addition of a statin to existing treatments in high-risk patients resulted in a 24% reduction (95% CI, 19–28) in the rate of major CVD events. A 22% reduction (95% CI, 13–30) in major vascular events (regardless of the presence of known coronary heart disease or cholesterol levels) and a 24% reduction (95% CI, 6–39;  $P = .01$ ) in strokes were found among 5963 diabetic individuals treated with the statin in addition to best medical care. The Collaborative Atorvastatin Diabetes Study (CARDS) reported that in patients with type 2 diabetes mellitus, at least one additional risk factor (retinopathy, albuminuria, current smoking, or hypertension) and an

LDL cholesterol level <160 mg/dL but without a history of CVD, treatment with a statin resulted in a 48% reduction (95% CI, 11–69) in stroke.

In a post hoc analysis of the Treating to New Targets (TNT) study, the effects of intensive lowering of LDL cholesterol with high-dose (80 mg daily) versus low-dose (10 mg daily) atorvastatin on CVD events were compared for patients with coronary heart disease and diabetes mellitus. After a median follow-up of 4.9 years, higher-dose treatment was associated with a 40% reduction in the time to a CVD event (HR, 0.69; 95% CI, 0.48–0.98;  $P = .037$ ).

Clinical trials with a statin or any other single intervention in patients with high CVD risk, including the presence of diabetes mellitus, are often insufficiently powered to determine an effect on incident stroke. In 2008 data from 18,686 individuals with diabetes mellitus (1466 with type 1 and 17,220 with type 2 diabetes mellitus) were assessed to determine the impact of a 1-mmol/L ( $\approx$ 40-mg/dL) reduction in LDL cholesterol. During a mean follow-up of 4.3 years, there were 3247 major cardiovascular events with a 9% proportional reduction in all-cause mortality per 1-mmol/L LDL cholesterol reduction (RR, 0.91; 95% CI, 0.82–1.01;  $P = .02$ ) and a 13% reduction in vascular death (RR, 0.87; 95% CI, 0.76–1.00;  $P = .008$ ). There were also reductions in MI or coronary death (RR, 0.78; 95% CI, 0.69–0.87;  $P < .0001$ ) and stroke (RR, 0.79; 95% CI, 0.67–0.93;  $P = .0002$ ). A subgroup analysis was carried out from the Department of Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT) in which subjects received either gemfibrozil (1200 mg/day) or placebo for 5.1 years. Compared with those with normal fasting plasma glucose, the risk for major cardiovascular events was higher in subjects with either known (HR, 1.87; 95% CI, 1.44–2.43;  $P = .001$ ) or newly diagnosed (HR, 1.72; 95% CI, 1.10–2.68;  $P = .02$ ) diabetes mellitus. Gemfibrozil treatment did not affect the risk of stroke among subjects without diabetes mellitus, but treatment was associated with a 40% reduction in stroke in those with diabetes mellitus (HR, 0.60; 95% CI, 0.37–0.99;  $P = .046$ ).

The FIELD study assessed the effect of fenofibrate on cardiovascular events in 9795 subjects age 50 to 75 years with type 2 diabetes mellitus who were not taking a statin therapy at study entry. The study population included 2131 people with and 7664 people without previous CVD. Over 5 years, 5.9% of patients ( $n = 288$ ) on placebo and 5.2% ( $n = 256$ ) on fenofibrate had a coronary event ( $P = .16$ ). There was a 24% (RR, 0.76; 95% CI, 0.62–0.94;  $P = .010$ ) reduction in nonfatal MI. There was no effect on stroke with fenofibrate. A higher rate of statin therapy initiation occurred in patients allocated to placebo, which might have masked a treatment effect. The ACCORD trial randomized 5518 patients with type 2 diabetes mellitus who were being treated with open-label simvastatin to double-blind treatment with fenofibrate or placebo. There was no effect of added fenofibrate on the primary outcome (first occurrence of nonfatal MI, nonfatal stroke, or death from cardiovascular causes [HR, 0.92; 95% CI, 0.79–1.08;  $P = .32$ ]) and

no effect on any secondary outcome, including stroke (HR, 1.05; 95% CI, 0.71–1.56;  $P = .80$ ).

A recent metaanalysis examining the effects of fibrates on stroke in 37,791 patients included some patients with diabetes mellitus. Overall, fibrate therapy was not associated with a significant reduction on the risk of stroke (RR, 1.02; 95% CI, 0.90–1.16;  $P = .78$ ). However, a subgroup analysis suggested that fibrate therapy reduced fatal stroke (RR, 0.49; 95% CI, 0.26–0.93;  $P = .03$ ) in patients with diabetes mellitus, CVD, or stroke.

### Diabetes Mellitus, Aspirin, and Stroke

The benefit of aspirin in the primary prevention of cardiovascular events, including stroke in patients with diabetes mellitus, remains unclear. A recent study at 163 institutions throughout Japan enrolled 2539 patients with type 2 diabetes mellitus and no history of atherosclerotic vascular disease. Patients were assigned to receive low-dose aspirin (81 or 100 mg/day) or no aspirin. Over 4.37 years, a total of 154 atherosclerotic vascular events occurred (68 in the aspirin group [13.6 per 1000 person-years] and 86 in the nonaspirin group [17.0 per 1000 person-years; HR, 0.80; 95% CI, 0.58–1.10;  $P = .16$ ]). Only a single fatal stroke occurred in the aspirin group, but five strokes occurred in the nonaspirin group; thus the study was insufficiently powered to detect an effect on stroke.

Several large primary prevention trials have included subgroup analyses of patients with diabetes mellitus. The Antithrombotic Trialists' Collaboration metaanalysis of 287 randomized trials reported effects of antiplatelet therapy (mainly aspirin) versus control in 135,000 patients. There was a nonsignificant 7% reduction in serious vascular events, including stroke, in the subgroup of 5126 patients with diabetes mellitus.

A metaanalysis covering the interval between 1950 and 2011 included seven studies in patients with diabetes mellitus without previous CVD and helps to shed new light on this controversial topic. A total of 11,618 participants were included in the analysis. The overall relative risk for major cardiovascular events was 0.91 (95% CI, 0.82–1.00), but an effect on stroke incidence was not found (RR, 0.84; 95% CI, 0.64–1.11). Because hyperglycemia reduces platelet sensitivity to aspirin, an important consideration in patients with diabetes mellitus is aspirin dose. In another metaanalysis, there was no evidence that aspirin dose explained the lack of an aspirin effect on cardiovascular and stroke mortality in patients with diabetes mellitus. However, the systematic review identified an important gap in randomized, controlled trials for using anywhere between 101 to 325 mg aspirin daily in patients with diabetes mellitus.

### Diabetes: Recommendations

1. Control of BP in accordance with an AHA/ACC/CDC Advisory to a target of <140/90 mm Hg is recommended in patients with type 1 or type 2 diabetes mellitus.
2. Treatment of adults with diabetes mellitus with a statin, especially those with additional risk factors, is recommended to lower the risk of first stroke.

3. The usefulness of aspirin for primary stroke prevention for patients with diabetes mellitus but low 10-year risk of CVD is unclear.
4. Adding a fibrate to a statin in people with diabetes mellitus is not useful for decreasing stroke risk.

### Cigarette Smoking

Virtually every multivariable assessment of stroke risk factors (e.g., Framingham, CHS, and the Honolulu Heart Study) has identified cigarette smoking as a potent risk factor for ischemic stroke, associated with an approximate doubling of risk. Data from studies largely conducted in older age groups also provide evidence of a dose-response relationship, and this has been extended to young women from an ethnically diverse cohort. Smoking is also associated with a 2-fold to 4-fold increased risk for SAH. The data for ICH (apart from SAH), however, are inconsistent. A multicenter case-control study found an adjusted OR of 1.58 (95% CI, 1.02–2.44) for ICH, and analyses from the Physicians' Health Study and WHS also found such an association, but other studies, including a pooled analysis of the ARIC and CHS cohorts, found no relationship between smoking and ICH risk. A metaanalysis of 32 studies estimated the RR for ischemic stroke to be 1.9 (95% CI, 1.7–2.2) for smokers versus nonsmokers, the RR for SAH to be 2.9 (95% CI, 2.5–3.5) and the RR for ICH to be 0.74 (95% CI, 0.56–0.98).

The annual number of stroke deaths attributed to smoking in the United States is estimated to be between 21,400 (without adjustment for potential confounding factors) and 17,800 (after adjustment), which suggests that smoking contributes to 12% to 14% of all stroke deaths. From data available from the National Health Interview Survey and death certificate data for 2000 through 2004, the Centers for Disease Control and Prevention estimated that smoking resulted in an annual average of 61,616 stroke deaths among men and 97,681 stroke deaths among women.

Cigarette smoking may potentiate the effects of other stroke risk factors, including SBP and oral contraceptives (OCs). For example, a synergistic effect exists between the use of OCs and smoking on the risk of cerebral infarction. With nonsmoking, non-OC users serving as the reference group, the odds of cerebral infarction were 1.3 times greater (95% CI, 0.7–2.1) for women who smoked but did not use OCs, 2.1 times greater (95% CI, 1.0–4.5) for nonsmoking OC users, and 7.2 times greater (95% CI, 3.2–16.1) for OC users who smoked. There was also a synergistic effect of smoking and OC use on hemorrhagic stroke risk. With nonsmoking, non-OC users as the reference group, the odds of hemorrhagic stroke were 1.6 times greater (95% CI, 1.2–2.0) for women who smoked but did not use OCs, 1.5 times greater (95% CI, 1.1–2.1) for nonsmoking OC users, and 3.7 times greater (95% CI, 2.4–5.7) for OC users who smoked.

Exposure to environmental tobacco smoke (also referred to as passive or second-hand smoke) is an established

risk factor for heart disease. Exposure to environmental tobacco smoke may also be a risk factor for stroke, with a risk approaching the doubling found for active smoking, although one study found no association. Because the dose of exposure to environmental tobacco smoke is substantially lower than for active smoking, the magnitude of the risk associated with environmental tobacco smoke is surprising. This apparent lack of a dose-response relationship may be explained in part by physiologic studies suggesting a tobacco smoke exposure threshold rather than a linear dose-response relationship. Recent studies of the effects of smoking bans in communities have also shown that these bans are associated with a reduction in the risk of stroke. After Arizona enacted a statewide ban on smoking in most indoor public places, including workspaces, restaurants, and bars, there was a 14% reduction in strokes in counties that had not previously had a ban in place. A study of New York State did not find a reduction in strokes despite a decrease in risk of MI when it enacted a comprehensive smoking ban in enclosed workspaces, restaurants, and construction sites.

Smoking likely contributes to increased stroke risk through both short-term effects on the risk of thrombus generation in atherosclerotic arteries and long-term effects related to increased atherosclerosis. Smoking as little as a single cigarette increases heart rate, mean BP, and cardiac index and decreases arterial distensibility. Beyond the immediate effects of smoking, both active and passive exposure to cigarette smoke is associated with the development of atherosclerosis. In addition to placing individuals at increased risk for both thrombotic and embolic stroke, cigarette smoking approximately triples the risk of cryptogenic stroke among individuals with a low atherosclerotic burden and no evidence of a cardiac source of emboli.

Although the most effective preventive measures are to never smoke and to minimize exposure to environmental tobacco smoke, risk is reduced with smoking cessation. Smoking cessation is associated with a rapid reduction in the risk of stroke and other cardiovascular events to a level that approaches, but does not reach, that of those who never smoked.

Although sustained smoking cessation is difficult to achieve, effective behavioral and pharmacologic treatments for nicotine dependence are available. Comprehensive reviews and recommendations for smoking cessation are provided in the 2008 Surgeon General's report, the 2008 update from the Public Health Service, and the 2009 affirmation of these recommendations from the USPSTF. The combination of counseling and medications is more effective than either therapy alone.

With regard to specific pharmacotherapy, in a metaanalysis current to January 2012, nicotine replacement therapy, bupropion, and varenicline were all superior to inert control medications, but varenicline was superior to each of the other active interventions in direct comparisons. Emerging evidence suggests that varenicline may be more cost effective than nicotine replacement therapy.

### Cigarette Smoking: Recommendations

1. Counseling, in combination with drug therapy using nicotine replacement, bupropion, or varenicline, is recommended for active smokers to assist in quitting smoking.
2. Abstinence from cigarette smoking is recommended for patients who have never smoked on the basis of epidemiologic studies showing a consistent and overwhelming relationship between smoking and both ischemic stroke and SAH.
3. Community-wide or statewide bans on smoking in public spaces are reasonable for reducing the risk of stroke and MI.

### Atrial Fibrillation

Atrial fibrillation (AF), even in the absence of cardiac valvular disease, is associated with a 4-fold to 5-fold increased risk of ischemic stroke resulting from embolism of stasis-induced thrombi forming in the left atrial appendage (LAA). About 2.3 million Americans have either sustained or paroxysmal AF. Embolism of appendage thrombi associated with AF accounts for  $\approx 10\%$  of all ischemic strokes and an even higher fraction in the very elderly in the United States. The absolute stroke rate averages  $\approx 3.5\%$  per year for 70-year-old individuals with AF, but the risk varies 20-fold among patients, depending on age and other clinical features (see later). AF is also an independent predictor of increased mortality. Paroxysmal AF increases stroke risk similar to sustained AF.

There is an important opportunity for primary stroke prevention in patients with AF because the dysrhythmia is diagnosed before stroke in many patients. However, a substantial minority of AF-related stroke occurs in patients without a prior diagnosis of the condition. Studies of active screening of patients age  $>65$  years for AF in primary care settings show that pulse assessment by trained personnel increases the detection of undiagnosed AF. Systematic pulse assessment during routine clinic visits followed by 12-lead EKG in those with an irregular pulse resulted in a 60% increase in the detection of AF.

### Risk Stratification in Patients With Atrial Fibrillation

Once the diagnosis of AF is established, the next step is to estimate an individual's risks for cardioembolic stroke and for hemorrhagic complications of antithrombotic therapy. For estimating risk of AF-related cardioembolic stroke, more than a dozen risk stratification schemes have been proposed on the basis of various combinations of clinical and echocardiographic predictors. The widely used CHADS<sub>2</sub> scheme yields a score of 0 to 6, with 1 point each given for congestive heart failure, hypertension, age  $\geq 75$  years, and diabetes mellitus and with 2 points given for prior stroke or transient ischemic attack (TIA).

This scheme has been tested in multiple independent cohorts of AF patients, with 0 points corresponding to low

risk (0.5%–1.7%), 1 point reflecting moderate risk (1.2%/year–2.2%/year), and  $\geq 2$  points indicating high risk (1.9%/year–7.6%/year). The CHA<sub>2</sub>DS<sub>2</sub>-VASc scheme modifies CHADS<sub>2</sub> by adding an age category (1 point for age 65 to 74 years, 2 points for age  $\geq 75$  years) and adding 1 point each for diagnosis of vascular disease (such as peripheral artery disease, MI, or aortic plaque) and for female sex. The main advantage of the more cumbersome CHA<sub>2</sub>DS<sub>2</sub>-VASc scheme for primary stroke prevention is improved stratification of individuals estimated to be at low-to-moderate risk using CHADS<sub>2</sub> (scores of 0 to 1). A study of 45,576 such patients found combined stroke and thromboembolism rates per 100 person-years ranging from 0.84 for CHADS<sub>2</sub> of 0 to 1 or CHA<sub>2</sub>DS<sub>2</sub>-VASc of 0 to 1.79, 3.67, 5.75, and 8.18 for CHA<sub>2</sub>DS<sub>2</sub>-VASc of 1, 2, 3, and 4, respectively, resulting in significantly improved prediction.

Instruments have also been proposed for stratifying risk of bleeding associated with warfarin treatment for AF. In the HAS-BLED scheme, 1 point is assigned each for hypertension, abnormal renal or liver function, past stroke, past bleeding history or predisposition, labile international normalized ratio (INR) (i.e., poor time in therapeutic range), older age (age  $>65$  years), and use of certain drugs (concomitant antiplatelet or nonsteroidal antiinflammatory agent use, alcohol abuse). In a validation analysis of data from 2293 subjects randomized to idraparinux or vitamin K antagonist therapy, the HAS-BLED score was moderately predictive (HAS-BLED  $>2$ : HR, 1.9 for clinically relevant bleeding; HR, 2.4 for major bleeding). The ATRIA Risk Score derived its point scheme from the Anticoagulation and Risk Factors in Atrial Fibrillation study, assigning 3 points for anemia or severe renal disease (estimated glomerular filtration rate  $<30$  mL/min or dialysis dependent), 2 for age  $\geq 75$  years, and 1 for any prior hemorrhage diagnosis or hypertension. Subjects in a validation cohort were successfully divided into groups at low (ATRIA score of 0 to 3,  $<1\%$ /year) and high (ATRIA score of 5 to 10,  $>5\%$ /year) risk for major hemorrhage. Most of these analyses stratifying risk of future bleeding have not focused on intracranial hemorrhages, the category of major bleeding with the greatest long-term effect on quality of life. Another limitation of prediction scales for hemorrhage is that several of their components such as age and hypertension are also risks for cardioembolic stroke.

### Selecting Treatment to Reduce Stroke Risk in Patients With Atrial Fibrillation

Adjusted-dose warfarin has generally been the treatment of choice for patients at high risk for cardioembolic stroke and acceptably low risk of hemorrhagic complications, particularly intracranial hemorrhage. Treatment with adjusted-dose warfarin (target INR, 2 to 3) robustly protects against stroke (RR reduction, 64%; 95% CI, 49–74), virtually eliminating the excess risk of ischemic stroke associated with AF if the intensity of anticoagulation is adequate and reducing all-cause mortality by 26% (95% CI, 3–23). In addition, anticoagulation reduces stroke severity and poststroke

mortality. Compared with aspirin, adjusted-dose warfarin reduces stroke by 39% (95% CI, 22–52).

Three newer oral anticoagulants have been approved in the United States for stroke prevention in patients with nonvalvular AF: the direct thrombin inhibitor dabigatran (dosed at 150 mg twice daily in patients with creatinine clearance  $\geq 30$  mL/min) and the direct factor Xa inhibitors rivaroxaban (20 mg once daily for patients with creatinine clearance  $\geq 50$  mL/min) and apixaban (5 mg twice daily for patients with no more than one of the following characteristics: age  $\geq 80$  years, serum creatinine  $\geq 1.5$  mg/dL, or body weight  $\leq 60$  kg). Clinical trial data and other information for these agents were recently reviewed in an AHA/American Stroke Association science advisory and are briefly summarized here.

The Randomized Evaluation of Long-Term Anticoagulant Therapy (RE-LY) trial randomized 18,113 patients to dabigatran 150 mg or 110 mg twice daily or adjusted-dose warfarin (target INR, 2 to 3). The study enrolled patients with and without a history of prior stroke but with overall moderate-to-high risk of stroke (mean CHADS<sub>2</sub> score, 2.1) and excluded patients who had stroke within 14 days (6 months for severe stroke), increased bleeding risk, creatinine clearance  $< 30$  mL/min, or active liver disease. The primary outcome of stroke or systemic embolism during the mean 2-year follow-up occurred at a rate of 1.7% per year in the warfarin (INR, 2 to 3) group compared with 1.11% per year in the 150-mg dabigatran group (RR = 0.66 vs. warfarin; 95% CI, 0.53–0.82;  $P < .001$  for superiority). Intracranial hemorrhage rates were strikingly lower with 150-mg dabigatran relative to adjusted-dose warfarin (0.30%/year vs. 0.74%/year; RR, 0.40; 95% CI, 0.27–0.60). However, the overall rates of major bleeding were not different between the groups (3.11%/year vs. 3.36%/year;  $P = .31$ ), and gastrointestinal bleeding was more frequent on 150-mg dabigatran (1.51%/year vs. 1.12%/year; RR, 1.50; 95% CI, 1.19–1.89). MI was also increased in the 150-mg dabigatran group (0.74%/year vs. 0.53%/year; RR, 1.38; 95% CI, 1.00–1.91), although this difference was no longer significant when silent MIs or unstable angina, cardiac arrest, and cardiac death were included. Metaanalysis of seven trials of dabigatran use for various indications has supported the possibility of a small but consistent increased risk of MI or acute coronary syndrome versus the risk observed in various control arms of these studies (OR, 1.33; 95% CI, 1.03–1.71;  $P = .03$ ). Finally, analyses of multiple patient subgroups, categorized by nationality, CHADS<sub>2</sub> score, and the presence or absence of prior TIA/stroke, have not found evidence for differences in the risk/benefit profile for dabigatran. In the subgroup of patients age  $\geq 75$  years, dabigatran 150 mg was associated with increased gastrointestinal hemorrhage relative to warfarin (OR, 1.79; 95% CI, 1.35–2.37) but reduced ICH (OR, 0.42; 95% CI, 0.25–0.70).

The Rivaroxaban Versus Warfarin in Nonvalvular Atrial Fibrillation (ROCKET AF) trial randomized 14,264 patients with nonvalvular AF to rivaroxaban 20 mg/day or adjusted-dose warfarin (target INR, 2 to 3). A CHADS<sub>2</sub> score of  $\geq 2$

was required, yielding a mean score for enrolled subjects of 3.5, which was higher than in the RE-LY and the Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE) trials; more than half of the participants had a stroke, TIA, or systemic embolism before enrollment. Over a median follow-up of 707 days, the primary endpoint of ischemic and hemorrhagic stroke and systemic embolism in patients as actually treated (the pre-specified analysis plan for efficacy in this study) occurred in 1.7% per year in those receiving rivaroxaban and 2.2% per year in those on warfarin (HR, 0.79; 95% CI, 0.66–0.96;  $P < .001$  for noninferiority; analyzed by intention to treat, HR, 0.88; 95% CI, 0.74–1.03;  $P < .001$  for noninferiority;  $P = .12$  for superiority). The primary safety endpoint of major or nonmajor bleeding occurred in 14.9% of patients per year in those receiving rivaroxaban and 14.5% in those on warfarin (HR, 1.03; 95% CI, 0.96–1.11;  $P = .44$ ). ICH (0.5% vs. 0.7%; HR, 0.67; 95% CI, 0.47–0.93) and fatal bleeding (0.2% vs. 0.5%; HR, 0.50; 95% CI, 0.31–0.79), however, were reduced on rivaroxaban relative to warfarin. Subsequent subgroup analysis of the 6796 subjects without previous stroke or TIA found rivaroxaban to have borderline superiority to warfarin in intention-to-treat analysis of efficacy (HR, 0.77; 95% CI, 0.58–1.01), supporting its use in primary prevention. Other subgroup analyses found no differences in the effectiveness of rivaroxaban according to age, sex, CHADS<sub>2</sub> score, or the presence of moderate renal insufficiency (creatinine clearance, 30 to 49 mL/min; these subjects were randomized to rivaroxaban 15 rather than 20 mg/day). Important concerns have been raised about the interpretation of ROCKET AF, most notably the relatively poor management of warfarin (mean time in therapeutic range, 55%) and the relatively high number of outcomes (stroke or systemic embolism) beyond the 2-day monitoring period after drug cessation.

Apixaban has been studied in two phase III trials. The Apixaban Versus Acetylsalicylic Acid to Prevent Strokes in Atrial Fibrillation Patients Who Have Failed or Are Unsuitable for Vitamin K Antagonist Treatment (AVERROES) trial compared apixaban 5 mg twice daily with aspirin 81 to 324 mg daily in 5599 subjects with nonvalvular AF unsuitable for warfarin therapy. The ARISTOTLE trial compared the same dose of apixaban with adjusted-dose warfarin (target INR, 2 to 3) among 18,201 patients with nonvalvular AF. Subjects in each study had at least one additional risk factor for stroke (prior stroke or TIA, age  $\geq 75$  years, hypertension, diabetes mellitus, heart failure, or peripheral artery disease). A reduced dose of apixaban 2.5 mg twice daily was used in both studies for subjects with at least two of the following: age  $\geq 80$  years, body mass  $\leq 60$  kg, or serum creatinine  $\geq 1.5$  mg/dL. AVERROES was terminated after a mean follow-up of 1.1 years when an interim analysis found apixaban to be markedly superior to aspirin for the prevention of stroke or systemic embolism (1.6%/year vs. 3.7%/year; HR, 0.45; 95% CI, 0.32–0.62) with similar rates of major bleeding (1.4%/year vs. 1.2%/year). Germane to primary prevention, apixaban was also superior to aspirin in subjects without

prior TIA or stroke (HR, 0.51; 95% CI, 0.35–0.74). Over a median 1.8 years of follow-up in ARISTOTLE, the primary outcome occurred in 1.27% per year in the apixaban group (analyzed as intention to treat) and 1.60% per year in the warfarin group (HR, 0.79; 95% CI, 0.66–0.95;  $P < .001$  for noninferiority;  $P = .01$  for superiority). Much of the difference between the groups could be attributed to a reduction in ICH in the apixaban group (0.24%/year vs. 0.47%/year); the differences in ischemic or uncertain type of stroke were minimal (0.97%/year vs. 1.05%/year). Major bleeding events were similarly less frequent on apixaban (2.13%/year vs. 3.09%/year; HR, 0.69; 95% CI, 0.60–0.80). Subgroup analysis found a similar magnitude effect for primary prevention of stroke or systemic embolism in subjects without prior stroke or TIA (1.01%/year vs. 1.23%/year; HR, 0.82; 95% CI, 0.65–1.03), with the sharpest difference again in risk of ICH (0.29%/year vs. 0.65%/year; HR, 0.44; 95% CI, 0.30–0.66). Another secondary analysis found consistent efficacy of apixaban in subjects with impaired renal function (estimated glomerular filtration rate  $<80$  mL/min) and significantly greater reduction in major bleeding among those with more advanced dysfunction (estimated glomerular filtration rate  $\leq 50$  mL/min). Because of the clustering of stroke observed after discontinuation of apixaban, a black box warning was required for this agent (as for rivaroxaban), indicating that coverage with another anticoagulant should be strongly considered at the time of cessation unless there is pathologic bleeding.

Early analyses suggest that the newer oral anticoagulants can be cost effective, particularly for patients at high risk of cardioembolism or hemorrhage. A Markov decision model using data from RE-LY, for example, found that dabigatran 150 mg twice daily provided 0.36 additional quality-adjusted life-years at a cost of \$9000, representing an incremental cost-effectiveness ratio (\$25,000 per quality-adjusted life-year) that is within the range tolerated by many health care systems. These analyses are based on only a single trial of dabigatran, however, and similar evaluations have yet to be performed for rivaroxaban and apixaban. The cost effectiveness of newer anticoagulants relative to adjusted-dose warfarin is predicted to be sensitive to the cost of the medications, the risk for cardioembolism or hemorrhage (cost effectiveness improving with increasing risk), and the quality of INR control on warfarin.

There are many factors to consider in the selection of an anticoagulant for patients with nonvalvular AF. The newer agents offer clearly attractive features such as fixed dose, lack of required blood monitoring, absence of known interaction with the immune complexes associated with heparin-induced thrombocytopenia, and fewer identified drug interactions than warfarin. Most notably, each appears to confer lower risk than adjusted-dose warfarin for ICH, arguably the strongest determinant of long-term safety for anticoagulation.

These agents also raise important concerns, however, including substantial cost to the health care system, renal clearance, short half-lives, general unavailability of a

monitoring test to ensure compliance, and lack of a specific agent to reverse their anticoagulant effects. Although a dabigatran dose of 75 mg twice daily was approved for patients with creatinine clearance of 15 to 30 mL/min, such subjects were in fact excluded from RE-LY and have not been extensively studied. The short half-lives of the newer anticoagulants raise the possibility of increased risk of cardioembolism if doses are missed, a concern heightened by the relatively large number of events in ROCKET AF occurring between 2 and 7 days after discontinuation of rivaroxaban. In assessments of the lack of reversing agent for the newer anticoagulants, it is important to consider that even warfarin-related ICH mortality rates are extremely high despite the availability of reversing agents. An analysis of ICH events occurring on dabigatran 150 mg twice daily and adjusted-dose warfarin in RE-LY found no difference in mortality (35% vs. 36%) and, because of the lower overall risk of bleeding with dabigatran, significantly fewer deaths caused by ICH (13 vs. 32;  $P < .01$ ).

In studies of antiplatelet agents for nonvalvular AF, aspirin offers modest protection against stroke (RR reduction, 22%; 95% CI, 6–35). No convincing data favor one dose of aspirin (50–325 mg daily) over another. Two randomized trials assessed the potential role of the combination of clopidogrel (75 mg daily) plus aspirin (75–100 mg daily) for preventing stroke in patients with AF. The AF Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE) investigators compared this combination antiplatelet regimen with adjusted-dose warfarin (target INR, 2–3) in AF patients with one additional risk factor for stroke in ACTIVE W and found a reduction in stroke risk with warfarin compared with the dual antiplatelet regimen (RR reduction, 40%; 95% CI, 18–56;  $P = .001$ ) and no significant difference in risk of major bleeding. ACTIVE A compared the combination of clopidogrel and aspirin with aspirin alone in AF patients who were deemed unsuitable for warfarin anticoagulation and who had at least one additional risk factor for stroke ( $\approx 25\%$  were deemed unsuitable because of concern for warfarin-associated bleeding). Dual antiplatelet therapy resulted in a significant reduction in all strokes (including parenchymal ICH) over treatment with aspirin alone (RR reduction, 28%; 95% CI, 17–38;  $P = .0002$ ) but also resulted in a significant increase in major bleeding (RR increase, 57%; 95% CI, 29–92;  $P < .001$ ). Overall and in absolute terms, major vascular events (the study primary endpoint) were decreased 0.8% per year, but major hemorrhages increased 0.7% per year (RR for major vascular events and major hemorrhages, 0.97; 95% CI, 0.89–1.06;  $P = .54$ ). Disabling/fatal stroke, however, was decreased by dual antiplatelet therapy (RR reduction, 26%; 95% CI, 11–38;  $P = .001$ ). A post hoc analysis of randomized trial data that used relative weighting of events suggested a modest net benefit from the combination of aspirin and clopidogrel over aspirin alone.

Recommendations for the selection of antithrombotic therapy for patients with nonvalvular AF have had to adjust for two emerging trends: a decreasing rate of stroke for any

given CHADS<sub>2</sub> risk category, possibly related to improving control of other stroke risk factors, and the appearance of the newer oral anticoagulants with a lower risk of ICH. These two trends tend to have opposing effects on the tipping point at which the benefits of anticoagulation outweigh its risks: a lower stroke risk argues for more limited use of anticoagulation, and safer agents argue for more extensive use. On the basis of the decreasing risk of AF-related stroke, the 2012 American College of Chest Physicians evidence-based practice guidelines suggested that patients with nonrheumatic AF at low stroke risk (i.e., CHADS<sub>2</sub> = 0) be treated with no therapy rather than any antithrombotic agent; for those patients preferring antithrombotic treatment, aspirin rather than anticoagulation was recommended. These guidelines also favored oral anticoagulation rather than antiplatelet therapy for those at moderate risk (i.e., CHADS<sub>2</sub> = 1; grade 2B) and for those at high risk (i.e., CHADS<sub>2</sub> ≥ 2; American College of Chest Physicians grade 1B, i.e., strong recommendation, moderate evidence) and the use of dabigatran (the only approved newer anticoagulant when the guidelines were formulated) rather than warfarin as oral anticoagulant (grade 2B). For patients in these groups who select antiplatelet rather than anticoagulant therapy, the guidelines recommended combination aspirin plus clopidogrel rather than aspirin alone (grade 2B). Of these clinical scenarios, the greatest uncertainty surrounds the management of patients at moderate risk (CHADS<sub>2</sub> = 1). A large cohort study did not find net clinical benefit of warfarin for AF patients with a CHADS<sub>2</sub> score of 1, and a decision-analysis model predicted that anticoagulation would be beneficial in this group only when the lower risk of ICH associated with the newer agents was assumed.

Most guidelines have not explicitly incorporated risk for anticoagulant-related hemorrhagic complications, largely because of the paucity of precise data on the risk of bleeding. Some of the risks for hemorrhage are also risks for cardioembolism and thus do not necessarily argue against anticoagulation. Age >75 years, for example, is a factor favoring rather than opposing anticoagulation. One bleeding risk that appears sufficient to tip the balance away from anticoagulation in nonvalvular AF is a history of lobar ICH suggestive of cerebral amyloid angiopathy. Other risks for ICH such as certain genetic profiles or the presence of asymptomatic cerebral microbleeds on neuroimaging do not currently appear sufficient by themselves to outweigh the benefits of anticoagulation in patients at average risk of cardioembolism.

For patients treated with adjusted-dose warfarin, the initial 3-month period is a particularly high-risk period for bleeding and requires especially close anticoagulation monitoring. ICH is the most devastating complication of anticoagulation, but the absolute increase in risk is small for INR ≤ 3.5. Treatment of hypertension in AF patients reduces the risk of both ICH and ischemic stroke and hence has dual benefits for anticoagulated patients with AF. A consensus statement on the delivery of optimal anticoagulant care (focusing primarily on warfarin) has been published. The

combined use of warfarin with antiplatelet therapy increases the risk of intracranial and extracranial hemorrhage. Because adjusted-dose warfarin (target INR, 2–3) appears to offer protection against MI comparable with that provided by aspirin in AF patients, the addition of aspirin is not recommended for most patients with AF and stable coronary artery disease. There are meager data on the type and duration of optimal antiplatelet therapy when combined with warfarin in AF patients with recent coronary angioplasty and stenting. The combination of clopidogrel, aspirin, and warfarin has been suggested for at least 1 month after placement of bare metal coronary stents in patients with AF. Because drug-eluting stents require even more prolonged antiplatelet therapy, bare metal stents are generally preferred for AF patients taking warfarin. A lower target INR of 2 to 2.5 has been recommended in patients requiring warfarin, aspirin, and clopidogrel after percutaneous coronary intervention during the period of combined antiplatelet and anticoagulant therapy.

Closure of the LAA has been evaluated as an alternative approach to stroke prevention in nonvalvular AF. In a trial of 707 subjects randomized 2:1 to percutaneous LAA closure with the WATCHMAN device (in which patients were treated with warfarin for at least 45 days after device placement, then aspirin plus clopidogrel from echocardiographically demonstrated closure of the LAA until 6 months after placement, then aspirin alone) versus adjusted-dose warfarin (target INR, 2–3), LAA closure was noninferior to warfarin for preventing the primary outcome of ischemic or hemorrhagic stroke, cardiac or unexplained death, or systemic embolism during the mean 18-month follow-up (RR, 0.62; 95% CI, 0.35–1.25; *P* < .001 for noninferiority). Hemorrhagic stroke was less frequent in the LAA closure group (RR, 0.09; 95% CI, 0–0.45), but ischemic stroke was insignificantly more frequent (RR, 1.34; 95% CI, 0.60–4.29), in part because of procedure-related strokes (occurring in 5 of the 449 patients in whom LAA closure was attempted, including 2 with long-term residual deficits). At 1588 patient-years of follow-up, the rate of the primary efficacy endpoint of stroke, systemic embolism, and cardiovascular death was not inferior for the WATCHMAN device compared with warfarin. Although this approach appears promising, there are substantial reasons for proceeding cautiously with this treatment, including the relatively modest power of the trial, the exclusion of subjects with firm contraindications to anticoagulation (who would otherwise appear to be ideal candidates for LAA closure), and the lack of comparison to the newer, potentially more effective oral anticoagulants. Other potential nonpharmacologic approaches such as therapeutic cardioversion and rhythm control do not reduce stroke risk. Intervals of asymptomatic AF also persist after apparently successful radiofrequency ablation, suggesting a persistent need for antithrombotic treatment after this procedure.

Several randomized, clinical trials have consistently shown that rhythm control does not protect against stroke relative to rate control. For patients with AF of ≥ 48 hours or

when duration is unknown, it is recommended that patients receive warfarin to an INR of 2 to 3 for 3 weeks before and 4 weeks after chemical or electrical cardioversion. Subgroup analyses of ROCKET AF and RE-LY suggest that protection from cardioembolism around the time of cardioversion appears to be comparable for warfarin and the novel oral anticoagulants.

### Atrial Fibrillation: Recommendations

1. For patients with valvular AF at high risk for stroke, defined as a CHA<sub>2</sub>DS<sub>2</sub>-VASc score of  $\geq 2$  and acceptably low risk for hemorrhagic complications, long-term oral anticoagulant therapy with warfarin at a target INR of 2 to 3 is recommended.
2. For patients with nonvalvular AF, a CHA<sub>2</sub>DS<sub>2</sub>-VASc score of  $\geq 2$ , and acceptably low risk for hemorrhagic complications, oral anticoagulants are recommended. Options include warfarin (INR, 2.0 to 3.0), dabigatran, apixaban, and rivaroxaban. The selection of antithrombotic agent should be individualized on the basis of patient risk factors (particularly risk for intracranial hemorrhage), cost, tolerability, patient preference, potential for drug interactions, and other clinical characteristics, including the time that the INR is in therapeutic range for patients taking warfarin.
3. Active screening for AF in the primary care setting in patients age  $>65$  years by pulse assessment followed by EKG as indicated can be useful.
4. For patients with nonvalvular AF and CHA<sub>2</sub>DS<sub>2</sub>-VASc score of 0, it is reasonable to omit antithrombotic therapy.
5. For patients with nonvalvular AF, a CHA<sub>2</sub>DS<sub>2</sub>-VASc score of 1, and an acceptably low risk for hemorrhagic complication, no antithrombotic therapy, anticoagulant therapy, or aspirin therapy may be considered. The selection of antithrombotic agent should be individualized on the basis of patient risk factors (particularly risk for intracranial hemorrhage), cost, tolerability, patient preference, potential for drug interactions, and other clinical characteristics, including the time that the INR is in the therapeutic range for patients taking warfarin.
6. Closure of the LAA may be considered for high-risk patients with AF who are deemed unsuitable for anticoagulation if performed at a center with low rates of periprocedural complications and the patient can tolerate the risk of at least 45 days of postprocedural complications.

### Other Cardiac Conditions

Cardiac conditions other than AF that are associated with an increased risk for stroke include acute MI; ischemic and nonischemic cardiomyopathy; valvular heart disease, including prosthetic valves and infective endocarditis; patent foramen ovale (PFO) and atrial septal aneurysms (ASAs); cardiac tumors; and aortic atherosclerosis.

### Acute Myocardial Infarction

A metaanalysis of population-based studies published between 1970 and 2004 found that the risk of ischemic stroke after acute MI was 11.1 per 1000 (95% CI, 10.7–11.5) during the index hospitalization, 12.2 per 1000 (95% CI, 10.4–14.0) at 30 days, and 21.4 (95% CI, 14.1–28.7) at 1 year. Factors associated with increased stroke risk included advanced age, hypertension, diabetes mellitus, anterior MI, AF, and congestive heart failure. Importantly, the risk of embolic stroke is increased in patients with anterior MI and left ventricular thrombus. Contemporary studies have found that left ventricular thrombus affects  $\approx 6\%$  to  $15\%$  of patients with anterior MI and  $\approx 27\%$  with anterior MI and left ventricular ejection fraction  $<40\%$ . Systemic embolism occurs in  $\approx 11\%$  of patients with left ventricular thrombus. In the Warfarin, Aspirin Reinfarction Study (WARIS II), warfarin, combined with aspirin or given alone, compared with aspirin alone reduced the risk of thromboembolic stroke but was associated with a greater risk of bleeding. A metaanalysis of 14 trials comprising 25,307 patients with an acute coronary syndrome reported that aspirin plus warfarin, in which the achieved INR was 2 to 3, compared with aspirin alone reduced the risk of death, nonfatal MI, and nonfatal thromboembolic stroke but doubled the risk of major bleeding. A metaanalysis of 24,542 patients in 10 randomized trials that evaluated the efficacy of warfarin after acute MI found a stroke incidence over 5 years of 2.4%. In this metaanalysis, warfarin decreased the risk of stroke (OR, 0.75; 95% CI, 0.63–0.89) but increased the risk of bleeding. The 2013 ACCF/AHA guideline for the management of ST segment elevation MI (STEMI) states that anticoagulant therapy with a vitamin K antagonist is reasonable for patients with STEMI and asymptomatic left ventricular mural thrombi and that anticoagulant therapy may be considered for patients with STEMI and anterior apical akinesis or dyskinesis.

### Cardiomyopathy

The incidence of stroke in patients with cardiomyopathy and sinus rhythm is  $\approx 1$  per 100 patient-years. The Warfarin/Aspirin Study in Heart Failure (WASH) randomized patients with heart failure, reduced left ventricular systolic function, and no other indications for anticoagulant therapy to warfarin, aspirin, or no treatment. There was no difference between groups in the primary composite cardiovascular endpoint, which included stroke. The Warfarin and Antiplatelet Therapy in Chronic Heart Failure trial randomized patients with heart failure, reduced left ventricular systolic function, and sinus rhythm to warfarin, clopidogrel, or aspirin. The study was terminated early because of slow enrollment. There was no difference in the composite primary endpoint of death, nonfatal MI, or nonfatal stroke, but warfarin was associated with fewer nonfatal strokes than aspirin or clopidogrel. The Warfarin Versus Aspirin in Reduced Cardiac Ejection Fraction (WARCEF) trial randomized 2305 patients with reduced left ventricular ejection fraction and sinus rhythm to warfarin or aspirin and

followed them up for up to 6 years. There was no difference in the primary composite outcome of ischemic stroke, ICH, or death resulting from any cause (HR, 0.93; 95% CI, 0.79–1.10), but there was a significant reduction in the rate of ischemic stroke with warfarin compared with aspirin (0.72 vs. 1.36 events per 100 patient-years; HR, 0.52; 95% CI, 0.33–0.82). The rate of major hemorrhage, however, was greater in the warfarin than in the aspirin group. The 2009 ACCF/AHA guideline for the diagnosis and management of heart failure in adults states that the usefulness of anticoagulation is not well established in patients with heart failure who do not have AF or a previous thromboembolic event. The American College of Chest Physicians guidelines on antithrombotic therapy and prevention of thrombosis state that the usefulness of anticoagulation is not well established in patients with heart failure who do not have AF or a previous thromboembolic event. Based on the more recent WARCEF trial, this recommendation is upgraded in this document to state that anticoagulants or antiplatelet agents are reasonable for patients with heart failure who do not have AF or a previous thromboembolic event.

### Valvular Heart Disease

The risk of embolic stroke is increased in patients with rheumatic mitral valve disease, even in the absence of AF, and in patients with prosthetic heart valves. Rheumatic carditis is the most common cause of mitral stenosis. Studies from the middle part of the last century found an annual incidence of systemic embolism among patients with rheumatic mitral valve disease of 1.5% to 4.7%. Thrombus and subsequent embolism may be more likely to occur in large left atria. The ACCF/AHA guidelines for the management of valvular heart disease recommend anticoagulation in patients with mitral stenosis and a prior embolic event, even in sinus rhythm and in patients with mitral stenosis with left atrial thrombus. Reports on the association of embolic stroke with mitral valve prolapse have been inconsistent. A population-based study of patients from Olmsted County, Minnesota, found an increased RR of stroke or TIA among patients with mitral valve prolapse who were initially in sinus rhythm (RR, 2.2; 95% CI, 1.5–3.2). Independent factors associated with stroke included older age, mitral valve thickening, and the development of AF. The ACCF/AHA guidelines for the management of valvular heart disease recommend aspirin therapy for patients with mitral valve prolapse who experience TIAs and warfarin for these patients with a history of stroke and mitral regurgitation, AF, or left atrial thrombus. The risk of stroke is also increased in patients with mitral annular calcification. There was an increased risk of stroke (RR, 2.1; 95% CI, 1.2–3.6) among participants in the Framingham study who had mitral annular calcification. Risk of stroke was associated with the severity of mitral annular calcification. Similarly, in the SHS, a cohort study of American Indians, stroke incidence was increased among those with mitral annular calcification (RR, 3.1; 95% CI, 1.8–5.2). In contrast, in the multiethnic NOMAS, mitral annular calcification was associated with an increased risk

of MI and vascular death but not ischemic stroke. There is no evidence that anticoagulant therapy reduces the risk of stroke in patients with mitral annular calcification. Calcific aortic stenosis is an uncommon cause of embolic stroke, unless disrupted by valvuloplasty, transcatheter aortic valve replacement, or open surgical aortic valve replacement.

Prosthetic heart valves can serve as a source of thromboembolism. The risk of embolic stroke is greater in patients with mechanical valves than bioprosthetic valves. The annual incidence of thromboembolism in patients with bioprosthetic valves and sinus rhythm is  $\approx$ 0.7%. Among patients with bioprosthetic valves, the risk of embolism is greatest within the first 3 months after implantation and is higher with mitral than aortic bioprosthetic valves. ACCF/AHA guidelines for the management of patients with valvular heart disease recommend aspirin after aortic or mitral valve replacement with a bioprosthesis in patients with no risk factors (i.e., AF, previous thromboembolism, left ventricular dysfunction, and hypercoagulable condition) and warfarin (INR, 2–3) after aortic or mitral valve replacement with a bioprosthesis in patients with additional risk factors. During the first 3 months after aortic or mitral valve replacement with a bioprosthesis, the guidelines indicate that it is reasonable to give warfarin to achieve an INR of 2 to 3.

In the first 3 months after bioprosthetic valve implantation, aspirin is recommended for aortic valves; the combination of aspirin and clopidogrel is recommended if the aortic valve is transcatheter; and vitamin K antagonist therapy with a target INR of 2.5 is recommended for mitral valves. After 3 months, aspirin is recommended.

A metaanalysis of 46 studies comprising 13,088 patients who received mechanical mitral or aortic valve prostheses reported an incidence of valve thrombosis or embolism in the absence of antithrombotic therapy of 8.6 per 100 patient-years (95% CI, 7.0–10.4). Risk of embolism was lower in patients with tilting disk and bileaflet valves than in those with caged ball valves (no longer used). Antithrombotic therapy with a vitamin K antagonist reduced the risk of thromboembolic events to 1.8 per 100 patient-years (95% CI, 1.7–1.9). Even among anticoagulated patients, the risk of embolism is higher among those with mechanical mitral valves than mechanical aortic valves. ACC/AHA guidelines for the management of patients with valvular heart disease recommend warfarin (INR, 2–3) after aortic valve replacement with bileaflet mechanical or Medtronic Hall prostheses in patients with no risk factors, warfarin (INR, 2.5–3.5) in patients with risk factors, and warfarin (INR, 2.5–3.5) after mitral valve replacement with any mechanical valve. The addition of low-dose aspirin to warfarin is recommended for all patients with mechanical valves.

The novel oral anticoagulants (factor Xa inhibitors and direct thrombin inhibitors) are not indicated for the prevention of thromboembolism associated with mechanical heart valves. The randomized, phase II study to evaluate the safety and pharmacokinetics of oral dabigatran etexilate in patients after heart valve replacement (RE-ALIGN) trial showed an increase in thromboembolic and bleeding

complications with dabigatran compared with warfarin in patients with mechanical heart valves.

About 20% to 40% of patients with endocarditis suffer embolic events, the majority of which affect the central nervous system. The rate of embolic events decreases rapidly after the initiation of antibiotic therapy. The risk of embolic stroke is associated with the size of the vegetation, involvement of the mitral valve, and infection by *Staphylococcus aureus*. Anticoagulant therapy does not reduce the risk of embolic stroke and may increase the risk of cerebral hemorrhage. Anticoagulant therapy should not be used to treat patients with infective endocarditis unless indicated for other cardiovascular conditions. Nonbacterial thrombotic endocarditis, also known as marantic endocarditis, is associated with malignant neoplasms, antiphospholipid antibodies (aPLs), and systemic lupus erythematosus (SLE) and may be a source of an embolic stroke. Anticoagulant therapy is indicated for patients with nonbacterial thrombotic endocarditis and systemic embolism.

### Patent Foramen Ovale and Atrial Septal Aneurysms

A PFO is present in  $\approx 15\%$  to  $25\%$  of the adult population, and ASA occurs in  $1\%$  to  $4\%$ . A PFO serves as a right-to-left conduit for paradoxical emboli originating in the veins, whereas ASA may be a nidus for thrombus formation. PFO and ASA have been associated with stroke in many, but not all, studies. In the Patent Foramen Ovale in Cryptogenic Stroke Study (PICSS), a PFO was detected by transesophageal echocardiography more often in patients with cryptogenic stroke than in those with known causes of stroke ( $39.2\%$  vs.  $29.9\%$ , respectively). Another study also found that the prevalence of PFO was greater among patients with cryptogenic stroke than among those with known causes of stroke, including patients age  $<55$  years (OR, 4.70; 95% CI, 1.89–11.68;  $P < .001$ ) and patients age  $\geq 55$  years (OR, 2.92; 95% CI, 1.70–5.01). A metaanalysis of case-control studies of patients who have had an ischemic stroke found that among patients age  $\leq 55$  years there are significant associations with PFO (OR, 3.10; 95% CI, 2.29–4.21), ASA (OR, 6.14; 95% CI, 2.47–15.22), and PFO plus ASA (OR, 15.59; 95% CI, 2.83–85.87). In patients age  $>55$  years, the association with PFO was not significant (OR, 1.27; 95% CI, 0.80–2.01), although it was for ASA (OR, 3.43; 95% CI, 1.89–6.22) and for PFO plus ASA (OR, 5.09; 95% CI, 1.25–20.74). In a population-based study from Olmstead County, Minnesota, in which the mean participant age was  $66.9 \pm 13.3$  years, PFO was not associated with increased risk of stroke (HR, 1.46; 95% CI, 0.74–2.88), whereas there was an association with ASA (HR, 3.72; 95% CI, 0.88–15.71). In the multiethnic NOMAS, in which the mean age was  $68.7 \pm 10.0$  years, PFO was not associated with increased risk of stroke (HR, 1.64; 95% CI, 0.87–3.09) nor was the coexistence of PFO and ASA (HR, 1.25; 95% CI, 0.17–9.24). Another study examining the characteristics of PFO observed larger PFOs, longer tunnels, and a greater frequency of ASA in patients with stroke than

in those without stroke. One study of patients with cryptogenic stroke found that the risk of recurrent stroke was  $2.3\%$  (95% CI, 0.3–4.3) among patients with PFO alone,  $0\%$  in those with ASA alone,  $15.2\%$  (95% CI, 1.8–28.6) in patients with both PFO and ASA, and  $4.2\%$  (95% CI, 1.8–6.6) in patients with neither. Further analyses from NOMAS with longer follow-up also failed to find evidence for an increased risk of first stroke with PFO (adjusted HR, 1.10; 95% CI, 0.64–1.91) and provided further evidence that PFO is not associated with subclinical cerebrovascular disease.

No study has examined treatments to prevent initial strokes in patients with PFO or ASA. Accordingly, given the uncertainties and relatively low risk of initial stroke caused by PFO or ASA and the potential risk of antithrombotic therapy or invasive treatments, no treatment is recommended for the primary prevention of stroke in people with PFO or ASA. Several studies have examined the treatment of PFO with antithrombotic therapy or percutaneous closure devices in patients with cryptogenic stroke.

### Cardiac Tumors

Benign primary cardiac tumors such as myxomas, papillary fibroelastomas, and primary malignant cardiac neoplasms such as sarcomas may embolize to the brain and cause ischemic stroke. Embolic stroke is most likely to occur with intracavitary tumors that have friable surfaces. Myxoma is the most common cardiac tumor, and the majority of them occur in the left atrium. About  $30\%$  to  $40\%$  of myxomas embolize. Stroke or TIA is the presenting symptoms in half of the patients with papillary fibroelastomas. Surgical excision of atrial myxomas is recommended. Surgical intervention, including removal or occasionally valve replacement, is recommended for symptomatic fibroelastomas and for fibroelastomas that are  $>1$  cm in diameter or appear mobile, even if asymptomatic, because they pose a risk for embolism.

### Aortic Atherosclerosis

Plaques  $\geq 4$  mm in size, particularly large, complex plaques, are associated with an increased risk of cryptogenic strokes. In the French Study of Aortic Plaques in Stroke, plaques  $>4$  mm were found to be independent predictors of recurrent stroke (RR, 3.8; 95% CI, 1.8–7.8). Among patients with cryptogenic stroke who participated in PICSS, large plaques detected by transesophageal echocardiography were associated with an increased risk of recurrent ischemic stroke or death over a 2-year follow-up (HR, 6.42; 95% CI, 1.62–25.46), as were those with complex morphology (HR, 9.50; 95% CI, 1.92–47.10). Atheroembolism from aortic plaques is also a cause of stroke associated with cardiac surgery. There are no prospective, randomized trials examining the efficacy of medical therapy to reduce the risk of stroke caused by embolic events from large thoracic aortic plaques. One nonrandomized study found that warfarin reduced the risk of recurrent stroke in patients with mobile thoracic atheroma detected by transesophageal echocardiography. In another nonrandomized study, patients with aortic plaques  $>4$  mm

thick treated with oral anticoagulants had fewer stroke and peripheral embolic events than those treated with antiplatelet therapy. A retrospective analysis of patients with severe thoracic aortic plaque found that statin therapy (OR, 0.3; 95% CI, 0.2–0.6), but not warfarin (OR, 0.7; 95% CI, 0.4–1.2) or antiplatelet therapy (OR, 1.4; 95% CI, 0.8–2.4), reduced the risk of stroke, TIA, and peripheral emboli.

### Other Cardiac Conditions: Recommendations

1. Anticoagulation is indicated in patients with mitral stenosis and a prior embolic event, even in sinus rhythm.
2. Anticoagulation is indicated in patients with mitral stenosis and left atrial thrombus.
3. Warfarin (target INR, 2–3) and low-dose aspirin are indicated after aortic valve replacement with bileaflet mechanical or current-generation, single-tilting-disk prostheses in patients with no risk factors, warfarin (target INR, 2.5–3.5) and low-dose aspirin are indicated in patients with mechanical aortic valve replacement and risk factors,<sup>a</sup> and warfarin (target INR, 2.5–3.5) and low-dose aspirin are indicated after mitral valve replacement with any mechanical valve.
4. Surgical excision is recommended for the treatment of atrial myxomas.
5. Surgical intervention is recommended for symptomatic fibroelastomas and for fibroelastomas that are >1 cm or appear mobile, even if asymptomatic.
6. Aspirin is reasonable after aortic or mitral valve replacement with a bioprosthesis.
7. It is reasonable to give warfarin to achieve an INR of 2 to 3 during the first 3 months after aortic or mitral valve replacement with a bioprosthesis.
8. Anticoagulants or antiplatelet agents are reasonable for patients with heart failure who do not have AF or a previous thromboembolic event.
9. Vitamin K antagonist therapy is reasonable for patients with STEMI and asymptomatic left ventricular mural thrombi.
10. Anticoagulation may be considered for asymptomatic patients with severe mitral stenosis and left atrial dimension  $\geq 55$  mm by echocardiography.
11. Anticoagulation may be considered for patients with severe mitral stenosis, an enlarged left atrium, and spontaneous contrast on echocardiography.
12. Anticoagulant therapy may be considered for patients with STEMI and anterior apical akinesis or dyskinesis.
13. Antithrombotic treatment and catheter-based closure are not recommended in patients with PFO for primary prevention of stroke.

### Asymptomatic Carotid Artery Stenosis

Atherosclerotic stenosis in the extracranial internal carotid artery or carotid bulb has been associated with an increased

risk of stroke. What follows is a summary of recommendations for managing asymptomatic patients with carotid atherosclerotic stenosis.

Previous randomized trials have shown that prophylactic carotid endarterectomy (CEA) in appropriately selected patients with carotid stenosis results in a relative risk reduction of stroke of 53% and an absolute 5-year risk reduction of 6% compared with patients treated by medical management alone. However, since these trials were performed, medical management has improved. The question has been raised if invasive treatment of carotid bifurcation disease remains an effective way to reduce stroke risk compared with contemporary medical management alone.

### Assessment of Carotid Stenosis

A hemodynamically significant carotid stenosis produces a pressure drop across the lesion, a flow reduction distal to the lesion, or both. This generally corresponds to a 60% diameter-reducing stenosis as reflected by catheter angiography as measured with the North American method. This method was first described in publications from the Joint Study of Extracranial Arterial Occlusive Disease of the 1960s and has been used in multiple trials carried out in North America. This method measures the minimal residual lumen at the level of the stenotic lesion compared with the diameter of the more distal internal carotid artery where the walls of the artery first become parallel. It uses the following formula:

$$\text{Stenosis} = (1 - N/D) \times 100\%$$

where  $N$  is the diameter at point of maximum stenosis and  $D$  is the diameter of the arterial segment distal to the stenosis where the arterial walls first become parallel. This method is in contrast to the European method, which estimates stenosis of the internal carotid bulb.

Because the randomized trials of CEA for symptomatic and asymptomatic disease in North America used catheter angiography, this has become the gold standard against which other imaging technologies are compared. Historically, catheter angiography carried an  $\approx 1\%$  risk of causing a stroke in patients with atherosclerotic disease. The complication rate has been dropping over the past several years, and the permanent stroke complication rate is  $< 0.2\%$ . Duplex ultrasound is the noninvasive method of screening the extracranial carotid artery for an atherosclerotic stenosis with the lowest cost and risk. Although there can be considerable variation in the accuracy of duplex scanning among laboratories, certification programs are available that set standards for levels of performance and accuracy. Duplex ultrasound may be insensitive to differentiating high-grade stenosis from complete occlusion. MR angiography (MRA), with and without contrast, is also used as a noninvasive method for evaluating arterial anatomy and has the advantage of providing images of both the cervical and intracranial portions of the carotid artery and its proximal intracranial branches. MRA may overestimate the degree of stenosis, and as with duplex ultrasound, there may be errors when high-grade stenosis is differentiated

<sup>a</sup>Risk factors include AF, previous thromboembolism, left ventricular dysfunction, and hypercoagulable condition.

from complete occlusion. MR contrast material may cause debilitating nephrogenic systemic fibrosis in patients with renal dysfunction. When concordant, the combination of duplex ultrasound and MRA is more accurate than either test alone. Computed tomographic angiography is another means of identifying and measuring stenosis of the extracranial carotid artery. Similar to MRA, it has the advantage of being able to evaluate the intracranial circulation. Disadvantages of CT angiography include radiation exposure and the need for intravenous injection of contrast material. Atherosclerotic calcification may confound accurate measurement of stenosis with CT angiography.

A variety of vascular risk factors reviewed in this guideline are associated with carotid atherosclerosis. Carotid bruit can reflect an underlying carotid stenosis. However, the sensitivity for detecting carotid stenosis is low. In NOMAS, auscultation had a sensitivity of 56% and a specificity of 98%.

### **Endarterectomy for Asymptomatic Carotid Stenosis**

The first study with >1000 patients comparing CEA plus best medical therapy to medical therapy alone was the Asymptomatic Carotid Atherosclerosis Study (ACAS). The primary outcome was the composite of any stroke or death occurring in the perioperative period and ipsilateral cerebral infarction thereafter. During follow-up after 34 centers randomized 1662 patients, the Data and Safety Monitoring Committee called a halt to the trial because of a clear benefit in favor of CEA. Patients randomized to surgery had contrast angiography showing diameter-reducing lesions of  $\geq 60\%$  using the North American method of measurement. Both treatment groups received what at the time was considered best medical management. The aggregate risk over 5 years for ipsilateral stroke, any perioperative stroke, and death was 5.1% for the surgical patients and 11% for the medical patients (RR reduction, 53%; 95% CI, 22–72). The 30-day stroke morbidity and all-cause mortality for CEA were 2.3%, which included a 1.2% stroke complication rate for catheter angiography. It was suggested that the complications of angiography should be considered part of the risk of surgery because an angiogram would not have been performed if surgery were not contemplated. It should be noted that ACAS was conducted at a time when best medical management was limited to control of BP, the control of diabetes mellitus, and the use of daily aspirin. The value of statins and newer antiplatelet drugs had not been established.

The Asymptomatic Carotid Surgery Trial (ACST), carried out primarily in European centers, included 3120 patients with asymptomatic carotid stenoses of  $\geq 70\%$ , as measured by duplex ultrasonography. Subjects were randomized to immediate CEA versus indefinite deferral of the operation. The trial used endpoints different from those used in ACAS (perioperative stroke, MI or death, and nonperioperative stroke). The net 5-year risks were 6.4% in the immediate surgery group and 11.8% in the deferred surgery group for any stroke or perioperative death (net gain, 5.4%; 95% CI,

3.0–7.8;  $P < .0001$ ). In subgroup analysis, the benefits of CEA were confined to patients age <75 years.

The National Institute of Neurological Disorders and Stroke–sponsored Carotid Revascularization of Primary Prevention of Stroke (CREST-2) trial will be comparing centrally managed, intensive medical therapy with or without CEA.

Careful screening of surgeons participating in clinical trials might lead to results that cannot be generalized to the community. This is particularly evident when the complications from angiography are removed from the surgical group. When this is done, the 30-day rate of stroke and death for CEA in ACAS was 1.54%. The perioperative complication rate in ACST was 3.1%.

The results of CEA for asymptomatic patients were examined in the National Hospital Discharge Database for 2003 and 2004. The rate of the combination of stroke and death for CEA was 1.16%. This compares favorably with the rate of the combination of stroke and death for carotid artery stent/angioplasty during the same interval, which was 2.24%. These estimates, however, are based on administrative data and are limited to the procedural hospitalization. A 10-state survey of 30-day complication rates after CEA performed in asymptomatic patients a few years earlier found rates that varied from 1.4% (Georgia) to 6% (Oklahoma). Thus it would appear the perioperative complication rates for CEA found in the ACAS trial could be similar or better in the community; however, in at least some areas, rates may be higher. More recently, complication rates from the CREST trial were reported. CEA in asymptomatic patients carried a combined risk of stroke and death of 1.4%. In addition, a registry maintained by the Society for Vascular Surgery documented a 30-day postoperative combined rate of stroke and death of 1.35%. This rate among unselected surgeons was comparable to the rate seen among surgeons selected to participate in a trial.

### **Endovascular Treatment for Asymptomatic Carotid Stenosis**

Carotid angioplasty and stenting (CAS) is being performed more frequently. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial found that CAS was not inferior (within 3%;  $P = .004$ ) to endarterectomy (based on a composite outcome of stroke, MI, or death within 30 days or death resulting from neurologic cause or ipsilateral stroke between 31 and 365 days) in a group of patients considered to be at high risk for CEA. About 70% of the subjects had an asymptomatic stenosis, with rates of stroke, MI, or death of 5.4% with stenting and 10.2% with endarterectomy ( $P = .20$ ) at 30 days. At 1 year, the composite endpoint occurred in 9.9% of the CAS patients and 21.5% of the CEA patients ( $P = .02$ ). Three-year outcomes from the SAPPHERE trial showed that patients receiving CAS had a significantly higher death rate (20%) than stroke rate (10.1%), raising questions about the long-term value of the procedure in this high-risk cohort. In addition, there was no medically treated control group, and

the complication rates in both treatment arms were high enough to raise questions about the benefit of either intervention over medical therapy alone.

Several industry-supported registries have reported periprocedural complication rates of 2.1% to 8.3%. The lack of medically treated control groups makes the results of these registries difficult to interpret.

CREST enrolled both symptomatic and asymptomatic patients with carotid stenosis who could technically undergo either CEA or CAS. Asymptomatic patients could be included if they had a stenosis of  $\geq 60\%$  on angiography,  $\geq 70\%$  on ultrasonography, or  $\geq 80\%$  on CT angiography or MRA if the stenosis on ultrasonography was 50% to 69%. Randomization was stratified according to symptom status. The primary endpoint was a composite of stroke, MI, or death resulting from any cause during the periprocedural period or any ipsilateral stroke within 4 years after randomization. There was no difference in the estimated 4-year occurrence of the composite primary endpoint between stenting (7.2%) and endarterectomy (6.8%; HR, 1.11; 95% CI, 0.81–1.51;  $P = .51$ ), with no significant heterogeneity based on symptom status. CREST demonstrated an interaction of age on the primary endpoint, with age  $>70$  years showing a significant benefit for CEA over CAS. CAS had a higher periprocedural stroke/death rate for patients age  $>64$  years. Patient age may be among the factors to consider when choosing between the two procedures. The periprocedural rate of stroke was higher with CAS than with CEA (4.1% vs. 2.3%;  $P = .01$ ), and the periprocedural rate of MI was lower with CAS than with CEA (1.1% vs. 2.3%;  $P = .03$ ). In the periprocedural period, point estimates for the rates of any stroke or death among asymptomatic patients were low (2.5% in CAS vs. 1.4% for CEA; HR, 1.88; 95% CI, 0.79–4.42;  $P = .15$ ). The overall estimated 4-year rate of any periprocedural stroke or death or postprocedural ipsilateral stroke, however, was higher with stenting compared with endarterectomy (HR, 1.50; 95% CI, 1.05–2.15;  $P = .03$ ). Although the trial was not powered to evaluate symptomatic and asymptomatic patients separately, there was a trend favoring CEA over CAS in both the symptomatic (HR, 1.37; 95% CI, 0.90–2.09;  $P = .14$ ) and asymptomatic (HR, 1.86; 95% CI, 0.95–3.66;  $P = .07$ ) groups. Post hoc analysis found that major and minor stroke negatively affected quality of life at 1 year (Short Form-36, physical component scale), with minor stroke affecting mental health at 1 year (Short Form-36, mental component scale), but the effect of periprocedural MI did not negatively affect quality of life. Having MI or stroke, including minor stroke, was associated with a higher mortality rate.

The advantage of revascularization over medical therapy by itself was not addressed by CREST, which did not randomize a group of asymptomatic subjects to medical therapy without revascularization. Hospital costs for CAS tend to be greater than for CEA. The National Institute of Neurological Disorders and Stroke–sponsored CREST-2 trial will be comparing centrally managed, intensive medical therapy with or without carotid stenting with embolic protection.

### Screening of Asymptomatic Carotid Stenosis

Although carotid artery stenosis is a risk factor for stroke, not every carotid stenosis carries the same risk for future stroke. There have been attempts to identify those patients with carotid stenosis who are at high risk for future events. Two methods have shown promise. The first method uses transcranial Doppler (TCD) to count the number of presumed embolic events, known as high-intensity transient signals per unit time. Although this technique has shown that patients with frequent high-intensity transient signals have a higher subsequent stroke rate than those without high-intensity transient signals, the test is time consuming to perform and has not received uniform acceptance. In addition, the effect of intensive medical therapy on high-intensity transient signals has not been adequately assessed. Another method of study uses plaque analysis in a computerized algorithm using B-mode insonation of the carotid plaque. Population screening for asymptomatic carotid artery stenosis is not recommended by the USPSTF, which found “no direct evidence that screening adults with duplex ultrasonography for asymptomatic stenosis reduces stroke.”

### Asymptomatic Carotid Stenosis: Summary and Gaps

Medical therapy has advanced since clinical trials have been completed comparing endarterectomy plus best medical therapy with best medical therapy alone in patients with an asymptomatic carotid artery stenosis. Recent studies suggest that the annual rate of stroke in medically treated patients with an asymptomatic carotid artery stenosis has fallen to  $\leq 1\%$ . In the ACST, the rate of absolute benefit from CEA per year was lower in patients on lipid-lowering therapy (0.6%/year) compared with patients not on lipid-lowering therapy (1.5%/year). ACST had no explicit targets for LDL, and intensive targets (e.g., LDL  $<70$  mg/dL) may further reduce the benefit of revascularization. Statin therapy is appropriate for patients with asymptomatic carotid stenosis, whether or not they undergo revascularization.

Interventional therapy has also advanced, particularly in terms of perioperative management and device design. Because the absolute reduction in stroke risk with CEA in patients with an asymptomatic stenosis is small, however, the benefit of revascularization may be reduced or eliminated with current medical therapy. The benefit of CEA for carotid stenosis in asymptomatic women remains controversial. Given the reported 30-day, 1-year, and 3-year results in the high-surgical-risk population, it remains uncertain whether this group of asymptomatic patients should have any revascularization procedure. More data are needed to compare long-term outcomes after CEA and CAS. Currently, the Centers for Medicare & Medicaid Services cover CAS for asymptomatic stenosis only in patients with  $>80\%$  stenosis at high risk for CEA who are participating in post-market approval studies.

For patients with asymptomatic carotid stenosis who defer revascularization, periodic reassessment of degree of stenosis may be helpful in identifying patients at higher

risk of stroke. A retrospective ultrasound-based study of the deferred surgery arm of the ACST trial found that patients who had carotid stenosis that worsened in 1 year by one stenosis category did not have an increased risk of ipsilateral ischemic events, with categories being 0% to 49%, 50% to 69%, 70% to 89%, 90% to 99%, and 100%. Patients who had a progression of more than two categories in 1 year were at high risk of ipsilateral ischemic events relative to nonprogressors.

The recommendations below reflect current best evidence. However, modern optimal medical therapy may obviate the need for carotid revascularization. The balance of risks and benefits of revascularization in the setting of modern optimal medical therapy is being assessed in ongoing multicenter clinical trials in the United States and elsewhere.

### **Asymptomatic Carotid Stenosis: Recommendations**

1. Patients with asymptomatic carotid stenosis should be prescribed daily aspirin and a statin. Patients should also be screened for other treatable risk factors for stroke, and appropriate medical therapies and lifestyle changes should be instituted.
2. In patients who are to undergo CEA, aspirin is recommended perioperatively and postoperatively unless contraindicated.
3. It is reasonable to consider performing CEA in asymptomatic patients who have >70% stenosis of the internal carotid artery if the risk of perioperative stroke, MI, and death is low (<3%). However, its effectiveness compared with contemporary best medical management alone is not well established.
4. It is reasonable to repeat duplex ultrasonography annually by a qualified technologist in a certified laboratory to assess the progression or regression of disease and response to therapeutic interventions in patients with atherosclerotic stenosis >50%.
5. Prophylactic CAS might be considered in highly selected patients with asymptomatic carotid stenosis (minimum, 60% by angiography, 70% by validated Doppler ultrasound), but its effectiveness compared with medical therapy alone in this situation is not well established.
6. In asymptomatic patients at high risk of complications for carotid revascularization by either CEA or CAS, the effectiveness of revascularization versus medical therapy alone is not well established.
7. Screening low-risk populations for asymptomatic carotid artery stenosis is not recommended.

### **Sickle Cell Disease**

Sickle cell disease (SCD), an autosomal-recessive disorder in which the abnormal gene product is an altered hemoglobin  $\beta$ -chain, typically manifests very early in life. Signs and symptoms associated with SCD are the result of chronic anemia or acute vasoocclusive crises, most commonly

manifesting as painful episodes. Complications of SCD include acute chest syndrome, pulmonary hypertension, bacterial infections, and organ infarctions, especially stroke. Other effects include cognitive deficits related to MRI-demonstrated strokes and otherwise asymptomatic white matter hyperintensities.

Stroke is a major complication of SCD, with the highest stroke rates occurring in early childhood. The prevalence of stroke by age 20 years is at least 11%, with a substantial number of strokes being silent strokes on brain MRI. Stroke prevention is most important for patients with homozygous SCD because the majority of the SCD-associated strokes occur in these patients. TCD ultrasound identifies those at high risk of stroke, allowing evidence-based decisions about optimal primary stroke prevention. Although the exact mechanism by which high blood flow velocities increase the risk for ischemic stroke is not known, the association is well established. The risk of stroke during childhood in those with SCD is 1% per year, but patients with TCD evidence of high cerebral blood flow velocities (time-averaged mean velocity >200 cm/s) have stroke rates >10% per year. Retrospective analysis of the Stroke Prevention Trial in Sickle Cell Anemia (STOP) data suggested that velocity >170 cm/s in the anterior cerebral artery is associated with increased stroke risk after controlling for the middle cerebral artery/internal carotid artery velocities. TCD surveillance of children with SCD remains the gold standard for stroke risk prediction, and its increased use coincides with a decrease in stroke among the pediatric SCD population.

The optimal frequency of screening to detect patients at high risk has not been determined. The STOP study, which compared periodic blood transfusion with standard care in 130 children with SCD, used time-averaged means of the maximum velocity. In addition, peak systolic velocity may be used, in which case a measurement of 250 cm/s is used as a threshold for prophylactic transfusion. In general, younger children and those with relatively high cerebral blood flow velocities should be monitored more frequently because of a higher risk of conversion to abnormal velocities in younger patients and in those with TCD velocities closer to 200 cm/s. Despite strong evidence of its value, overall TCD screening rates continue to be suboptimal as a result of patient and provider factors. The National Institutes of Health and the American Academy of Pediatrics recommend annual TCD screening from age 2 to 16 years.

Few studies have been done to determine whether TCD also predicts stroke in adults with SCD. One study comparing TCD velocities in SCD adults with those of healthy control subjects found that velocities in SCD adults were lower than those found in children, higher than in healthy control subjects, and negatively correlated with the hematocrit in both SCD groups. Another study found no examples of high TCD (>200 cm/s) in adults with SCD. The mean velocity was 110 cm/s, which is higher than in normal adults but lower than in children with SCD. At present, there are no validated TCD criteria for predicting stroke in adults with SCD.

Although TCD remains the most extensively validated stroke prediction tool, other clinical characteristics are also associated with increased risk of stroke. One study found that nocturnal desaturation predicted neurologic events in 95 patients with SCD (median age, 7.7 years; range, 1 to 23 years) followed up for a median of 6 years. There were seven strokes among 19 individuals with events. Mean overnight oxygen saturation and TCD independently predicted events. Nocturnal oxygen desaturation appears to place children at risk for developing executive dysfunction, which was not associated with MRI-demonstrable infarcts. There is no proven therapy for the cognitive impairment associated with nocturnal desaturation.

MRI has also been used to identify children with SCD who are at high risk of stroke. The Cooperative Study of Sickle Cell Disease, which preceded the use of TCD-based monitoring, found that 8.1% of children with an asymptomatic MRI lesion versus 0.5% of those with a normal MRI had a stroke during the ensuing 5 years. The Silent Cerebral Infarct Multicenter Clinical Trial (SIT), a randomized, controlled trial MRI-guided prophylactic transfusion, found that regular blood transfusion significantly reduced the incidence of the recurrence of cerebral infarction in children with sickle cell anemia. In a cohort of 67 patients with indication for cervical internal carotid artery MRA, 15% of patients had occlusions or stenoses. The role of cervical MRA in stroke risk prediction remains undefined.

Additional clinical features identify children at risk for developing elevated TCD velocities and stroke. Glucose-6-phosphate dehydrogenase (G6PD) deficiency, absence of  $\alpha$ -thalassemia (OR, 6.45; 95% CI, 2.21–18.87;  $P = .001$ ), hemoglobin levels (OR, 0.63 per 1 g/dL; 95% CI, 0.41–0.97;  $P = .038$ ), and lactate dehydrogenase levels (OR, 1.001 per 1 IU/L; 95% CI, 1.000–1.002;  $P = .047$ ) are independent risk factors for abnormally high velocities. This confirmed a previously reported protective effect of  $\alpha$ -thalassemia and found for the first time that G6PD deficiency and hemolysis independently increased the risk of abnormal TCD. Another study found independent effects of hemoglobin and aspartate transaminase levels on TCD velocities, whereas age had an unclear association. Several recent studies of children with SCD identified increased lactate dehydrogenase concentrations and baseline reticulocyte counts to be predictive of stroke and elevated plasma glial fibrillary acidic protein concentrations to be predictive of cognitive impairment, suggesting subclinical injury. Markers of systemic inflammation such as interleukin-1 $\beta$  also have been associated with stroke risk. A future process that integrates blood biomarkers and TCD blood flow findings may identify children at greatest risk.

Other genetic factors also affect stroke risk in patients with SCD. A study evaluated 108 single nucleotide polymorphisms (SNPs) in 39 candidate genes in 1398 individuals with SCD using Bayesian networks and found that 31 SNPs in 12 genes interact with fetal hemoglobin to modulate the risk of stroke. This network of interactions includes three genes in the transforming growth factor- $\beta$  pathway

and selectin P, which is associated with stroke in the general population. The model was validated in a different population, predicting the occurrence of stroke in 114 individuals with 98.2% accuracy. STOP data were used to confirm previous findings of associations between the tumor necrosis factor (-308) G/A, IL4R 503 S/P, and ADRB2 27 Q/E polymorphisms and risk of large-vessel stroke in SCD. Consistent with prior findings, the tumor necrosis factor (-308) GG genotype increased the risk of large-vessel disease by >3-fold (OR, 3.27; 95% CI, 1.6–6.9;  $P = .006$ ). Unadjusted analyses also showed a previously unidentified association between the leukotriene C4-synthase (-444) A/C variant and risk of large-vessel stroke. The Stroke With Transfusions Changing to Hydroxyurea (SWiTCH) study found that of the 38 candidate SNPs in 22 genes studied, five polymorphisms had significant influence on stroke risk; SNPs in the *ANXA2*, *TGFBR3*, and *TEK* genes were associated with increased stroke risk, and  $\alpha$ -thalassemia and an SNP in the *ADCY9* gene was linked to decreased stroke risk. The SIT trial found that two variations in the *G6PD* gene that are linked to reduced enzymatic function, rs1050828 and rs1050829, were associated with vasculopathy in male participants with SCD (OR, 2.78; 95% CI, 1.04–7.42;  $P = .04$ ). Further validation of these findings is required before these genetic variations can be used for stroke risk prediction.

Periodic red cell transfusion is the only intervention proven in randomized trials to prevent stroke in patients with SCD. STOP randomized children with SCD who had abnormal high-risk TCD profiles to either standard care, which included episodic transfusion as needed for pain, or periodic red cell transfusion an average of 14 times per year for >2 years with a target reduction of hemoglobin S from a baseline of >90% to <30%. The risk of stroke was reduced from 10% per year to <1% per year. Unless exchange methods in which blood is removed from the patient with each transfusion are used, long-term transfusion results in iron toxicity that requires treatment with chelation. In STOP, there was no evidence of transfusion-related infection, but iron overload and alloimmunization remain important transfusion risks. To address these risks, STOP II tested whether long-term transfusions for primary stroke prevention could be safely discontinued after at least 30 months (range, 30–91 months) in children who had not had an overt stroke and who had reversion to low-risk TCD velocities (time-averaged mean velocity in middle cerebral or internal carotid artery, <170 cm/s) with long-term transfusion therapy. The study endpoint was the first occurrence of reversion of TCD to abnormal confirmed by  $\geq 2$  TCDs with mean velocities of  $\geq 200$  cm/s or stroke. The study was terminated earlier than planned when an interim analysis showed worse outcomes with discontinuation of transfusion therapy. Eight children ( $\approx 20\%$ ) tolerated removal from long-term transfusion therapy, but there was a high TCD reversion rate and a small risk of stroke despite frequent TCD surveillance. Further analyses from STOP II also demonstrated increased rates of silent infarcts on MRI

in the discontinuation group (27.5% vs. 8.1%;  $P = .03$ ). Primary stroke prevention for children with SCD remains centered on red cell transfusions.

Therapies other than transfusion such as hydroxyurea or bone marrow transplantation that reduce the number of painful crises have an uncertain effect on organ damage, including stroke. Of the 127 children with SCD enrolled in the Belgian Hydroxyurea SCD registry, 72 patients were evaluated by TCD. Of these 72, 34 were found at risk of stroke, and only 1 had a cerebrovascular event after a follow-up of 96 patient-years, suggesting a benefit of hydroxyurea in stroke prevention. A study of 291 children with SCD included clinical and imaging follow-up of 35 children with abnormal TCDs who were placed on transfusion therapy (median follow-up, 4.4 years). Of 13 patients with normalized velocities on transfusion, 10 had normal MRAs, and transfusion therapy was replaced with hydroxyurea. Four of these 10 patients redeveloped high velocities, so only 6 remained transfusion free. In another study, the adjusted mean change in TCD velocities was  $-13.0$  cm/s (95% CI,  $-20.19$  to  $-5.92$ ) in a hydroxyurea-treated group and  $4.72$  cm/s (95% CI,  $-3.24$  to  $12.69$ ) in control subjects ( $P < .001$ ). In a study of 59 initiating hydroxyurea therapy for severe vasoocclusive complications who had pretreatment baseline TCD measurements, 37 had increased time-averaged maximum velocities  $\geq 140$  cm/s and were enrolled in a trial with TCD velocities measured at maximum tolerated dose and 1 year later. At the hydroxyurea maximum tolerated dose (mean  $\pm$  standard deviation =  $27.9 \pm 2.7$  mg/kg per day), decreases were observed in bilateral middle cerebral artery velocities. The magnitude of the TCD velocity decline correlated with the maximal baseline TCD value. Most recently, the phase III Pediatric Hydroxyurea Clinical Trial (BABY HUG) demonstrated significantly lower increases in TCD velocities in the hydroxyurea group, but neurocognitive testing of the infants was not statistically different between groups. The SWiTCH study, a phase III noninferiority trial comparing standard treatment (transfusions/chelation) with alternative treatment (hydroxyurea/phlebotomy) for children with sickle cell anemia, stroke, and iron overload, was stopped for safety reasons when adjudication documented no strokes in patients on transfusions/chelation but a 10% stroke rate in patients on hydroxyurea/phlebotomy. Hydroxyurea therapy for stroke prevention is promising for primary stroke prevention but requires additional study. Results from the ongoing Transcranial Doppler With Transfusions Changing to Hydroxyurea (TWiTCH) trial may provide greater insight into the benefit of hydroxyurea in stroke prevention.

Bone marrow transplantation is usually entertained after stroke, but TCD and other indexes of cerebral vasculopathy have also been used as an indication for myeloablative stem-cell transplantation. One study of 55 patients with a median follow-up of 6 years found overall and event-free survival rates of 93% and 85%, respectively. No new ischemic lesions were reported, and TCD velocities decreased. In a study of 55 children who underwent bone marrow

transplantation for severe SCD, 16 patients without prior stroke and unremarkable MRI before bone marrow transplantation had no clinical or silent stroke on follow-up, and the 10 patients with prior silent ischemia had no further events. Bone marrow transplantation is promising for primary stroke prevention but requires additional study.

No trial has been done on the primary prevention of stroke in adults with SCD. Improvements in care have increased life expectancy in people with SCD, and it is anticipated that stroke prophylaxis in older patients with SCD will pose an increasing challenge in the future.

### Sickle Cell Disease: Recommendations

1. TCD screening for children with SCD is indicated starting at age 2 years and continuing annually to age 16 years. (Class I; Level of Evidence B)
2. Transfusion therapy (target reduction of hemoglobin S,  $<30\%$ ) is effective for reducing stroke risk in those children at elevated risk.
3. Although the optimal screening interval has not been established, it is reasonable for younger children and those with borderline abnormal TCD velocities to be screened more frequently to detect the development of high-risk TCD indications for intervention.
4. Pending further studies, continued transfusion, even in those whose TCD velocities revert to normal, is probably indicated.
5. In children at high risk for stroke who are unable or unwilling to be treated with periodic red cell transfusion, it might be reasonable to consider hydroxyurea or bone marrow transplantation.
6. MRI and MRA criteria for selection of children for primary stroke prevention with transfusion have not been established, and these tests are not recommended in place of TCD for this purpose.
7. Less well-documented or potentially modifiable risk factors.

### Migraine

Migraine headache has been most consistently associated with stroke in young women, especially those with migraine with aura. A metaanalysis of 21 studies (13 case-control and 8 cohorts) reported an overall pooled RR of 2.04 (95% CI, 1.72–2.43). The risk was greater in migraine with aura (pooled adjusted OR for 7 studies, 2.51; 95% CI, 1.52–4.14) compared with the association of ischemic stroke and migraine without aura (pooled adjusted OR for 6 studies, 1.29; 95% CI, 0.81–2.06). A second metaanalysis of 9 studies (6 case-control and 3 cohorts) reported a pooled RR of 1.73 (95% CI, 1.31–2.29) between any migraine and ischemic stroke. This study also found a significantly higher risk of stroke among individuals with migraine with aura (RR, 2.16; 95% CI, 1.53–3.03) compared with individuals with migraine without aura (RR, 1.23; 95% CI, 0.90–1.69; metaregression for aura status,  $P = .02$ ). Furthermore, there was a significant risk among women (RR,

2.08, 95% CI, 1.13–3.84) but not among men (RR, 1.37; 95% CI, 0.89–2.11). Age <45 years, especially in women (RR, 3.65; 95% CI, 2.21–6.04), smoking (RR, 9.03; 95% CI, 4.22–19.34), and OC use (RR, 7.02; 95% CI, 1.51–32.68) further increased the risk. Both metaanalyses are in general agreement with prior studies. Counseling on possible alternative forms of birth control other than OCs in women with migraine may lower the risk of stroke, but this recommendation should be placed in the context of overall health implications of such a change.

The WHS, a primary prevention trial of women age  $\geq 45$  years and free of CVD at enrollment, continues to inform the association between women with migraine and stroke. After a mean follow-up of 11.9 years, multivariable-adjusted analysis found that high migraine frequency (more than weekly) had an increased association with ischemic stroke (HR, 2.77; 95% CI, 1.03–7.46) but not in lower frequencies. When migraine aura status was taken into account, a significant association of migraine frequency was found only in the migraine with aura group (HR, 4.25; 95% CI, 1.36–13.29). From this analysis, increased frequency of attacks in migraine with aura appears to increase the risk for ischemic stroke. However, caution in overly interpreting these results is needed because the incident numbers for these subgroup analyses were small. In a separate analysis of the WHS, the association of migraine with aura and ischemic stroke was found to be more pronounced in the absence (HR, 3.27; 95% CI, 1.93–5.51) than in the presence (HR, 0.91; 95% CI, 0.43–1.93) of nausea/vomiting. Overall, the WHS found that increased frequency in patients with migraine with aura increases ischemic stroke risk and that this increased risk is more pronounced in the absence of typical migraine features.

The WHS also investigated the association between migraines and ICH. Although there was no increased risk of ICH in those who reported any history of migraine compared with those without a history of migraine (HR, 0.98; 95% CI, 0.56–1.71), there was an increased risk for ICH in women with active migraine with aura (HR, 2.25; 95% CI, 1.11–4.54). The age-adjusted increased risk was stronger for ICH (HR, 2.78; 95% CI, 1.09–7.07) and for fatal events (HR, 3.56; 95% CI, 1.23–10.31). From this study, it is estimated that four additional ICH events are attributable to migraine with aura per 10,000 women per year. Women who reported active migraine without aura had no increased risk for ICH. This increase in risk for ICH for women with migraine with aura, but not for women with migraine without aura, was similar to the increased risk found with ischemic strokes.

The association of migraine in middle-aged to late-life infarct-like lesions on imaging was studied in a Reykjavik, Iceland, population-based cohort. After multivariable adjustment, midlife migraine with aura had an increased risk of late-life infarct-like lesions (OR, 1.4; 95% CI, 1.1–1.8). This was particularly reflected by an association with cerebellar lesions in women (OR, 1.9; 95% CI, 1.4–2.6), but not in men, with migraine with aura (OR, 1.0; 95% CI,

0.6–1.8). Migraine without aura and nonmigraine headache were not associated with an increased risk. Therefore similar to the risk for ischemic stroke found in women with migraine with aura in the WHS, in this Icelandic population, women with migraine with aura had an increased risk for late-life ischemic lesions as seen on brain MRI; however this association was not appreciated in men or in those with migraine without aura or nonmigraine headaches. Overall, the Icelandic study is in agreement with the previous studies, including the Cerebral Abnormalities in Migraine, an Epidemiological Risk Analysis study, which found that, on the basis of MRI, migraineurs with aura had higher prevalence of subclinical infarcts in the posterior circulation (OR, 13.7; 95% CI, 1.7–112), with female migraineurs at an independent increased risk of white matter lesions (OR, 2.1; 95% CI, 1.0–4.1). The mechanism and relevance of the migraine–brain lesion association are unclear. In one cohort study based on MRA, there was a significant association between anatomic variants of the circle of Willis and both migraines without aura (OR, 2.4; 95% CI, 1.5–3.9) and migraines with aura (OR, 3.2; 95% CI, 1.6–4.1). Unilateral posterior variants with basilar hypoplasia were statistically associated only with migraines with aura (OR, 9.2; 95% CI, 2.3–37.2). However, there was no statistical association between the presence of circle of Willis variants and ischemic lesions on MRI (OR, 1.5; 95% CI, 0.68–1.94) or with infratentorial lacunar lesions (OR, 1.58; 95% CI, 0.48–5.24). The relationship between these vascular anatomic variants in migraineurs to ischemic strokes is unclear.

Once considered a disease of cerebral blood vessels, recent experimental and clinical data have indicated that migraine results from a complex interaction of several converging pathogenic factors. These include disturbance of cortical excitability, cortical spreading depression, meningeal inflammation, and activation of the trigeminovascular system. However, factors contributing to the increased risk of stroke with migraine remain elusive. Clinical-epidemiologic studies have suggested several mechanisms. In one prospective study of patients age <55 years, hypercoagulable states were more frequent in the migraine than the nonmigraine group (38.6% vs. 16.4%;  $P < .01$ ). Multivariate analysis showed that migraine without aura was associated with a 2.88-fold increased risk for hypercoagulable diagnosis (95% CI, 1.14–7.28), but in the group with brain infarcts who were age <50 years, only migraine with aura was independently associated with hypercoagulable states (OR, 6.81; 95% CI, 1.01–45.79). The Stoke Prevention in Young Women Study reported a 50% increased risk of ischemic stroke in those with probable migraine and visual aura (OR, 1.5; 95% CI, 1.1–2.0). Interrelationships among the ACE deletion/insertion (D/I) polymorphism (rs1799752), migraine, and CVD, including ischemic stroke, were investigated in the WHS cohort. The increased risk for CVD among migraineurs with aura was apparent only for carriers of the DD (RR, 2.10; 95% CI, 1.22–3.59;  $P = .007$ ) and DI (RR, 2.31; 95% CI, 1.52–3.51) genotypes, suggesting that the DD/DI genotype may play a role in, or at least be

a marker for, this complex association. However, because of the small numbers, further studies are warranted.

Perhaps the most heavily investigated potential mechanistic link between migraine and stroke is the association of migraine and PFO. Initial studies found that PFOs are more common in young patients with cryptogenic stroke and those with migraine, particularly migraine with aura. The speculated relationship between PFO and migraine includes microemboli that flow through the PFO, causing brain ischemia and thereby triggering migraine. The Migraine Intervention with STARFlex Technology trial, a randomized, double-blind, sham-controlled trial, showed no benefit of PFO closure on the cessation of migraine headaches (primary outcome; 3 of 74 vs. 3 of 73;  $P = .51$ ). There is much controversy concerning the results of this trial, and it was not designed to evaluate the primary prevention of stroke in patients with migraines with aura. Furthermore, recent studies have found a lack of association between migraine and PFO in a large population-based study among elderly individuals, in a hospital-based case-control study, and in a recent metaanalysis, placing some doubt on whether PFO has a causal role in migraines.

In terms of primary prevention of stroke in patients with migraine, aspirin reduced risk of ischemic stroke (RR, 0.76; 95% CI, 0.63–0.93) but no other clinical atherothrombotic endpoints in the WHS group. In subgroup analyses, the protective effect of aspirin on ischemic stroke was similar among women with or without migraines. However, women with migraine with aura on aspirin had an increased risk of MI (RR, 3.72; 95% CI, 1.39–9.95), primarily women with history of smoking or hypertension. The clinical significance of this increased risk for this subgroup is unclear because of small numbers.

### Migraine: Recommendations

1. Smoking cessation should be strongly recommended in women with migraine headaches with aura.
2. Alternatives to OCs, especially those containing estrogen, might be considered in women with active migraine headaches with aura.
3. Treatments to reduce migraine frequency might be reasonable to reduce the risk of stroke.
4. Closure of PFO is not indicated for preventing stroke in patients with migraine.

### Metabolic Syndrome

The National Cholesterol Education Program (Adult Treatment Panel III) originally defined metabolic syndrome as the presence of  $\geq 3$  of the following: (1) abdominal obesity as determined by waist circumference  $>102$  cm ( $>40$  in) for men and  $>88$  cm ( $>35$  in) for women; (2) triglycerides  $\geq 150$  mg/dL; (3) HDL cholesterol  $<40$  mg/dL for men and  $<50$  mg/dL for women; (4) BP  $\geq 130/\geq 85$  mm Hg; and (5) fasting glucose  $\geq 110$  mg/dL. A modified criterion for fasting glucose was published in 2004. The International Diabetes Foundation (IDF) then modified the definition by requiring

inclusion of a waist circumference  $>88$  cm for men and  $>80$  cm in women plus 2 of the other National Cholesterol Education Program–Adult Treatment Panel III criteria. In 2009 a harmonized definition was proposed wherein an identical set of thresholds was used for all components except waist circumference, an area in which further evidence for the relationship to CVD events was felt to be required. In the interim, the Harmonized Definition Work Group suggested that national or regional cut points for waist circumference should be used. Thus because the waist circumference and risk for CVD and diabetes mellitus vary around the world, the National Cholesterol Education Program–Adult Treatment Panel III, IDF, and harmonized definitions all make a provision for an ethnic/racial/geographic modification of waist circumference. Obesity and sedentary lifestyle, in addition to other genetic or acquired factors, seem to interact to produce the metabolic syndrome. Screening for the syndrome requires no more than a routine physical examination and routine blood tests.

Obesity, discussed separately, is an important component of the metabolic syndrome and is associated with major health risk factors (such as diabetes mellitus, hypertension, and dyslipidemia), poor health status, and, when extreme, lower life expectancy. The visceral adiposity characteristic of the metabolic syndrome is associated with insulin resistance, inflammation, diabetes mellitus, and other metabolic and cardiovascular derangements. Visceral adipocytes provoke insulin resistance by promoting extensive lipolysis and release of fatty acids into the splanchnic circulation. Leptin, plasminogen activator inhibitor-1, tumor necrosis factor- $\alpha$ , and other proinflammatory cytokines, in addition to reduced production and release of adiponectin by adipocytes, have all been implicated in this pathophysiologic process.

The metabolic syndrome is highly prevalent in the United States. Applying the harmonized definition of the metabolic syndrome to data from the National Health and Nutrition Examination (2003–2006) in up to 3461 participants age  $\geq 20$  years with a waist circumference threshold of  $\geq 102$  cm for men and  $\geq 88$  cm for women, the age-adjusted prevalence of metabolic syndrome was 34.3% among all adults, 36.1% among men, and 32.4% among women. With the use of race-specific or ethnicity-specific IDF criteria for waist circumference, the age-adjusted prevalence was 38.5% for all participants, 41.9% for men, and 35% for women. Prevalence increased with age, with the highest prevalence in subjects between age 60 to 69 years. Prevalence was lower among black men than white or Mexican-American men and lower among white women than among black or Mexican-American women. Mostly attributable to the obligatory use of a lower waist circumference for the IDF, the IDF definition led to higher estimates of prevalence in all demographic groups, especially among Mexican-American men.

Hyperinsulinemia/insulin resistance is an important marker of the metabolic syndrome; however, results concerning a relationship between glucose intolerance and stroke risk are conflicting. In 18,990 men and women who

were screened for entry into the Diabetes Reduction Assessment with Ramipril and Rosiglitazone Medication trial from 21 different countries, 8000 subjects were normoglycemic, 8427 had impaired fasting glucose or impaired glucose tolerance, and 2563 had newly diagnosed type 2 diabetes mellitus. Among all subjects, an 18-mg/dL increase in fasting plasma glucose or a 45-mg/dL increase in the 2-hour glucose after an oral glucose tolerance test was associated with an increase in cardiovascular events, including stroke or death (HR, 1.17; 95% CI, 1.13–1.22). The relationships between other individual components of the metabolic syndrome and stroke risk, including elevated BP, are reviewed in other sections of this guideline.

The metabolic syndrome is a predictor of CVD and vascular death; however, this risk does not appear to be any larger than the sum of the components of the syndrome. A similar lack of greater predictability is true for the metabolic syndrome and stroke. This lack of relationship may be because of sample size or a small number of stroke events. In the National Health and Nutrition Examination Survey, among 10,357 subjects, the prevalence of metabolic syndrome was higher in people with self-reported history of stroke (43.5%) than in those with no history of stroke or myocardial infarct (22.8%;  $P \leq .001$ ). The metabolic syndrome was independently associated with stroke history in all ethnic groups and in both sexes (OR, 2.16; 95% CI, 0.48–3.16). The association between metabolic syndrome and stroke has been confirmed in other populations, including those enriched with elderly subjects, and the frequency of the metabolic syndrome was notably higher in patients with a history of nonhemorrhagic stroke but also in Korean patients with spontaneous ICH. The adjusted RRs for ischemic stroke associated with the metabolic syndrome in prospective studies have ranged between 2.1 and 2.47, and an HR as high as 5.15 has been reported. This predictive capacity does not appear to be influenced by the definition used for the metabolic syndrome and showed no significant variation across sex, age, or ethnic groups. Yet, in the Stroke Prevention by Aggressive Reduction in Cholesterol Levels trial, the 642 subjects with the metabolic syndrome and a previous stroke or TIA did not experience an increased risk of stroke. Although many studies have used more than one definition of the metabolic syndrome to assess the risk for stroke, the harmonized definition may prove to be superior in establishing the relationship.

There are essentially no trial data that have addressed the effects of treatment on cardiovascular morbidity and mortality in patients with the metabolic syndrome. In the JUPITER trial, 17,802 healthy men and women with LDL cholesterol levels  $<130$  mg/dL and hs-CRP levels  $\geq 2$  mg/L were randomized to receive rosuvastatin 20 mg daily or placebo and followed up for the occurrence of the combined primary endpoint of MI, stroke, arterial revascularization, hospitalization for unstable angina, or death resulting from cardiovascular causes. The rates were reduced by a hazard ratio of 0.56 (95% CI, 0.46–0.69) for the primary endpoint, 0.46 (95% CI, 0.30–0.70) for MI, and 0.52 (95%

CI, 0.34–0.79) for stroke. Patients with or without the metabolic syndrome had similar reductions in CVD events. The TNT study included 10,001 patients with clinically evident coronary heart disease. Treating to an LDL cholesterol substantially  $<100$  mg/dL with a high dose of a high-potency statin reduced both stroke and cardiovascular events by an additional 20% to 25% compared with a lower dose. Of these subjects, 5584 patients with the metabolic syndrome were randomly assigned to a high-dose or low-dose statin. As expected, the higher dose led to greater reductions in LDL cholesterol (73 vs. 99 mg/dL at 3 months). Regardless of treatment assignment, more patients with the metabolic syndrome (11.3%) had a major cardiovascular event than those without the metabolic syndrome (8.0%, HR, 1.44; 95% CI, 1.26–1.64;  $P < .0001$ ). At a median follow-up of 4.9 years, major cardiovascular events occurred in 13% patients receiving the low-dose statin compared with 9.5% receiving the higher dose (HR, 0.71; 95% CI, 0.61–0.84;  $P < .0001$ ), and cardiovascular events were reduced by 26% (HR, 0.74; 95% CI, 0.59–0.93;  $P = .011$ ).

### Metabolic Syndrome: Recommendations

Management of individual components of the metabolic syndrome is recommended, including lifestyle measures (i.e., exercise, appropriate weight loss, proper diet) and pharmacotherapy (i.e., medications for BP lowering, lipid lowering, glycemic control, and antiplatelet therapy).

### Alcohol Consumption

The National Institute on Alcohol Abuse and Alcoholism defines heavy drinking for a man as  $>4$  drinks in any single day or  $>14$  drinks per week and defines heavy drinking for a woman as  $>3$  drinks any single day and  $>7$  drinks per week. A standard drink is defined as 12 fl oz of regular beer, 5 fl oz of table wine, or a 1.5-fl oz shot of 80-proof spirits. Heavy alcohol consumption can lead to multiple medical complications, including stroke. Heavy alcohol consumption is a risk factor for all types of stroke. Most studies suggest a J-shaped association between alcohol consumption and the risk of total and ischemic stroke, with a protective effect in light ( $<151$  g/week) or moderate (151 to 300 g/week) drinkers and an elevated risk with heavy ( $>300$  g/week) alcohol consumption. In contrast, a linear association exists between alcohol consumption and the risk of ICH. In a prospective cohort study of 540 patients with spontaneous ICH, heavy alcohol intake was associated with ICH at a young age (median age, 60 vs. 74 years in nonabusers;  $P < .001$ ).

Light-to-moderate alcohol consumption is associated with higher levels of HDL cholesterol, reduced platelet aggregation, lower fibrinogen concentration, and increased insulin sensitivity and glucose metabolism. Heavy alcohol consumption can result in hypertension, hypercoagulability, reduced cerebral blood flow, and an increased risk of AF. Studies show an increased risk for stroke in hypertensive patients who consume alcohol, as well as poor BP control in heavy drinkers with hypertension.

A study of 43,685 men from the Health Professionals Follow-Up Study and 71,243 women from the Nurses' Health Study showed that alcohol intake had a J-shaped association for risk of stroke. A lower risk for stroke was found in women who were light drinkers, but women who drank  $\geq 30$  g alcohol per day had a 40% increased risk for stroke (RR, 1.41; 95% CI, 1.07–1.88 for ischemic stroke; RR, 1.40; 95% CI, 0.86–2.28 for ICH). There was a similar but nonsignificant pattern for men. In the WHS, alcohol consumption was not associated with risk for stroke, even for  $\geq 10.5$  drinks per week. However, a recent metaanalysis showed a higher mortality risk for women compared with men who drank  $>3$  drinks per day.

A prospective study of Chinese men supports the association between heavy alcohol and risk for stroke. A 22% increase in stroke occurred for those consuming at least 21 drinks per week, whereas consumption of 1 to 6 drinks per week was associated with the lowest risk. In a metaanalysis of 35 observational studies, consumption of 60 g alcohol per day was associated with a 64% increased risk for all stroke (RR, 1.64; 95% CI, 1.39–1.93), a 69% increase for ischemic stroke (RR, 1.69; 95% CI, 1.34–2.15), and more than doubling for hemorrhagic stroke (RR, 2.18; 95% CI, 1.48–3.20). Consumption of  $<12$  g/day was associated with a reduced risk of total (RR, 0.83; 95% CI, 0.75–0.91) and ischemic (RR, 0.80; 95% CI, 0.67–0.96) stroke, with consumption of 12 to 24 g/day associated with a lower risk of ischemic stroke (RR, 0.72; 95% CI, 0.57–0.91). A systematic review of triggers of ischemic stroke showed a significant association between ischemic stroke and alcohol abuse of  $>40$  to 60 g within the preceding 24 hours (OR, 2.66; 95% CI, 1.54–4.61) or  $>150$  g within the previous week (OR, 2.47; 95% CI, 1.52–4.02).

### Alcohol Consumption: Recommendations

1. Reduction or elimination of alcohol consumption in heavy drinkers through established screening and counseling strategies as described in the 2004 USPSTF update is recommended.
2. For individuals who choose to drink alcohol, consumption of  $\leq 2$  drinks per day for men and  $\leq 1$  drink per day for nonpregnant women might be reasonable.

### Sleep-Disordered Breathing

Approximately 4% of adults in the United States have sleep apnea. The diagnosis of sleep apnea is based on the apnea-hypopnea index (AHI), which describes the number of respiratory events (cessations or reductions in air flow) observed during sleep. Sleep apnea is defined as present if the AHI is  $\geq 5$  events per hour, and an increasing AHI indicates increasing severity.

Several longitudinal studies have identified sleep apnea as an independent risk factor for stroke. The first prospective data demonstrating an association between sleep apnea and stroke risk came from the Wisconsin Sleep Cohort Study. This cohort included 1189 subjects followed up for 4 years.

There was a 3-fold increase in the risk of stroke (OR, 3.09; 95% CI, 0.74–12.81) for subjects with an AHI  $\geq 20$  events per hour. The Sleep Heart Health Study followed up 5422 adults who were age  $\geq 40$  years without a history of stroke but with untreated sleep apnea for a median of 8.7 years. The unadjusted stroke risk associated with sleep apnea was somewhat higher in men than in women; the OR for ischemic stroke per 10 years was 2.26 (95% CI, 1.45–3.52) for men and 1.65 (95% CI, 1.45–3.52) for women. After adjustment for age, BMI, race, smoking, SBP, antihypertensive medications, and diabetes mellitus, sleep apnea was associated with stroke risk in men but not women. Among men, there was a progressive increase in ischemic stroke risk with increasing sleep apnea severity: AHI 9.5 to 19.1 events per hour, adjusted OR, 1.86 (95% CI, 0.70–4.95); AHI  $>19.1$  events per hour, adjusted OR, 2.86 (95% CI, 1.10–7.39). A metaanalysis of five prospective studies that included 8435 participants identified an OR for incident stroke risk of 2.24 (95% CI, 1.57–3.19). This metaanalysis also found that increased stroke risk is associated with increasing sleep apnea severity with an OR of 1.35 (95% CI, 1.25–1.45) for every 10-unit increase in AHI. A study of 50 men with sleep apnea and 15 obese male control subjects found that silent brain infarctions on MRI were more common among patients with moderate-to-severe sleep apnea than among control subjects or patients with mild sleep apnea (25% vs. 7.7% vs. 6.7%, respectively;  $P < .05$ ).

Although alternative therapeutic strategies exist, the mainstay of sleep apnea treatment is continuous positive-airway pressure (CPAP), which improves a variety of clinical outcomes (e.g., daytime sleepiness). No randomized trial has evaluated the effectiveness of CPAP on primary stroke prevention. The existing longitudinal cohort data indicate that CPAP treatment is associated with a reduction in cardiovascular risk among patients with sleep apnea compared with patients who are not treated with CPAP even after adjustment for vascular risk factors and that this finding is most robust for patients with the most severe sleep apnea. For example, a study of 264 healthy subjects, 403 untreated patients with sleep apnea, and 372 patients with CPAP treatment for 10 years had a combined vascular event endpoint that included fatal or nonfatal stroke or MI or acute coronary syndrome requiring cardiac intervention. In this cohort, severe untreated sleep apnea was associated with a 3-fold increased risk of vascular events (adjusted OR, 2.87; 95% CI, 1.17–7.51 for cardiovascular death; OR, 3.17; 95% CI, 1.12–7.52 for nonfatal cardiovascular events), but patients with treated sleep apnea had vascular event risks that were similar to those of patients with mild untreated sleep apnea and healthy subjects. A cardiovascular endpoint benefit was observed with CPAP treatment among 364 patients receiving CPAP compared with 85 untreated patients. The adjusted HR was 0.34 (95% CI, 0.20–0.58) for CPAP treatment.

Although no randomized, controlled trials have been published on primary prevention, several randomized, controlled trials and cohort studies have evaluated the

effectiveness of CPAP among patients with stroke and TIA (these data are reviewed in detail in the AHA secondary stroke prevention guidelines). Among these secondary prevention studies, the one with the longest follow-up studied 189 patients after stroke with sleep apnea for 7 years, finding that patients who did not use CPAP had a much higher recurrent stroke rate than patients who used CPAP (32% vs. 14%;  $P = .021$ ) and a higher adjusted incidence of nonfatal vascular events (HR, 2.87; 95% CI, 1.11–7.71). The number needed to treat to prevent one new vascular event was 4.9 patients (95% CI, 2–19).

Adherence to CPAP can be measured directly by CPAP machines in hours per night used and proportion of nights used. The reported CPAP adherence has varied considerably across studies and across populations, with mixed data about differences in adherence related to differences in CPAP mode (e.g., autotitrating vs. fixed pressure) or humidification use. Cognitive-behavioral interventions appear to improve CPAP adherence. Several studies have sought to identify predictors of CPAP adherence, and results have varied across studies. In general, however, patients who are most symptomatic (e.g., excessive daytime sleepiness) are most likely to adhere to treatment in the long term. A CPAP use study among 1155 patients with sleep apnea found that 68% were continuing to use the CPAP after 5 years of follow-up.

Patients with sleep apnea often have concomitant stroke risk factors, including hypertension, AF, diabetes mellitus, obesity, and hyperlipidemia, and several studies have demonstrated the importance of adjusting for these factors when examining the relationship between sleep apnea and risk of stroke. Given the robust relationship between sleep apnea and hypertension, numerous studies have specifically examined the degree to which CPAP treatment is associated with improvements in BP. Several metaanalyses suggest that the difference in SBP that can be expected with CPAP ranges from a decrease of 1.4 to 7.2 mm Hg, with most of the estimates closer to the lower end of this range.

Despite being highly prevalent, as many as 70% to 80% of patients with sleep apnea are neither diagnosed nor treated. The American Academy of Sleep Medicine advocates screening high-risk patients for symptoms of sleep apnea. High-risk populations include those with risk factors for stroke (e.g., AF, refractory hypertension) and patients with stroke. The recommended screening includes a sleep history (e.g., snoring, witnessed apneas, daytime sleepiness), an evaluation of conditions that may occur as a consequence of sleep apnea (e.g., motor vehicle accidents, stroke), and physical examination (e.g., BMI  $\geq 35$ , neck circumference  $>17$  in for men or 16 in for women). The Epworth Sleepiness Scale and Berlin Questionnaire are tools for screening for sleep apnea. However, most clinical screening tests miss a significant proportion of patients. Patients who are considered to be high risk on the basis of this screening should be referred for polysomnography.

### Sleep-Disordered Breathing: Recommendations

1. Because of its association with stroke risk, screening for sleep apnea through a detailed history, including structured questionnaires such as the Epworth Sleepiness Scale and Berlin Questionnaire, physical examination, and, if indicated, polysomnography may be considered.
2. Treatment of sleep apnea to reduce the risk of stroke may be reasonable, although its effectiveness for primary prevention of stroke is unknown.

### Hypercoagulability

The acquired and hereditary hypercoagulable states (thrombophilias) are associated with venous thrombosis, but a relationship with arterial cerebral infarction is based largely on case series or case-control studies. Of these, the presence of aPLs, generally an acquired condition, is most strongly associated with arterial thrombosis. Lupus anticoagulant (less prevalent but more specific) and aCL (more prevalent but less specific) are most frequently used to detect aPLs. Retrospective and prospective studies suggested an association between aCL and first ischemic stroke. From limited, often uncontrolled data that include predominantly patients with SLE and potentially other vascular risk factors that are poorly detailed, asymptomatic patients with aPL are estimated to have a 0% to 3.8% annual thrombosis risk.

### Acquired Hypercoagulable State: Relationship to Ischemic Stroke

Case-control studies of aPL in young stroke patients have uniformly demonstrated an association, as have most studies of unselected stroke populations. However, this is not the case for case-control studies among older adults with ischemic stroke. The Sneddon syndrome was formerly thought to be a manifestation of aPL syndrome, but it may be present in patients with or without aPLs, and the risk of ischemic stroke is increased only in those patients with increased aPLs.

Several prospective cohort studies have assessed the relationship between aPL and ischemic stroke. Stored frozen plasma from the Physicians' Health Study was used to determine whether aCL was a risk factor for ischemic stroke and venous thrombosis in healthy adult men. This was a nested, case-control study in a prospective cohort with 60.2 months of follow-up. At entry into the study, 68% of 22,071 participants submitted plasma samples. A control was matched by age, smoking history, and length of follow-up to each of the 100 patients with ischemic stroke and the 90 patients with deep vein thrombosis or pulmonary embolus. The aCL titers were higher in cases with deep vein thrombosis or pulmonary embolus than in matched controls ( $P = .01$ ). People with aCL titers  $>95$ th percentile had an RR for developing deep vein thrombosis or pulmonary embolus of 5.3 (95% CI, 1.55–18.3;  $P = .01$ ). Although an aCL level  $>95$ th percentile was an important risk factor for deep vein thrombosis or pulmonary embolus, there was no effect on stroke (an

RR of 2 for ischemic stroke could not, however, be excluded because of low power).

The Honolulu Heart Study was a nested case-control study examining aCL as a risk factor for ischemic stroke and MI. The study used stored frozen sera obtained from subjects in the Honolulu Heart Program who were followed for up to 20 years. aCL ( $\beta_2$ -glycoprotein I [ $\beta_2$ GPI] dependent) was tested in 259 men who developed ischemic stroke, 374 men who developed MI, and a control group of 1360 men who remained free of both conditions. aCL was significantly associated with both incident ischemic stroke and MI. Men with a positive aCL had higher risk of stroke relative to men with negative aCL (OR, 2.2 [95% CI, 1.5–3.4] at 15 years and OR, 1.5 [95% CI, 1.0–2.3] at 20 years). These data suggest that aCL is an important predictor of future stroke and MI in men.

The Framingham Offspring Cohort Study, a longitudinal observational study, used an enzyme-linked immunosorbent assay (ELISA) to measure aCL from stored frozen sera. This study found an association between aCL titers and ischemic stroke or TIA, but only in women. Overall, although elevated aCL titers may be commonly found in ischemic stroke patients, the strength of the association between elevated aCL titers and stroke origin or risk is uncertain.

The shortcoming of many studies evaluating aCL in stroke patients such as the Framingham Offspring Cohort study has been the use of the aCL ELISA, a test with low sensitivity. The assay for anti- $\beta_2$ GPI antibodies, a cofactor for antiphospholipid binding, may be more specific for thrombosis, including stroke and MI. Only a few studies have investigated  $\beta_2$ GPI in the absence of SLE. Because most studies involved patients with SLE, lupus anticoagulant, or aCL, it is difficult to establish the value of anti- $\beta_2$ GPI as an independent risk factor. Therefore the clinical significance of these antibodies requires further investigation. A prospective, observational study was performed to establish the incidence of first-time thromboembolic events in subjects with a high-risk aPL profile (positive lupus anticoagulant, positive aCL, and positive  $\beta_2$ GPI). The incidence of first thromboembolus was 5.3% annually compared with an annual rate of 1.9% in a study from the same group looking at subjects with only a single positive aPL test. Forty percent of thromboembolic events were stroke or TIA, and aspirin did not affect the incidence.

### Hypercoagulability: Recommendations

1. The usefulness of genetic screening to detect inherited hypercoagulable states for the prevention of first stroke is not well established.
2. The usefulness of specific treatments for primary stroke prevention in asymptomatic patients with a hereditary or acquired thrombophilia is not well established.
3. Low-dose aspirin (81 mg/day) is not indicated for primary stroke prevention in individuals who are persistently aPL positive.

## Antiplatelet Agents for Primary Prevention of Stroke

Aspirin use is associated with an increased risk of gastrointestinal bleeding. For example, one observational study found that the overall hemorrhagic event incidence was 5.58 (95% CI, 5.39–5.77) per 1000 person-years for aspirin users compared with 3.60 (95% CI, 3.48–3.72) per 1000 person-years for nonusers (incidence rate ratio, 1.55; 95% CI, 1.48–1.63). A metaanalysis of nine clinical trials including 50,868 subjects found no overall benefit of aspirin for the primary prevention of stroke (OR, 0.919; 95% CI, 0.828–1.021;  $P = .116$ ), with no heterogeneity among trials. Similarly, a second metaanalysis of nine trials with 100,076 subjects found that aspirin reduced the risk of ischemic stroke (RR, 0.86; 95% CI, 0.75–0.98), but this benefit was offset by an increase in hemorrhagic stroke (RR, 1.36; 95% CI, 1.01–1.82), again with no heterogeneity among trials. A third metaanalysis had similar results (risk of stroke, 0.20%/year vs. 0.21%/year,  $P = .4$ ; hemorrhagic stroke, 0.04%/year vs. 0.03%/year,  $P = .05$ ; other stroke, 0.16%/year vs. 0.18%/year,  $P = .08$ , aspirin vs. control, respectively). Taken together, these results reflect risk but no benefit of aspirin for the prevention of a first stroke in the general population. The USPSTF recommends aspirin at a dose of 75 mg/day to prevent MI (but not stroke) in men age 45 to 79 years and to prevent stroke in women age 55 to 79 years on the basis of their vascular risk and the chances of serious gastrointestinal hemorrhage. The USPSTF further notes that the 10-year level of cardiovascular risk for which the benefit exceeds bleeding risk varies from 3% to 11%, depending on age and sex. The most recent AHA guideline for the primary prevention of CVD and stroke also recommends aspirin for primary cardiovascular prevention in those with a 10-year coronary heart risk  $\geq 10\%$ . There is no evidence that antiplatelet medications reduce the risk of stroke in the general population at low risk. Although stroke was not analyzed as a separate endpoint, lack of aspirin use was independently associated with a 16% higher risk of cardiovascular events (HR, 1.16; 95% CI, 1.03–1.31) among healthy male physicians age  $\geq 65$  years. The benefit of aspirin for primary prevention of stroke is therefore limited to selected subgroups of patients. Several relevant trials further inform the use of aspirin and other antiplatelet agents for the prevention of a first stroke.

The Japanese Primary Prevention of Atherosclerosis with Aspirin for Diabetes (JPAD) trial randomized 2539 patients with type 2 diabetes mellitus but without a history of atherosclerotic disease (including stroke) to either low-dose aspirin (81 or 100 mg/day) or no aspirin. The primary outcome was the occurrence of atherosclerotic events (fatal or nonfatal ischemic heart disease, fatal or nonfatal stroke, and peripheral arterial disease). There was no effect of aspirin on the primary endpoint (HR, 0.80; 95% CI, 0.58–1.10;  $P = .16$ ) and no effect on cerebrovascular events (2.2% with aspirin vs. 2.5% with no aspirin; HR, 0.84; 95% CI, 0.53–1.32;  $P = .44$ ). There was no difference in the combined rates of

hemorrhagic stroke and severe gastrointestinal bleeding. A subgroup analysis of the JPAD trial noted that aspirin therapy lowered the rate of cerebrovascular events in patients with diabetes mellitus with uncontrolled hypertension (SBP  $\geq 140$  mm Hg and/or DBP  $\geq 90$  mm Hg) compared with those with controlled BP (HR, 1.64; 95% CI, 0.83–3.29), although the 95% CI includes the possibility of no benefit.

The Prevention of Progression of Arterial Disease and Diabetes trial was a randomized, double-blind, placebo-controlled trial including 1276 adults with type 1 or 2 diabetes mellitus and an ankle-brachial index of  $\leq 0.99$  but no symptomatic CVD who were randomized in a 2-by-2 factorial design to 100 mg aspirin or placebo plus antioxidants or placebo daily. The study had two primary endpoints: (1) death resulting from coronary heart disease or stroke, nonfatal MI or stroke, or amputation above the ankle for critical limb ischemia and (2) death resulting from coronary heart disease or stroke. There was no interaction between aspirin and antioxidant. There was no effect of aspirin on the composite primary endpoints (HR, 0.98; 95% CI, 0.76–1.26;  $P = .86$ ) or on death resulting from coronary heart disease or stroke (HR, 1.23; 95% CI, 0.79–1.93;  $P = .36$ ). There was no effect of aspirin on fatal stroke (HR, 0.89; 95% CI, 0.34–2.30;  $P = .80$ ) or nonfatal stroke (HR, 0.71; 95% CI, 0.44–1.14;  $P = .15$ ). There was no difference in the risk of gastrointestinal hemorrhage (HR, 0.90; 95% CI, 0.53–1.52;  $P = .69$ ). The lack of increased bleeding risk with aspirin in those with diabetes mellitus was also found in the observational study cited previously (incidence rate ratio for aspirin users vs. nonusers, 1.09; 95% CI, 0.97–1.22). Diabetes mellitus was independently associated with an increased risk of major bleeding regardless of aspirin use (RR, 1.36; 95% CI, 1.28–1.44). A metaanalysis of seven trials (11,618 subjects) of the effects of aspirin in patients with diabetes mellitus found a treatment-associated 9% reduction in major cardiovascular events (RR, 0.91; 95% CI, 0.82–1.00) but found no significant reduction in stroke (RR, 0.84; 95% CI, 0.64–1.11). Four additional metaanalyses also found no reduction in stroke with aspirin in subjects with diabetes mellitus.

A focused, multisociety position paper on the primary prevention of cardiovascular events in people with diabetes mellitus considered these and other studies and recommended low-dose aspirin for adults with diabetes mellitus who have a 10-year cardiovascular risk  $>10\%$  (men age  $>50$  years and women age  $>60$  years who have at least one additional major risk factor such as smoking, hypertension, dyslipidemia, a family history of premature CVD, or albuminuria) and who are not at high risk of aspirin-related bleeding complications. It was further recommended that aspirin not be used for cardiovascular prevention among those with diabetes mellitus at low risk and that aspirin might be considered for those at intermediate (10-year risk in the 5%–10% range) risk.

Relatively few women were enrolled in the primary prevention trials that showed a benefit of aspirin in the prevention of coronary heart events but no reduction in stroke.

The WHS randomized 39,876 initially asymptomatic women age  $\geq 45$  years to receive 100 mg aspirin on alternate days or placebo and followed them up for 10 years for a first major vascular event (nonfatal MI, nonfatal stroke, or cardiovascular death). Unlike data from earlier studies that included mainly men, this study found a nonsignificant 9% reduction (RR, 0.91; 95% CI, 0.80–1.03;  $P = .13$ ) for the combined primary endpoint among women but a 17% reduction in the risk of stroke (RR, 0.83; 95% CI 0.69–0.99;  $P = .04$ ). This was based on a 24% reduction in the risk of ischemic stroke (RR, 0.76; 95% CI, 0.63–0.93;  $P = .009$ ) and a nonsignificant increase in the risk of hemorrhagic stroke (RR, 1.24; 95% CI, 0.82–1.87;  $P = .31$ ). The overall average stroke rates were 0.11% per year in aspirin-treated women and 0.13% per year in placebo-treated women (RR, 0.02%/year; number needed to treat, 5000). Gastrointestinal hemorrhage requiring transfusion was more frequent in the aspirin group (RR, 1.40; 95% CI, 1.07–1.83;  $P = .02$ ). The average gastrointestinal hemorrhage rates were 0.06% per year for aspirin and 0.05% per year for placebo (absolute risk increase, 0.01%/year; number needed to harm, 10,000). The most consistent benefit for aspirin was in women age  $\geq 65$  years at study entry, among whom the risk of major cardiovascular events was reduced by 26% (RR, 0.74; 95% CI, 0.59–0.92;  $P = .008$ ), including a 30% reduction in the risk of ischemic stroke (RR, 0.70; 95% CI, 0.49–1.00;  $P = .05$ ); however, there was only a trend in the reduction of the overall risk of all types of stroke (RR, 0.78; 95% CI, 0.57–1.08;  $P = .13$ ), likely related to an increase in the risk of brain hemorrhages. Subgroup analyses showed a reduction in stroke for those women with a history of hypertension (RR, 0.76; 95% CI, 0.59–0.98;  $P = .04$ ), hyperlipidemia (RR, 0.62; 95% CI, 0.47–0.83;  $P = .001$ ), or diabetes mellitus (RR, 0.46; 95% CI, 0.25–0.85;  $P = .01$ ) or having a 10-year cardiovascular risk  $\geq 10\%$  (RR, 0.54; 95% CI, 0.30–0.98;  $P = .04$ ). A further post hoc subgroup WHS analysis found that the overall effect of aspirin was not modified in women with migraine (with or without aura), but aspirin use was associated with an increased risk of MI in those with migraine with aura (RR, 3.72; 95% CI, 1.39–9.95), an unexpected finding that may have been attributable to chance. The AHA evidence-based guidelines for CVD prevention in women also endorse the use of aspirin in high-risk women, unless contraindicated, in women age  $\geq 65$  years if BP is controlled and benefit for ischemic stroke and MI prevention outweighs the risk of gastrointestinal bleeding and hemorrhagic stroke, as well as in women age  $<65$  years when benefit for ischemic stroke prevention is likely to outweigh complications.

There are several other subpopulations for whom aspirin might be helpful in reducing risk of stroke. Patients with a reduced ankle-brachial index are at higher risk of vascular events. One trial evaluated the benefit of aspirin in a screened general population cohort with a low ankle-brachial index. There was no benefit of aspirin in reducing the rate of fatal or nonfatal coronary events, stroke, or revascularization procedures (HR, 1.03; 95% CI, 0.84–1.27). One metaanalysis

evaluated cilostazol versus placebo in 3782, 1187, and 705 patients with peripheral artery disease, cerebrovascular disease, and coronary stenting, respectively. The incidence of vascular events was lower in the cilostazol group compared with the placebo group (RR, 0.86; 95% CI, 0.74–0.99;  $P = .038$ ), including a lower incidence of cerebrovascular events (RR, 0.58; 95% CI, 0.43–0.78;  $P < .001$ ), with no increase in serious bleeding complications (RR, 1.00; 95% CI, 0.66–1.51;  $P = .996$ ). The primary and secondary prevention populations were not analyzed separately; however, there was no statistic heterogeneity among the trials.

In a subgroup analysis of the Hypertension Optimal Treatment (HOT) trial, subjects with renal failure (estimated glomerular filtration rate  $<45$  mL/min/1.73 m<sup>2</sup>) had a reduction in stroke risk with aspirin (HR, 0.21; 95% CI, 0.06–0.75). In addition, total mortality was reduced by half (HR, 0.51; 95% CI, 0.27–0.94) and cardiovascular mortality by 64% (HR, 0.36; 95% CI, 0.14–0.90). These results, however, were based on a post hoc analysis. Given the small number of participants with stage 4 or 5 chronic kidney disease (estimated glomerular filtration rate  $<30$  mL/min/1.73 m<sup>2</sup>) in the HOT trial, the RRs and benefits of aspirin in this population are not known.

### Antiplatelet Agents and Aspirin: Recommendations

1. The use of aspirin for cardiovascular (including but not specific to stroke) prophylaxis is reasonable for people whose risk is sufficiently high (10-year risk  $>10\%$ ) for the benefits to outweigh the risks associated with treatment. A cardiovascular risk calculator to assist in estimating 10-year risk can be found online at <http://my.americanheart.org/cvriskcalculator>.
2. Aspirin (81 mg daily or 100 mg every other day) can be useful for the prevention of a first stroke among women, including those with diabetes mellitus, whose risk is sufficiently high for the benefits to outweigh the risks associated with treatment.

### Additional Reading

- Hankey GJ. Secondary stroke prevention. *Lancet Neurol.* 2014;13(2):178–194.
- Hankey GJ. Stroke. *Lancet.* 2017;389(10069):641–654.

3. Aspirin might be considered for the prevention of a first stroke in people with chronic kidney disease (i.e., estimated glomerular filtration rate  $<45$  mL/min/1.73 m<sup>2</sup>). This recommendation does not apply to severe kidney disease (stage 4 or 5; estimated glomerular filtration rate  $<30$  mL/min/1.73 m<sup>2</sup>).
4. Cilostazol may be reasonable for the prevention of a first stroke in people with peripheral arterial disease.
5. Aspirin is not useful for preventing a first stroke in low-risk individuals.
6. Aspirin is not useful for preventing a first stroke in people with diabetes mellitus in the absence of other high-risk conditions.
7. Aspirin is not useful for preventing a first stroke in people with diabetes mellitus and asymptomatic peripheral artery disease (defined as asymptomatic in the presence of an ankle-brachial index  $\leq 0.99$ ).
8. The use of aspirin for other specific situations (e.g., AF, carotid artery stenosis) is discussed in the relevant sections of this statement.
9. As a result of a lack of relevant clinical trials, antiplatelet regimens other than aspirin and cilostazol are not recommended for the prevention of a first stroke.

### Conclusion

Physicians and scientists should take pride in the advances that continue to be made in preventing stroke. Medications to control BP and lipids, anticoagulants for at-risk individuals with AF, revascularization, cigarette smoking cessation, diet, and exercise are among the interventions broadly applicable to the general public. With so many interventions, optimization of stroke prevention for individuals requires systems of care that identify risk factors as they emerge and that gain control of emerging risk factors safely, expeditiously, and cost effectively. Access to care is necessary but not sufficient to guarantee optimal stroke prevention.

## Dementia

KATHERINE W. TURK AND ANDREW E. BUDSON

**D**ementia is a decline of cognitive function that eventually impairs the ability to carry out everyday activities. Dementia affects approximately over 5 million people in the United States to varying degrees. Only approximately 1 in 100 individuals age <65 years are thought to be affected by dementia, but this proportion reaches as many as one-half of individuals age >85 years. A number of common causes of cognitive impairment are reviewed in this chapter (Box 94.1).

### Alzheimer Disease

Alzheimer disease (AD) is a neurodegenerative disease of the brain with specific neuropathology including extracellular senile plaques formed by amyloid-beta protein and intracellular neurofibrillary tangles made of tau protein. AD progresses from a prodromal, asymptomatic stage, to a mild cognitive impairment (MCI) stage (in which cognition is impaired but function is normal, see later), to a dementia stage. Memory impairment is typically prominent. In 2016 11% of people age  $\geq 65$  years had a diagnosis of AD dementia, and that number jumps to 32% of people age  $\geq 85$  years. Of those with AD dementia, 4% are age <65 years, 15% are age 65 to 74 years, 44% are age 75 to 84 years, and 37% are age  $\geq 85$  years and older. AD causes approximately 80% of dementia cases either alone or as part of a mixed dementia. The overall prevalence in the community is estimated at about 10% in population-based studies. AD increases with age—5% to 10% of individuals age >65 years and 50% of those age >85 years. AD is the sixth leading cause of death in the United States and the only cause of death that has increased over the last 10 years. In 2016 an estimated 476,000 people in the United States or one in three seniors, will die with AD or another dementia. In 2016, 15.9 million caregivers provided an estimated 18.1 billion hours of unpaid care valued at more than \$221 billion. By 2016 the cost to the United States of care for those with AD has reached \$236 billion, and the costs continue to climb.

### Overview

AD has a typical onset from age 60 to 100 years. The average patient lives approximately 10 years from diagnosis until

death (average range 4–12 years). The mini-mental state examination (MMSE) declines approximately 2 to 3 points per year on average in AD. The risk factors are depicted in Box 94.2. Notably, although aging is the primary risk factor for AD, the latter is not part of normal aging. Family history is also an important risk factor; a first-degree relative with AD increases the risk of developing AD approximately 2-fold to 4-fold. Family history of multiple relatives with AD can be a risk factor, and there can be a genetic predisposition; late-onset AD has been associated with the *APOE E4* allele on chromosome 19. Early-onset familial AD has been associated with mutations of the amyloid precursor protein (APP), presenilin 1, and presenilin 2 on chromosomes 21, 14, and 1, respectively. APP and presenilin 1 and 2 mutations are the cause of AD in >1% of all cases but are much more common in younger onset patients where the disease begins before age 65 years and can occur as young as age 30 years. Note that the vast majority of AD cases occur in the absence of a family history. Other risk factors for AD include female gender, prior traumatic brain injury, and low educational attainment (more education reduces the risk of AD, possibly

#### • BOX 94.1 Common Causes of Cognitive Impairment

- Alzheimer disease
- Mild cognitive impairment
- Dementia with Lewy bodies
- Vascular dementia

  - Progressive supranuclear palsy
  - Corticobasal degeneration

#### • BOX 94.2 Risk Factors in Alzheimer Disease

- Aging
- Family history
- Genetic predisposition
- Female gender
- Low education
- Prior traumatic brain injury
- Stroke

by creating a “cognitive reserve” that delays the onset of clinical symptoms). Strokes do not cause Alzheimer pathology, but they may contribute to cognitive dysfunction in patients who already have Alzheimer pathology. Small vessel ischemic strokes, common in aging, are seen most commonly in the white matter, basal ganglia, and thalamus and do not necessarily mean that the patient has vascular dementia.

AD is pathologically defined by both intraneuronal neurofibrillary tangles and extracellular amyloid beta-peptide senile plaques leading to severe neuronal loss. The pathophysiology is attributable both to the direct loss of synapses and cortical neurons and to neuronal loss in the nucleus basalis of Meynert, resulting in reduced acetylcholine. Other important pathologic features include reduced brain weight by approximately 200 to 300 g, atrophy of hippocampus and of temporal, parietal, and frontal cortex, and cerebral amyloid angiopathy (often found in blood vessels) leading to small hemorrhages.

### Clinical Presentation

AD typically presents first with episodic memory loss, followed by word-finding difficulty, visuospatial impairment, and frontal/executive dysfunction. Patients cannot remember new information, become disoriented, and show poor judgment and problem-solving skills. Apathy develops early, whereas other behavioral problems such as irritability, exacerbation of premorbid personality traits, and aggression often develop later. Patients continue to lose function until they require around-the-clock care, usually in a long-term care facility. Although depression and anxiety were once thought to be a common cause of memory loss, it is now clear that these symptoms are common in the early stages of AD, making it likely that an elderly patient with depression and memory loss has early AD.

### Diagnostic Criteria

The pathophysiologic process underlying AD likely starts decades before clinical symptoms as preclinical AD, then progresses to mildly symptomatic but predementia MCI caused by the AD pathophysiologic process (MCI resulting from AD), and finally to AD dementia. Reflecting this current understanding, new diagnostic criteria were published in 2011 by the National Institute on Aging and the Alzheimer’s Association workgroup for dementia of any cause, for AD dementia, and for MCI caused by AD (Boxes 94.3 to 94.5). The new criteria include biomarkers for AD that when positive, increase the likelihood of an AD diagnosis (Box 94.6).

### Workup

Essential elements of any evaluation for dementia can be found in Box 94.7. Additional tests that may be important for diagnosis in specific circumstances are in Box 94.8.

Commonly used cognitive tests in the office or at the bedside include MMSE, Mini-Cog, and Montreal cognitive assessment (MoCA).

#### • BOX 94.3 Summary of Diagnostic Criteria for All-Cause Dementia

- Decline from the patient’s prior level of functioning
- Impairment in at least two of the following cognitive and/or behavioral domains:
  - Memory
  - Reasoning and judgment
  - Visuospatial ability
  - Language
  - Personality, behavior, comportment
- Cannot be explained by a delirium or major psychiatric disorder

#### • BOX 94.4 Summary of Diagnostic Criteria for Probable Alzheimer Disease Dementia

- Meets criteria for “all-cause dementia” (see Box 94.3)
- Insidious onset over months to years
- Initial cognitive deficits are evident as:
  - Amnesic presentation (memory dysfunction, most common presentation)
  - Language (typically word-finding problems)
  - Visuospatial (gets lost, impaired face recognition)
  - Executive (reasoning, judgment, problem solving)
- Exclusionary criteria: evidence of another dementia or disorder affecting cognition
- An “increased level of certainty” is present when:
  - There is also documented decline in cognition, or
  - There is a causative Alzheimer disease genetic mutation in the *APP*, *PSEN1*, or *PSEN2* genes
- Report biomarker positivity, if present (see Box 94.6)

#### • BOX 94.5 Summary of Diagnostic Criteria for Mild Cognitive Impairment Caused by Alzheimer Disease

- Concern of change in cognition by patient, informant, or clinician
- Objective impairment in one or more areas of cognition
  - Memory
  - Reasoning and judgment
  - Visuospatial ability
  - Language
  - Attention
- Preservation of functional abilities, not demented
- Causes of cognitive decline other than AD are ruled out
- Longitudinal decline in cognition is present
- Report causative AD genetic mutation in the *APP*, *PSEN1*, or *PSEN2* genes
- Report biomarker positivity, if present (see Box 94.6)
- The decline in function cannot be explained by another medical or brain disease

AD, Alzheimer disease.

### Structural Imaging

CT or MRI scan usually demonstrates atrophy of hippocampus, anterior temporal, and parietal lobes, and such atrophy is now considered a positive biomarker suggesting neurodegeneration. However, AD cannot be either ruled in or ruled out by such atrophy. Most older adults show mild

### • BOX 94.6 Putative Biomarkers for the Alzheimer Disease Pathophysiologic Process Currently Being Used

Markers of amyloid-beta ( $A\beta$ ) protein deposition in the brain  
Low CSF  $A\beta_{42}$

Positive PET amyloid imaging

Markers of downstream neurodegeneration

Elevated CSF tau (total and phosphorylated)

Decreased metabolism in temporal and parietal cortex on

### • BOX 94.7 Essential Elements in the Workup of Memory Loss and Dementia

- History from the patient and caregiver, including whether there are problems with memory, word-finding, getting lost, reasoning and judgment, mood, behavior, delusions, hallucinations, activities of daily living (eating, dressing, etc.), and/or instrumental activities of daily living (shopping, preparing a simple meal, etc.)
- Review of systems and past medical history including a significant head injury in which the patient lost consciousness, stroke or a transient ischemic attack, a seizure, fluctuating levels of alertness or periods of being relatively unresponsive, visual hallucinations of people or animals, a disturbance of gait, falls, tremor, rigidity and other signs of parkinsonism, a dramatic change in personality such that the patient seems like a different person, major psychiatric problems earlier in life, incontinence of bowel or bladder, and/or sleep disturbances including acting out dreams during sleep
- Previous education and occupation
- Family history of Alzheimer disease, memory loss, or other neurologic disorder
- Physical and neurologic examination including a search for focal signs, parkinsonism, and a careful evaluation of eye-movements
- Cognitive testing with brief cognitive screening instrument such as mini-mental state examination or Montreal cognitive assessment
- Laboratory studies including  $B_{12}$  and TSH
- Structural imaging study, either MRI or CT (both noncontrast)

TSH, Thyroid stimulating hormone.

or moderate small vessel ischemic disease; this does not necessarily mean they have vascular dementia. Structural imaging is also important to rule out other etiologies such as large strokes, tumors, hemorrhages, and hydrocephalus.

### Additional Tests

Box 94.8 lists additional tests to be considered in the evaluation of memory loss and dementia. These tests are not needed when the patient presents in the typical way and the diagnosis is straightforward. One or more of these tests may be useful, however, when a patient is young (particularly age <70

### • BOX 94.8 Additional Elements to Consider in the Workup of Memory Loss and Dementia

- Consultations: neuropsychology, psychiatry, driving evaluation can be considered for safety
- Laboratory studies: RPR; Lyme titer; ESR; antibodies to detect limbic encephalitis and/or Hashimoto thyroiditis; CSF evaluation for cells,  $A\beta_{42}$ , total tau, and p-tau; ApoE4 testing; genetic testing for familial early onset Alzheimer disease
- Imaging studies: MRI with magnetic susceptibility (or other sequence looking for blood products); technetium-99 SPECT; fluorodeoxyglucose PET; amyloid PET
- EEG
- Sleep study

CSF, Cerebrospinal fluid; EEG, electroencephalogram; ESR, erythrocyte sedimentation rate; PET, positron emission tomography; RPR, rapid reagin test.

years), when it is not clear whether the patient has AD or another type of dementia, when accurate prognosis is important for the family's planning, or when the treatment of the patient would be different depending upon the diagnosis. For example, if a patient appears to have AD but is 55 years old, it would be worthwhile obtaining one or more of these tests because the prevalence of AD is low in someone so young, and therefore a different disorder may be causing the cognitive impairment. Neuropsychology evaluations are helpful in evaluating patients with a high level of education who may be performing normally on office tests such as the Mini-Cog or MMSE. Laboratory studies can look for inflammatory and infectious causes. Biomarkers for AD include cerebrospinal fluid (CSF) examination (expected pattern in AD is decreased  $A\beta_{42}$  and increased total tau and p-tau) and functional imaging. Fluorodeoxyglucose positron emission tomography (FDG-PET) or Tc99 single proton emission CT (SPECT) demonstrates temporal and parietal dysfunction in AD and different patterns in other dementias such as frontotemporal or dementia with Lewy bodies (DLB). Three amyloid PET tracers have been approved by the US Food and Drug Administration (FDA) for use in diagnosing patients with AD: florbetapir (Amyvid), flutemetamol (Vizamyl), and florbetaben (Neuraceq). These amyloid PET scans detect  $\beta$ -amyloid in the brains of patients with the AD pathophysiologic process in AD dementia, MCI caused by AD, and preclinical AD. This technology therefore has the potential to diagnose Alzheimer's pathology in a sensitive and specific manner, perhaps even before the onset of subtle cognitive symptoms. This type of imaging technique may be extremely helpful when the diagnosis of a patient is in doubt. It is not necessary, however, in the evaluation of the routine patient whose diagnosis is straightforward. Currently, although approved by the FDA, insurance companies have not paid for these PET scans, and thus they are mainly used in research settings.

### Stages of Alzheimer Disease Dementia

Very mild: A slight but definite decline in memory and sometimes word-finding; fully oriented; slight impairments in

judgment and problem solving, community affairs, and home life and hobbies; typically able to prepare simple meals and can usually be on their own for a few days without getting into trouble; MMSE 24 to 27, MoCA 21 to 26.

**Mild:** Noticeable declines in memory and often word-finding, interfering with everyday activities; shows some disorientation to time and place; judgment and problem solving are moderately impaired; unable to function independently in community affairs; cannot perform complicated hobbies and household tasks but may still be able to perform simple ones; able to perform personal care tasks such as brushing teeth, changing clothes, and bathing, although may need reminding to do these activities; patient usually safe to be on his or her own for a few hours but may forget to eat, take medications, bathe, and change clothes if left alone for a few days; MMSE 16 to 26, MoCA 13 to 23.

**Moderate:** Memory loss is severe with only remote and/or very important memories retained; almost all new material is rapidly lost; disorientation to time and place are common; judgment and problem solving show severe impairment; only simple hobbies and household tasks can be maintained; patient appears well enough to be taken to activities outside the home; there is no pretense of independent function; assistance is needed in personal care activities such as dressing and hygiene, and urinary incontinence often develops; patient should not be left alone because of potential issues of wandering, incontinence, and safety; MMSE 6 to 17, MoCA 3 to 14.

**Severe:** Memory is severely impaired, and only fragments of memory remain; patient is typically only oriented to self; judgment and problem solving are not possible; patient appears too ill to be taken to activities outside the home, and the patient is not capable of pursuing hobbies or performing household tasks; patient requires help with all aspects of personal care and is frequently incontinent of both urine and feces; patient is usually managed in a long-term care facility; MMSE 0 to 10, MoCA 0 to 7.

These stages of AD dementia are summarized in [Table 94.1](#).

## Differential Diagnosis

Nondementia causes of cognitive impairment are listed in [Box 94.9](#). The most common disorders to be confused with AD are the following other degenerative dementias:

Frontotemporal dementia should be considered if the patient showed personality changes or problems with behavior, language, judgment, or reasoning first and foremost.

DLB should be considered if there is any evidence of parkinsonism and/or visual hallucinations and visual misperceptions.

Progressive supranuclear palsy and corticobasal degeneration should also be considered if there is parkinsonism.

Vascular dementia should be considered if there are many large strokes or severe small ischemic disease on the CT

**TABLE 94.1** Stages of Alzheimer Disease

Very mild	<ul style="list-style-type: none"> <li>Slight decline in memory</li> <li>Fully oriented</li> <li>Slight impairments in problem solving and judgments</li> <li>Can still function in day-to-day life without any problems</li> </ul>
Mild	<ul style="list-style-type: none"> <li>Noticeable decline in memory to the point it interferes with activities</li> <li>Slight disorientation to time and place</li> <li>Cannot perform complex tasks or hobbies</li> <li>Able to maintain personal care alone, but not for several days</li> </ul>
Moderate	<ul style="list-style-type: none"> <li>Memory loss is severe</li> <li>Ability to learn new material is significantly impaired</li> <li>Severe impairment in problem solving and judgment</li> <li>Cannot function independently</li> <li>Should not be left alone</li> </ul>
Severe	<ul style="list-style-type: none"> <li>Memory is severely impaired, and only fragments remain</li> <li>Patient needs constant maintenance and attention</li> <li>No independent activities are possible</li> <li>Patients usually need care in a long-term facility</li> </ul>

## • BOX 94.9 Other Causes of Cognitive Impairment

Encephalitis  
 Traumatic brain injury  
 Concussion  
 Stroke  
 Hypoxic-ischemic injury  
 Cardiopulmonary bypass  
 Subdural or epidural hematoma  
 Intracerebral hemorrhage  
 Seizure disorder  
 Temporal lobe surgery  
 Multiple sclerosis  
 Infections (including HIV)  
 Psychiatric disorders  
 Medication side effects  
 Hypoglycemia  
 Delirium secondary to a medical disorder  
 Sleep disorders  
 Hyperthyroidism/hypothyroidism  
 Other endocrine disorders  
 B<sub>12</sub> and other vitamin deficiencies  
 Lyme disease  
 Neurosyphilis (rare)  
 Wernicke-Korsakoff syndrome

or MRI scan. However, if the history and cognitive examination suggest AD, then the patient most likely has a mixed dementia, AD plus vascular disease.

Chronic traumatic encephalopathy should be considered if there is a history of repetitive head trauma, usually associated with military combat, football, boxing, or other contact sports.

### • BOX 94.10 Pharmacologic Treatment for Alzheimer Disease

#### Cholinesterase Inhibitors

Donepezil (Aricept)  
Galantamine (Razadyne)  
Rivastigmine (Exelon)

#### N-Methyl-D-Aspartate Antagonists

Memantine (Namenda)

### Treatment of Alzheimer Disease

Anticholinergic medications should be avoided. Currently only symptomatic therapy is available (Box 94.10), and there are no proven disease-modifying therapies. The overarching goal of therapy is to modulate neurotransmitters—either acetylcholine or glutamate. Delaying the onset of disease and/or slowing the rate of progression with medical therapy is currently not possible; studies suggest these medications can, however, turn the clock back on AD symptoms for 6 to 12 months provided they are continued. The standard medical treatment for very mild, mild, moderate, and severe AD dementia starts with the cholinesterase inhibitors: donepezil (Aricept), galantamine (Razadyne), and rivastigmine (Exelon). The partial N-methyl-D-aspartate (NMDA) antagonist memantine (Namenda) should be added when the patient reaches the moderate or severe stage. Memantine is believed to work by improving the signal-to-noise ratio of glutamatergic transmission at the NMDA receptor, although its clinical effects may also be related to its activity as a dopamine agonist. Cholinesterase inhibitors are FDA approved for mild, moderate, and severe AD, whereas memantine is FDA approved for moderate-to-severe AD. Patients with AD who have anxiety or depression typically benefit from a selective serotonin reuptake inhibitor (SSRI) medication such as sertraline (Zoloft) or escitalopram (Lexapro).

### Mild Cognitive Impairment

Because degenerative diseases such as AD progress over years, patients with such disorders must have gone through a prodromal stage before impairment in function. The term *MCI* is used to indicate patients who are presumed to be in this prodromal stage. Patients with MCI show abnormal cognition but do not meet criteria for dementia. Although we have already discussed MCI caused by AD earlier, MCI can also be brought about by other causes of cognitive impairment. MCI is usually divided into amnestic versus nonamnestic and single versus multiple domains of impairment, leading to four common types (Table 94.2).

The incidence of MCI has been reported to be 1% to 6% per year, with the prevalence ranging from 15% to 20% in individuals age >65 years and rising with increasing age. About 70% of patients with a diagnostic label of MCI convert to AD or another dementia at a rate of about 10% to 15% per year

**TABLE 94.2 Common Types of Mild Cognitive Impairment**

	Amnestic (Memory Impaired)	Nonamnestic (Memory Not Impaired)
Single domain (only one impairment)	Amnestic MCI single domain <ul style="list-style-type: none"> <li>• Only slight memory impairment</li> </ul>	Nonamnestic MCI single domain <ul style="list-style-type: none"> <li>• Single nonmemory cognitive impairment</li> </ul>
Multiple domain (several impairments)	Amnestic MCI multiple domain <ul style="list-style-type: none"> <li>• Slight memory and other cognitive impairments</li> </ul>	Nonamnestic MCI multiple domain <ul style="list-style-type: none"> <li>• Multiple nonmemory cognitive impairments</li> </ul>
Likely etiology	Alzheimer disease	Other (cerebrovascular disease, non-Alzheimer neurodegenerative diseases)

*MCI, Mild cognitive impairment.*

(compared with 1%–2% of the general population). Over a 5-year period, an average of 32% of MCI patients will develop AD. The risk factors are similar to those for AD or other underlying disorder. Because MCI is not a specific disease, the pathology and pathogenesis depend on the etiology causing the cognitive impairment. It is important to remember that MCI can develop for other reasons than Alzheimer's pathology and that MCI does not always lead to dementia. The main difference between MCI and dementia is that the decline in cognition is not yet to the point where it interferes with daily life.

### Clinical Presentation

The chief clinical manifestation is memory and/or other cognitive loss reported by the patient or informant or noted by the clinician. By neuropsychologic testing, the memory and/or other cognitive impairment is greater than what one would expect adjusted for age and education. However, general cognitive function may be essentially normal, and screening office tests such as the MMSE and Mini-Cog are often normal, although the MoCA (which is more sensitive) may detect an abnormality. Insight is often preserved. Activities of daily living are also largely preserved, and, as a result, the patient is not considered demented.

### Workup

Workup for MCI is similar to that for AD.

### Structural Imaging

As in AD, structural imaging studies are necessary to evaluate for the presence of large strokes, tumors, hemorrhages,

hydrocephalus, the extent of small vessel ischemic disease, and other such pathology. MCI attributable to cerebrovascular disease is often called *vascular cognitive impairment*; these patients typically show moderate-to-severe small vessel ischemic disease.

### Functional Imaging

FDG-PET and Tc99 SPECT are neither sensitive nor specific enough to detect and/or determine the underlying etiology in a patient with MCI and are not recommended. An amyloid PET will be positive in a patient with MCI caused by AD. We would only recommend ordering such a scan, however, for one of the reasons discussed earlier.

### Differential Diagnosis

The differential diagnosis of MCI is quite broad because it includes everything from normal aging to mild forms of all dementia types. Common disorders that can cause MCI include AD; cerebrovascular disease; other dementias; normal aging; depression and other psychiatric disorders; disorders that cause a static encephalopathy (encephalitis, head injury, subdural fluid collection, stroke); and medical disorders (e.g., renal failure).

### Treatment

There are currently no FDA-approved treatments for patients with MCI. However, studies have shown that patients with amnesic MCI are improved by donepezil (Aricept); thus treatment with donepezil or another cholinesterase inhibitor for patients with amnesic MCI is appropriate. Patients with MCI are often anxious and depressed because of their awareness of their cognitive deficits and benefit from an SSRI such as sertraline (Zoloft) or escitalopram (Lexapro).

## Dementia With Lewy Bodies (Including Parkinson Disease Dementia)

DLB is a neurodegenerative disease characterized clinically by a dementia, visual hallucinations, and parkinsonism. DLB is the same as Parkinson's disease dementia (same clinical picture in late stages, same pathology) with the only difference being that the initial symptoms are cognitive (dementia) in the former and motor (parkinsonism) in the latter.

DLB accounts for up to 15% of cases of dementia (often mixed with AD). It is the second most common degenerative dementia in the older adult after AD. The combination of dementia, parkinsonism, and visual hallucinations typically leads to nursing home placement and death earlier than in AD. Risk factors include age and male gender. The pathology is one of neurodegeneration associated with abnormal alpha-synuclein metabolism and formation of intracellular Lewy bodies in various brain regions including the brainstem, basal forebrain, limbic regions, and neocortical regions.

The pathophysiology is attributable both to the direct loss of neurons and to neuronal loss in brainstem centers that produce neurotransmitters, including the substantia nigra (producing dopamine) and the nucleus basalis of Meynert (producing acetylcholine). The key differences from AD are parkinsonism (although up to 25% of DLB patients do not present with parkinsonism), visual hallucinations, and similar cognitive testing, but DLB patients may show relatively greater impairment on measures of attention and executive function and less impairment in memory.

### Differential Diagnosis

When considering a diagnosis of DLB, one should determine whether the patient's dementia would be best characterized by that diagnosis alone, AD alone, or both (Box 94.11). If the patient meets criteria for both dementias, then the patient has a mixed dementia: DLB plus AD.

#### • BOX 94.11 Selected Revised Criteria for Clinical Diagnosis of Dementia With Lewy Bodies

- Essential for a diagnosis of Dementia
  - Impairment in attention, executive function, and visuospatial ability are often prominent; memory impairment may or may not be prominent initially
- Core features (two are sufficient for a diagnosis of probable dementia with Lewy bodies, one for a possible diagnosis)
  - Fluctuating cognition (pronounced variations in attention and alertness)
  - Visual hallucinations (recurrent, well-formed, detailed, of people and/or animals)
  - Spontaneous features of parkinsonism
- Suggestive features (one or more plus one core feature allows a probable diagnosis; one or more without any core features allows a possible diagnosis)
  - Rapid-eye-movement sleep behavior disorder
  - Severe neuroleptic sensitivity
  - Low dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET imaging
- Supportive features (commonly present but have not proven to have diagnostic specificity)
  - Repeated falls
  - Transient unexplained loss of consciousness
  - Orthostatic hypotension
  - Reduced occipital activity and generalized low uptake on SPECT/PET perfusion scan
- A diagnosis of dementia with Lewy bodies is less likely:
  - In the presence of clinically significant cerebrovascular disease noted on examination or radiology study
  - If parkinsonism only appears for the first time at a stage of severe dementia
  - In the presence of any other disorder sufficient to account for some or all of the clinical picture

*PET*, Positron emission tomography; *SPECT*, single-photon emission computed tomography.

Modified from McKeith IG, Dickson DW, Lowe J, et al. Diagnosis and management of dementia with Lewy bodies: third report of the DLB consortium. *Neurology*. 2005;65:1863-1872.

## Features of Dementia With Lewy Bodies

Features of dementia with Lewy bodies include dementia, parkinsonism, visual hallucinations, visual perceptual problems, fluctuating cognition (attention and alertness), rapid-eye movement sleep behavior disorder, and neuroleptic sensitivity.

### Workup

The laboratory workup of DLB is very similar to the workup of AD or MCI.

### Structural Imaging

There are no features of DLB that are commonly observed on structural imaging. In fact, structural imaging often looks normal, without atrophy in DLB.

### Functional Imaging

FDG-PET and Tc99 SPECT often show occipital dysfunction. Functional imaging is not necessary for the straightforward patient. Research into imaging of the dopamine transporter system by either SPECT or PET using specialized tracers is currently being developed.

### Treatment

As in AD, anticholinergic medications should be avoided in DLB. The cholinesterase inhibitor rivastigmine (Exelon) has been approved for Parkinson disease dementia, which, as discussed earlier, is the same as DLB. The motor symptoms of parkinsonism are generally best treated with levodopa (along with carbidopa, usually referred to as Sinemet) in low dose. Successfully treating hallucinations is difficult, and pharmacologic treatment should be initiated when hallucinations become threatening or otherwise problematic. Only atypical neuroleptics should be used, such as quetiapine (Seroquel) at bedtime, because traditional neuroleptics such as haloperidol (Haldol) are highly likely to cause worsening parkinsonism. (Note black box warning: Neuroleptics are not approved for dementia-related use in elderly patients; increased deaths because of cardiovascular or infectious events.) As in AD and MCI, depression and anxiety are common in patients with mild DLB and preserved insight; if these symptoms are present, an SSRI such as sertraline (Zoloft) or escitalopram (Lexapro) is helpful.

## Other Parkinsonism Syndromes

### Progressive Supranuclear Palsy

Progressive supranuclear palsy (PSP) is a neurodegenerative disease of the brain arising from the accumulation of hyperphosphorylated tau protein isoforms in the brain. It has a prevalence of 5 per 100,000. The main features of PSP include slowing or other abnormalities of vertical (or other) eye movements (supranuclear palsy), postural instability with falls, axial

rigidity, frontal lobe signs and symptoms, and difficulty swallowing and, eventually, talking (pseudobulbar palsy).

Early cognitive and affective symptoms may include irritability, irascibility, apathy, introversion, and depression. Inappropriate sexual behavior may also be present. The patient may complain of visual symptoms including blurred vision, difficulty focusing, dry eyes, photophobia, and double vision. The gait, sometimes described as that of a drunken sailor, becomes more abnormal as the disease progresses. Impulsiveness may lead to suddenly rising from sitting, increasing risk of falls. Fractures and bruises are common because of falls. The “sloppy eating” that is frequently observed with PSP is attributable to the combination of loss of dexterity, swallowing difficulties, and difficulty looking down at the plate of food. In the severe stages, the patient is typically confined to a wheelchair, and more severe chewing and swallowing difficulties, drooling, coughing, spluttering, and choking are common. Death is usually caused by aspiration pneumonia.

There are no FDA-approved treatments for PSP. Symptomatic treatments that are worth trying include levodopa/carbidopa (Sinemet) and memantine or amantadine.

### Corticobasal Degeneration

Corticobasal degeneration (CBD) is a neurodegenerative disease of the brain characterized by asymmetric cortical dysfunction, often affecting motor control of a limb, along with cognitive dysfunction, rigidity, a jerky postural tremor, myoclonus, dystonia, and a gait disorder. Similar to PSP, it is caused by the accumulation of hyperphosphorylated tau isoforms. CBD has a prevalence of about 2 per 100,000.

The most characteristic feature is asymmetric limb dysfunction. Other common signs and symptoms include useless limb (which in extreme cases may not be recognized as one's own; i.e., alien limb), focal apraxias, sensory symptoms including numbness and tingling, rigidity, a jerky postural tremor, myoclonus, dystonia, speech disturbance, executive dysfunction, and behavioral disorder. Over time the affected limbs become more rigid, where rapid movements such as pronation/supination and alternating finger tapping become impaired. Eventually even passive stretch may not be possible. In the dementia of CBD, frontal and parietal dysfunction are common, leading to difficulties with executive function, visuospatial function, language, and praxis; memory function, by contrast, is somewhat more preserved in the early stages of disease.

There are no FDA-approved treatments for CBD. Antidepressants should be used to treat depression, which is often present. Dystonia may be relieved with botulinum toxin. Clonazepam may be helpful for myoclonus and tremor.

### Vascular Dementia/Vascular Cognitive Impairment

Vascular dementia (VaD) can be defined as occurring concurrently with AD or other dementia etiologies or as a pure vascular dementia. If the patient shows no signs of any other etiology of his or her cognitive impairment, the term *pure*

*vascular dementia* is most appropriate. If the patient has a neurodegenerative disease (such as AD) and has the average amount of cerebrovascular disease that a nondemented, non-cognitively impaired older adult has, we would describe him or her as simply having that neurodegenerative disease (such as AD). If the patient has a neurodegenerative disease (such as AD) and has a greater-than-average amount of cerebrovascular disease such that it is highly likely that the cerebrovascular disease is making a significant contribution to the patient's dementia, then we would describe him or her as having a mixed dementia and would then further specify, for example, a mixed dementia of AD and vascular dementia.

## Overview

Patients classified as having mixed dementia of cerebrovascular disease plus a neurodegenerative disease probably make up 10% to 15% of all dementias. Pure vascular dementia occurs in about 1% to 5% of all dementias. The prognosis varies depending on etiology and severity. Risk factors are depicted in [Box 94.12](#). The pathology is variable. Cognitive impairment and dementia can occur in a variety of ways, with etiologies including large cortical strokes, small vessel ischemic disease, lacunar infarcts, and other etiologies. These different types of cerebrovascular diseases can cause a variety of different signs and symptoms depending on where the damage occurs.

Small vessel ischemic disease (subcortical ischemic vascular disease) is attributable to two processes, lipohyalinosis and microemboli.

Multiinfarct dementia (cortical vascular dementia or poststroke dementia) is typically as a result of multiple cortical strokes and most commonly caused by large emboli because of a proximal source such as cardioemboli arising from atrial fibrillation.

Strategic infarct dementia is caused by a focal lesion (or lesions), often quite small, that damage a brain region critical for cognitive brain function; the lesions are typically

### • BOX 94.12 Risk Factors for Vascular Dementia and Vascular Cognitive Impairment

#### Cardiovascular

Clinical strokes or transient ischemic attacks  
Hypertension  
Atrial fibrillation  
Coronary artery disease  
Atherosclerosis

#### Metabolic

Diabetes  
Increased cholesterol

#### Habits

Smoking

#### Demographics

Old age  
Low educational attainment

lacunar infarcts or embolic strokes, although hypertensive hemorrhages can also damage these regions.

Cerebral amyloid angiopathy (CAA) is caused by deposits of beta-amyloid in the media of small to medium arteries in the leptomeninges and superficial cortex, particularly in the parietooccipital, temporoparietal, and sometimes frontal regions; it is more common in patients with AD.

Others forms of vascular dementias include lesions due to hypoperfusion, hemorrhages, and rare genetic disorders such as CADASIL (cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy).

VaD differs from AD in the following ways: VaD can affect any number of brain regions at any time with varying severity; stepwise progression is common but can also appear clinically as a gradual decline, particularly when caused by small vessel ischemic disease; frontal/executive system dysfunction is common; and focal neurologic signs are common.

## Clinical Features

The typical symptoms of the different types of VaD are shown in [Table 94.3](#). The signs and symptoms depend on both the type of cerebrovascular disease and the particular brain structures affected. The finding of sudden, as opposed to gradual, symptoms is key. Signs of strokes or transient ischemic attacks are usually present.

## Differential Diagnosis

VaD can be confused with AD and other neurodegenerative diseases, multiple sclerosis, vasculitis, and/or systemic lupus erythematosus.

**TABLE 94.3** Typical Symptoms of Vascular Dementias

Small vessel ischemic disease	<ul style="list-style-type: none"> <li>• Frontal subcortical dysfunction leading to difficulties in attention</li> <li>• Disrupted gait (frontal gait)</li> <li>• Incontinence</li> <li>• Pseudobulbar symptoms</li> </ul>
Multiinfarct dementia	<ul style="list-style-type: none"> <li>• Poor attention</li> <li>• Aphasia</li> <li>• Disinhibition</li> <li>• Hemiparesis</li> <li>• Impairment of vision and other sensory modalities</li> </ul>
Strategic infarct dementia	<ul style="list-style-type: none"> <li>• Poor attention</li> <li>• Slurred speech (dysarthria)</li> <li>• Aphasia</li> <li>• Hemiparesis</li> <li>• Incontinence</li> <li>• Impaired coordination</li> </ul>
Cerebral amyloid angiopathy	<ul style="list-style-type: none"> <li>• Often first present with signs of Alzheimer disease</li> <li>• Visual disturbances</li> <li>• Wernicke aphasia</li> <li>• Word-finding difficulties</li> <li>• Visuospatial impairments</li> </ul>

## Workup

The laboratory workup of VaD is very similar to the workup of AD or other forms of dementia.

## Structural Imaging

Structural imaging is key to making a diagnosis of VaD. To make a diagnosis of pure vascular dementia or vascular cognitive impairment, there needs to be sufficient cerebrovascular disease present on the CT or MRI scan to explain the degree of cognitive impairment. To make a diagnosis of a mixed dementia, with vascular dementia as a contributing factor, there must be more cerebrovascular disease present on the CT or MRI scan than may be commonly present in an older adult without cognitive impairment.

## Functional Imaging

Functional imaging is helpful only in excluding neurodegenerative diseases such as AD or frontotemporal dementia.

## Treatment

The treatment of VaD is targeted to reduction of stroke risk factors. Although there are no FDA-approved medications for VaD, studies suggest both cholinesterase inhibitors and memantine provide significant benefit.

## Frontotemporal Dementia

Frontotemporal dementia (FTD) is defined as dementia attributable to neurodegeneration of the frontal and/or temporal lobes, with or without Pick bodies. There are three primary variants: (1) frontal variant or behavioral variant (bv-FTD); (2) temporal variant or semantic dementia (SD); and (3) progressive nonfluent aphasia (PNFA).

## Overview

FTD accounts for 20% of patients with early-onset dementia (age <65 years) and approximately 2% to 5% of all dementias. FTD typically develops at a younger age (35–75 years) than AD. Its duration ranges, depending on the variant, from age 2 to 20 years for bv-FTD, age 3 to 15 years for SD, and age 4 to 12 years for PNFA. The median survival is age 6 to 8 years. The pathology is characterized by neuronal loss and gliosis caused by tau inclusions, ubiquitin-positive inclusions, neuronal intermediate-filament inclusions, and/or microvacuolar degeneration. Pick bodies may or may not be present. There is atrophy of frontal and/or temporal lobes. The atrophy can be asymmetric and also affect basal ganglia. The differences from AD are depicted in [Table 94.4](#) and include earlier onset; behavioral and language symptoms, rather than memory loss, predominate early in the disease; atrophy of frontal and/or temporal

lobes; and/or behavioral variant where patients maintain relatively good orientation to time and place, have relatively intact memory, and do not become geographically disoriented.

SD patients show much more impairment in naming and language comprehension caused by temporal lobe atrophy.

Progressive nonfluent aphasia is characterized by effortful speech, phonologic and grammatical errors, reading and writing difficulty, and progressive loss of speech.

## Differential Diagnosis

FTD can be confused with AD, CBD, PSP, DLB, and VaD. Characteristics of FTD are summarized in [Table 94.5](#).

## Workup

Laboratory workup for FTD is similar to that for AD.

**TABLE 94.4 Frontotemporal Dementia Versus Alzheimer Disease**

Function	Alzheimer Disease	Frontotemporal Dementias
Memory	Impaired early	Variable
Personality	Withdrawn, less confident	Apathetic, disinhibited
Social skills	Preserved early on	Early deterioration
Language	Fluent with normal output	Decreased output

**TABLE 94.5 Clinical Features of Frontotemporal Dementias**

Behavioral variant frontotemporal dementia	<ul style="list-style-type: none"> <li>• Uninhibited, socially inappropriate behavior</li> <li>• Lacks awareness/concern for behavior</li> <li>• Loss of concern about personal appearance and hygiene</li> <li>• Loss of empathy</li> <li>• Mental rigidity</li> <li>• Impaired insight</li> <li>• Impaired judgment and planning</li> <li>• Stereotyped, ritualistic behavior</li> <li>• Memory relatively spared</li> </ul>
Semantic dementia	<ul style="list-style-type: none"> <li>• Loss of memory for words</li> <li>• Anomia</li> <li>• Impaired word comprehension</li> <li>• Impaired person recognition</li> <li>• Personality changes</li> </ul>
Progressive nonfluent aphasia	<ul style="list-style-type: none"> <li>• Reduced speech rate</li> <li>• Repetition impaired</li> <li>• Phonologic and grammatical errors</li> <li>• Comprehends words</li> </ul>

## Structural Imaging

Structural imaging may reveal lobar atrophy in frontal lobes (bv-FTD) and/or temporal lobes (SD). Progressive nonfluent aphasia may show left-sided perisylvian atrophy.

## Functional Imaging

Once the disease is established, FDG-PET and Tc99 SPECT typically show frontal (bv-FTD) and/or anterior temporal (SD) or left perisylvian (PNFA) dysfunction.

## Chapter Review

### Questions

1. An 82-year-old woman is brought by her daughter for evaluation of memory loss. The patient's daughter describes her mother as having trouble with short-term memory for the past 2 years. She says that her mother complains of dizziness and unsteadiness on her feet. She is moody but sometimes seems depressed. She has developed urinary incontinence over the past 3 months. She has a past medical history of long-standing hypertension, diabetes mellitus, and peripheral vascular disease. On the MMSE, the patient scored 19/30 with abnormal clock drawing. On the geriatric depression scale, the patient scored 3/15. Her brain MRI shows evidence of severe small vessel ischemic disease in frontal and parietal white matter, as well as pons and cerebellum. The most likely diagnosis is:
  - A. AD
  - B. Vascular dementia
  - C. Creutzfeldt-Jakob disease
  - D. Huntington disease
  - E. Lewy body dementia
2. A 60-year-old man presents for evaluation of behavioral changes. His wife reports that he seems like a different person over the past year. Whereas in the past he was very calm and pleasant, he has become "nasty"—cursing in public and making unwanted advances toward women. His work performance is also suffering, and he has been given a warning by his employer that he needs to begin meeting deadlines. MMSE is 30/30, and he

## Treatment

There are currently no FDA-approved treatments for FTD. Treatment is supportive, including SSRIs and atypical neuroleptics (such as risperidone) to reducing unwanted behavioral symptoms. (Note black box warning: Neuroleptics are not approved for dementia-related use in elderly patients; increased deaths because of cardiovascular or infectious events.)

denies memory deficits. MRI of the brain reveals right frontal and temporal lobe atrophy more so than left.

The most likely diagnosis is:

- A. AD
  - B. CBD
  - C. LBD
  - D. Bv-FTD
  - E. Primary progressive aphasia
3. A 75-year-old man presents for evaluation of memory loss that started 3 years ago and has worsened progressively. He often misplaces his belongings, and his wife says he repeats questions often and is no longer able to manage his bills or do their taxes. His MMSE score is 24/30, missing points for recall, figure copy, as well as orientation to day and date. MRI of the brain shows atrophy of the parietal, frontal, and temporal lobes as well as bilateral hippocampi. What is the most likely finding on his FDG-PET scan?
    - A. Global hypometabolism
    - B. Frontal lobe hypometabolism
    - C. Occipital hypometabolism
    - D. Temporal and parietal hypometabolism
    - E. Normal study

## Seizure Disorders

P. EMANUELA VOINESCU AND SHAHRAM KHOSHBIN

Seizures and epilepsy are either the presenting issue or complicating problem in a large and diverse group of disorders for which patients seek medical attention in an office practice. Although the prevalence of epilepsy is estimated to be around 3%, approximately 11% of the population gives a history of having had a seizure at some time in their life. Among patients visiting an outpatient neurology facility, seizure disorder or epilepsy constitutes one of the five most common conditions. In terms of physical and emotional disability, as well as the expense involved in evaluation and drug treatment, seizures constitute a major public health problem.

Despite their prevalence and importance, seizure disorders are poorly understood by the general public and some general physicians are not comfortable in managing them. This situation arises in part from the variety of neurologic manifestations that may result from seizures, ranging from the sudden loss of consciousness to complex patterns of seemingly meaningful behavior. In addition, epilepsy is not one entity, but it represents diverse conditions with varied causes and mechanisms. A further source of difficulty is the relatively recently expanded palette of antiepileptic drugs (AEDs) with different pharmacology and side-effects profile.

A seizure is a transient alteration in neurologic function resulting from a sudden, abnormal, excessive discharge in the cerebral cortex or underlying hemispheric structure. The term *seizure disorder* refers to all forms of seizures, regardless of their cause or clinical manifestations; the term *epilepsy* is generally reserved for patients with a lifelong or prolonged tendency to seizures, often genetically based, in distinction to patients with seizures related to events such as stroke, head injury, or metabolic abnormality.

### Classification

Since 1970 seizures have been classified by most neurologists according to the International Classification described initially by Gastaut. Table 95.1 provides its most popular version, from 1981, and the 2017 operational classifications by the International League Against Epilepsy (ILAE).

According to this scheme, febrile convulsions are generalized motor tonic-clonic seizures (grand mal)

occurring in children age 0 to 6 years in the context of a rapidly rising body temperature; temporal lobe epilepsy (a common term for seizures with atypical cognitive or physical symptoms) includes either focal aware/simple partial seizures or focal with impaired awareness/complex partial seizures.

### Clinical Diagnoses

Accurate characterization of the seizure type is crucial to effective management, both for diagnostic evaluation and for choice of drug therapy. In seizures with impaired awareness, reports from both the patient and bystanders may contribute to accurate classification. The clinical clue is the patient reporting an aura of almost any kind; this indicates a focal onset. The electroencephalogram (EEG) does not always establish the type of seizure, but often in the case of absence seizures/*petit mal*, it reveals bursts of bilateral, synchronous 3-per-second spike-and-wave activity, diagnostic for a generalized epilepsy, thus helping distinguish starring spells associated with absence seizures versus focal seizures with impaired awareness. It is crucial to recognize that there is often a progression from one seizure type to another (e.g., focal to bilateral tonic-clonic versus absence to generalized tonic-clonic seizures). This progression may be rapid.

The distinction between the different seizure types primarily has an etiologic significance. Generalized seizures primarily denote metabolic or genetic etiologies; focal seizures primarily denote structural anomalies or damage to the cortex, although genetic factors may also be at play. Most generalized epilepsies have their onset during childhood/adolescence, whereas focal epilepsies tend to be more prevalent in adults.

### Differential Diagnosis

Absence seizures, previously called *petit mal seizures*, are a disorder of children, beginning after the age of 2 years and before puberty, often with tens or hundreds of episodes per day. Each episode consists of a sudden, very brief (several seconds) interruption of consciousness, during which the patient stops attending, stares, and may undergo several clonic movements of eyelids, facial muscles, or arms

**TABLE 95.1** Corresponding Seizure Nomenclature When Comparing the 1981 and the 2017 ILAE Seizure Classification Schemes

or automatisms in the form of lip smacking, chewing, or fumbling movements of the fingers. Simultaneous with the clinical “absence” is bilateral, synchronous 3-per-second spike-and-wave activity in the EEG. Both the absence and the EEG changes may frequently be induced by 2 or 3 minutes of hyperventilation. Such patients rarely fall during an episode and may continue their activity immediately after the spell because they do not experience postictal confusion.

Childhood/juvenile absence epilepsy is not a common disease, accounting for only 12% of epilepsy diagnoses in one of the largest prospective community-based studies. Absence seizures are most often confused with focal nonmotor seizures with impaired awareness, in which the only manifestation of the seizure, at least from the patient’s point of view, is a gap in his or her experience. If prolonged, focal nonmotor seizures with impaired awareness may present as nothing more dramatic to the patient than a period of several minutes for which the patient has no recollection. To observers, the behavior during that period may have been characterized by continuation of well-practiced skills, such as driving or riding a bicycle, accompanied by a vacant stare and lack of contact with the surroundings. Unlike absence seizures, such episodes are not invariably related to 3-per-second spike-and-wave activity, and they occur much less frequently.

Absence seizures invariably begin before age 15 years and cease by age 20 years in 80% to 90% of afflicted individuals. If persisting beyond age 25 or 30 years, they may suggest a

diagnosis of focal seizures with impaired awareness. Approximately 50% of children with absence/petit mal seizures develop generalized/grand mal seizures that may persist into adult life.

Absence seizures may be complicated by the occurrence of other types of seizure, including episodes of myoclonic jerking and drop attacks. If the absence seizures in such patients display typical 3-per-second synchronous spike-and-wave activity, the prognosis is good. On the other hand, association with atypical spike-and-wave activity (2–2.5 Hz) constitutes a variant of Lennox-Gastaut syndrome and is often associated with cerebral disease and a high incidence of mental deterioration.

Absence status (i.e., attacks occurring for hours with no intervening normal mentation) is an uncommon disorder affecting adults and children equally. An EEG showing the 3-per-second spike-and-wave activity is diagnostic in this condition.

Generalized motor seizures or focal to bilateral tonic-clonic seizures, previously called *primary or secondary generalized/“grand mal”* seizures, are easily diagnosable to the bystander, although the patient may be unaware of anything other than a “black out” and the sore muscles, headache, confusion, and fatigue that often follow. The prodrome may extend over hours, marked by a feeling of apathy, irritability, or a sense of foreboding. Myoclonic jerks of the arms or trunk muscles may precede the actual seizure. The aura, which immediately precedes the loss of

consciousness, may involve a turning of the head or eyes, a strange feeling of fullness in the epigastrium, palpitation, or generalized malaise. No aura is experienced in about half of generalized seizures, presumably because of the rapid spread of seizure activity. The actual seizure is usually heralded by forceful tonic contractions of the limbs and jaw, a strangled cry, arrest of respiration, pupillary dilation, and a sudden fall to the ground, during which there is mild generalized trembling or shivering, succeeded by forceful rhythmic contractions of the arms and legs and facial grimacing, accompanied by cyanosis, grunting, and salivation. Incontinence may occur, as may subconjunctival hemorrhages.

After 2 or 3 minutes, the clonic phase ends with a deep inspiration, the musculature relaxes, and color returns to the face and extremities. After another few minutes, consciousness returns, although the person is often confused and may be agitated. Complete recovery follows a period of several hours of sleep, although some patients may exhibit focal neurologic deficits, such as hemiparesis, hemisensory loss, or aphasia that gradually resolve over 48 to 72 hours. This postictal paralysis of nervous function, a so-called Todd paralysis, has important localizing value, although the lesion that is localized may be old or new. Some patients with a "new" stroke may in fact have a postictal paralysis following a seizure from the scar left by a previous stroke.

Generalized seizures often occur in small flurries of several seizures over a few hours; this is a common pattern in alcohol withdrawal seizures during the first 6 to 36 hours after the sudden cessation or reduction in the consumption of alcohol. A small percentage of epileptic patients will at some time have a series of seizures between which consciousness is not recovered, status epilepticus. This life-threatening condition frequently results from sudden reduction in anticonvulsant medication. However, withdrawal from other drugs (e.g., sedatives, hypnotics) or alcohol, exposure to drugs known to precipitate epilepsy (e.g., penicillin) and metabolic disorders (e.g., hypoglycemia, hypernatremia, hyponatremia [especially if rapidly developed], hypocalcemia, and hyperglycemia with hyperosmolality, uremia) and sepsis, as well as acute or long-standing brain injury (hemorrhage, cerebral hypoxia/ischemia, infectious lesions, arteriovenous malformations or tumors) may also precipitate status.

The diagnosis of a generalized motor seizure is readily apparent in fully developed cases that have been witnessed; otherwise, a diagnosis of transient ischemic attacks or syncope of any cause may be considered when the patient can report only a loss of consciousness or is found in the postictal phase. However, transient ischemic attacks rarely lead to loss of consciousness, whereas prolonged confusion or postictal sleepiness does not follow syncope. Moreover, the patient with vasodepressor syncope has a more prolonged premonitory phase consisting of nonneurologic symptoms including weakness, nausea, lightheadedness, and diaphoresis, as opposed to the sudden loss of consciousness that can occur in seizures. Although a brief tonic phase, sometimes

followed by a few clonic jerks, can occur in syncope of any cause when it is accompanied by cerebral hypoxia; fecal incontinence, cyanosis, stertorous breathing, and a prolonged course (>1 minute) usually implies a true seizure occurrence.

Generalized myoclonic seizures consist of sudden flexion of head and neck with upward jerking of the arms, sometimes of sufficient force to throw a child to the ground; occasionally, the movements are asymmetric or even unilateral. They are part of different syndromes (epilepsy with myoclonic absences, myoclonic atonic/astatic epilepsy) with more or less favorable outcomes.

Tonic and atonic seizures, as well as infantile spasms, are seen primarily in certain pediatric conditions and are not discussed further.

Focal, previously called *partial seizures* are classified according to the predominant symptoms. Such seizures reflect a specific cortical lesion, either macroscopic or microscopic, that serves as an autonomous focus for excessive electrical discharge. The lesion becomes symptomatic when it spreads beyond the local epileptic focus, either to a sufficient number of adjacent neurons or via white matter pathways to distant portions of the cerebrum.

Focal motor seizures generally arise from the frontal or rolandic cortex, although similar movements may be induced experimentally by cortical stimulation at distant sites from the frontal lobes. Simple motor seizures often consist of adersive movements of head, eyes, and trunk in a tonic fashion away from the hemisphere involved, after which clonic movements or progression to a generalized seizure may occur. A special variant is the jacksonian form of motor seizure, in which a tonic contraction of one side of the face, the fingers, or one foot is followed immediately by clonic movements of the extremity, which then spread or march in a regular fashion up the extremity to eventually involve the adjacent extremity and finally, if the seizure persists, all the muscles on one side. This condition may persist for some minutes and then subside, or it may progress to a generalized seizure.

Such a march is held by most neurologists to indicate a macroscopic lesion in a very high percentage of cases, usually involving the opposite rolandic cortex or adjacent portions of the cerebrum. Such patients should undergo extensive investigation for a lesion and be followed closely for many years if a lesion is not initially demonstrated. Focal aware seizures, without jacksonian march, are often associated with a pathologic condition in adults, although they may emanate from old microscopic or macroscopic lesions and are occasionally seen in states of metabolic derangement, especially hyperglycemia. In children, simple focal seizures and even Todd postictal paralysis may be associated with no demonstrable pathologic condition in many cases.

In some cases, especially after cerebral infarction or in the case of a brain tumor, focal motor seizures may persist for hours or days without impairing consciousness. This condition, called *epilepsia partialis continua*, should not be

confused with status epilepticus because it rarely poses the threat to survival that the latter does. The treatments are quite different.

Other focal seizures depend on the location of the inciting lesion. Disturbances in the rolandic parietal area may give rise to episodes of numbness, tingling, or prickling sensations, which may also march in a fashion characteristic of jacksonian seizures. Occipital lesions may rarely produce visual phenomena, usually of an elemental nature and positive in character. Colored or white lights, moving or stationary, in the opposite visual field or straight ahead have been described. On the other hand, complex visual hallucinations, such as distortions of size (micropsia or macropsia), shape, or arrangement, arise from the posterior temporal lobe. Uncinate seizures consist of brief sensations of unusual or disagreeable smells or tastes; they reflect discharge in the most medial portion of the temporal lobe, usually secondary to a discrete lesion in that area.

Auditory phenomena and vertiginous sensations have been described but occur infrequently and are usually accompanied by other seizure manifestations.

Because of their localized nature and the variety of their manifestations, focal seizures may be mistaken for transient ischemic attacks or for neurologic symptoms associated with migraine. In general, transient ischemic attacks are distinguished from focal seizures because they do not involve convulsive movements, they occur in an older age group, and they exhibit a full range of prominent neurologic deficits at the start. Migraine is usually distinguished by the initial visual manifestations of fortification scintillations; by the more gradual march of the neurologic symptoms over a 15- to 20-minute period; by the absence of convulsive movements in an extremity; and by the prolonged, pulsating headache that usually follows the neurologic symptoms in migraine.

Compared with the relative simplicity of the symptoms associated with focal aware seizures, focal seizures with impaired awareness present such a bewildering variety of clinical phenomena that the precise boundaries of the diagnosis are still unclear. Typically, a focal seizure with impaired awareness has three elements: (1) an aura, which is usually a complex hallucination, perception, or emotional feeling and constitutes the beginning of the seizure; (2) a dreamy state, in which consciousness is altered and contact with the surroundings is deficient, although not completely suspended; and (3) behavioral automatisms. The aura, the content of which can often be recalled by the patient, may consist of a complex hallucination (visual, auditory, olfactory, or vertiginous); a perceptual distortion; a feeling of unreality (*jamaïs vu*) or familiarity (*déjà vu*); or an affective state such as fear, anxiety, or rage. Automatisms often involve either repetitive inappropriate acts (e.g., washing hands, repeating incoherent words, pacing) or movements around the mouth (e.g., sucking, chewing, swallowing). Highly practiced motor acts, such as driving or dressing, may continue during a seizure. In such cases, only the failure to respond to a question or a suggestion

indicates the altered consciousness. Rarely, such individuals will become hostile if restrained, but persistent, directed aggressive behavior is unusual.

Fully two-thirds of patients with focal seizures with impaired awareness will experience focal to bilateral tonic-clonic seizures at some time in their lives, and the conjunction of these two phenomena often permits the clinician to make the correct diagnosis. Whereas a population of patients with focal seizures with impaired awareness exhibits a seemingly endless variety of seizure patterns, the pattern in any given patient is most often stereotyped.

Several studies have focused on a disturbance of personality in patients with temporal lobe seizures. We have referred to this as Geschwind syndrome. These patients sometimes display a socially viscous quality, hyperreligiosity, tendency to abstraction in their concerns, hyposexuality, and proclivity to engage in excessive literary composition in their spare time. These changes certainly occur in only a minority of patients with focal seizures, and their relationship to the seizures is problematic. There is general agreement, however, that most of these changes are interictal and are not direct manifestations of a discharging focus in the temporal lobe.

Psychiatric disorders may be difficult to distinguish at times from focal seizures with impaired awareness; this is particularly true of extreme anxiety states, disorders of impulse control, and schizophrenia. In these psychiatric conditions, the often-normal EEG result and the absence of a clear history of convulsive disorder may help in the diagnosis, but distinction is sometimes difficult.

There is no question that patients with temporal lobe epilepsy are more prone to develop eventual psychosis, which may be difficult to distinguish from more classic schizophrenia. Prolonged episodes lasting days without intervening periods of lucidity suggest schizophrenia and are unusual in focal seizures, as is the performance during episodes of psychologically meaningful behavior of a complex nature. Amnesia for at least part of the episode is common in seizure disorders but relatively uncommon in psychiatric disease. During interictal periods, patients with focal epilepsy can be distinguished from those with schizophrenia if they display a normal and appropriate affect, maintain close interpersonal relationships, and are capable of clear and logical thinking.

The diagnosis of psychogenic nonepileptic seizures (PNES) poses special problems. Some of the patients presenting with these spells have epileptic seizures as well, making the differentiation of their events both important and doubly difficult. PNES should be suspected when frequent seizure episodes are accompanied by a normal EEG taken during and immediately before the episode of altered behavior; when seizures occur frequently; when consciousness is preserved despite bilateral movements or movements during the seizure consisting of alternately flailing each arm or leg or side-to-side movement of the head, and typically, pelvic thrusting; when generalized

seizures are not followed by confusion, dilated pupils, extensor plantars, and increased tendon reflexes; and when medication produces no improvement and results in bizarre reactions. One requirement for the diagnosis of PNES, pointed out by Charcot in the 19th century, is familiarity with the pattern of an epileptic seizure. Despite this familiarity, however, distinguishing nonepileptic from epileptic seizures may be challenging even if the examiner has a chance to witness the episode. A confounding factor at times, however, is the possibility that the nonepileptic seizures, although themselves not representing seizure activity, may occur in the postictal state of a patient who has experienced a seizure. Therefore the gold standard test to diagnose PNES is video-EEG monitoring.

## Diagnostic Studies and Evaluation

The cause of seizure disorders may be genetic, congenital, or acquired; it may reflect either concurrent systemic disease or disorders confined to the central nervous system. In any given patient, the likelihood of the various causes depends on both the age of onset and the type of seizure.

By age group, the most common causes are the following:

**Infancy:** congenital lesions, perinatal encephalopathy, pyridoxine deficiency, and metabolic abnormalities (hypocalcemia, hypoglycemia)

**Childhood:** perinatal trauma or anoxia, febrile condition, and idiopathic disorder

**Adulthood:** idiopathic disorder, alcohol or drug withdrawal, tumor, and trauma

**Old age:** vascular lesion, tumor, trauma, and degenerative disorder

The older the patient, the more likely it is that a cause will be found in unselected adult populations with bilateral tonic-clonic or generalized seizures. The largest group of causes is related to vascular disease in those age >50 years, but tumor remains an important concern. If evaluation with noninvasive tests and a thorough neurologic examination are undertaken at the onset and close follow-up is ensured for the first 5 years, it is unlikely that serious correctable lesions will be missed.

Certain aspects of the clinical situation should alert one to the possibility of a tumor manifesting itself as a seizure. Abnormalities on the neurologic examination, especially if focal and if suggestive of a hemispheric lesion, should prompt the ordering of MRI or CT scanning, if an MRI is contraindicated. The patient's age plays a role. Tumors of the cerebral cortex are rare in children; unless the examination or EEG points to a focal disorder, studies beyond EEG and MRI are not likely to be helpful. In adults, the percentage of patients with tumors increases with age but varies considerably from series to series.

With focal seizures, other than the temporal lobe type, the yield in terms of new central nervous system lesions is much higher; this is especially true if either focal EEG abnormalities or focal neurologic abnormalities are

present. In summary, focal seizure disorders deserve more careful and extended scrutiny than generalized seizure disorders.

The first step in evaluation is a careful history, both of the seizures and of other past medical problems (infections, trauma, perinatal injury, hemorrhagic/ischemic/neoplastic pathology, and drug use). In hospitalized patients, causes for acute symptomatic seizures should be first reviewed (electrolyte abnormalities, metabolic derangements, administration of certain drugs).

A number of blood tests, including complete blood count, serology, electrolytes, blood urea nitrogen, blood sugar, and calcium, are required at the time of initial evaluation as screening for occult medical disease. A complete neurologic evaluation, including some assessment of cortical function (e.g., language, visual fields, construction, calculation, praxis), is mandatory. Lumbar puncture should be performed in any patient in whom acute or chronic infection is possible, as judged by the medical history or the neurologic examination; in others, its yield is extremely low.

Here are several reasons why an EEG should be performed initially in every patient suspected of having seizures. First, an EEG may add further evidence for a diagnosis of seizure disorder in patients in whom this diagnosis is uncertain, if interictal abnormalities are identified. Second, it serves as a baseline assessment for comparison if seizures become more frequent or harder to control. Third, an EEG may help distinguish between a focal epilepsy (focal abnormalities of cortical function in the form of local slow waves or a spike or sharp-wave focus) versus a generalized epilepsy (generalized spikes/polyspike and wave) and may assist with the diagnosis of a specific syndrome (e.g., childhood absence epilepsy). The prior administration of anticonvulsants may marginally reduce the yield of paroxysmal EEG abnormalities but will not significantly alter the chances of finding a focal abnormality. For this reason, anticonvulsants should not be withheld pending completion of an EEG when the presence of a seizure disorder is certain.

The reliability of the EEG in diagnosing seizure disorders varies according to the type of seizure exhibited by the patient. In generalized epilepsies, the EEG reading is invariably abnormal during the seizure, usually showing a high frequency train of spikes initially, followed by spike-and-wave or sharp-and-slow activity, which is succeeded after some seconds or minutes by high-amplitude, irregular, diffuse slowing (postictal phase). The diagnosis of focal epilepsies is more difficult because focal seizures may present a normal record even during the occurrence of a seizure. The interictal record, on the other hand, for either generalized or focal epilepsies, may or may not be abnormal.

The sensitivity of interictal EEG recording depends on several factors. The percentage of EEG results positive for epileptic activity decreases with age and increases with the frequency of the seizures. Curiously, some studies suggest that the administration of anticonvulsant medication did not significantly lower the incidence of epileptiform

abnormalities in the EEG. Repeat EEGs, especially if performed during a period of maximum seizure susceptibility, may increase the yield of positive results, and provocative techniques (sleep deprivation, hyperventilation, photic stimulation) are useful.

In withdrawal states, the EEG is often normal or marked by abundant low-voltage fast activity. In metabolic encephalopathies, the EEG is usually diffusely slow, and epileptiform discharges may not be apparent or, if occurring, may have a sporadic or periodic pattern.

The major purpose of the diagnostic evaluation in patients known to have seizures is the exclusion of brain neoplasms or other focal pathologic conditions that might be correctable. MRI has dramatically improved the evaluation of epilepsy. MRI brain or CT head, in those cases where an MR is contraindicated, are now routinely done (Box 95.1). If the results of MRI or CT scanning are negative, but there is a very strong suspicion of a focal lesion (e.g., a young person with repeated partial motor seizures, especially jacksonian, without other explanation), cerebral angiography (MRA or CTA head) can be considered.

## Management

### Initiating Treatment

In general, an epilepsy diagnosis is a sufficient indication for treatment. If using the modern definition of epilepsy proposed by the ILAE as “a disorder of the brain characterized by an enduring predisposition to generate

#### • BOX 95.1 MRI Findings in Patients With Focal Seizures

##### Nonspecific

- Asymmetry of lateral and temporal horns (coronal cuts)
- Focal areas of cerebral atrophy
- Compensatory enlargement of adjacent ventricle
- Compensatory enlargement of adjacent sulci
- Subarachnoid cysts (compensatory)

##### Specific

- Neurodevelopmental problems
  - Heterotopic gray matter: nodular (usually subependymal) or focal cortical dysplasia
  - Tuberous sclerosis
  - Pachygyria-polymicrogyria
  - Lissencephaly
- Acquired pathology (secondary to trauma, stroke, or infection)
  - Encephalomalacia and/or gliosis
- Foreign tissue
  - Tumors (high grade, low grade)
  - Hamartomas
- Vascular malformation
  - Arteriovenous malformations
  - Cavernous hemangiomas
- Hippocampal sclerosis with or without dysplasia/architectural distortion

epileptic seizures,” only one unprovoked seizure is sufficient to make the diagnosis and start treatment in certain circumstances: a prior brain insult such as a stroke or trauma, an EEG with epileptiform abnormalities, a significant brain-imaging abnormality, or a nocturnal seizure. In these cases, the risk for a recurrent seizure is estimated to be >60%, similar to the risk of a recurrent seizure after two unprovoked seizures (57% by 1 year and 73% by 4 years) and significantly different from the risk of a recurrent seizure after a first unprovoked seizure in the absence of the above-mentioned factors (21%–45% in the first 2 years after a first seizure).

In the case of acute symptomatic seizures occurring in the context of an intercurrent medical illness with hypoglycemia, severe electrolyte or blood gas abnormality, or other precipitating factors, a workup should be undertaken to exclude an underlying seizure focus within the cortex. In the absence of such a focus, treatment of the underlying medical problem is the solution and not commitment to long-term AEDs. The management of withdrawal seizures from barbiturates, tranquilizers, or alcohol consists mostly of supportive care and symptom control, with benzodiazepines frequently used to treat psychomotor agitation secondary to alcohol withdrawal. A workup to assess for alternative or coexisting diagnosis, such as meningitis, intracranial bleed, or toxic-metabolic disarray, is required. Some alcoholics, often because of previous head trauma, have an underlying seizure disorder. This poses a difficult problem in management because the seizures may be exacerbated by varying alcohol intake and erratic compliance with medications. Except for these patients, once withdrawal seizures have run their course, long-term anticonvulsant therapy is not indicated.

### Choosing the Right Antiepileptic Drug Regimen

Several principles guide the selection and administration of long-term anticonvulsant therapy. First, therapy should be initiated with a single drug, the dosage of which is gradually increased at intervals of several days or weeks until either toxicity supervenes or control occurs. When seizures persist despite therapeutic levels of one drug, a second drug may be added, and the first drug can often be carefully discontinued if seizure control is attained. Seizure control is more readily achieved for generalized epilepsy, frequently requiring only a single drug at therapeutic dosage, compared with focal epilepsies that more often require polytherapy for satisfactory control. One-third of patients will have refractory epilepsy, and studies have repeatedly shown that rather than resorting to polypharmacy, patients at this stage may benefit from evaluation for respective surgery or the use of nonpharmacologic techniques such as vagus nerve stimulation (VNS) or responsive neurostimulation (RNS) devices.

The choice of drugs is guided by the seizure type, the epilepsy type/syndrome, the patient’s previous response to the medication, and the relative desirability or undesirability

of particular side effects (Tables 95.2 and 95.3). Valproate is commonly considered the drug of choice for the treatment of most generalized epilepsies, except in women of childbearing age because of its high teratogenicity and negative impact on a child's neurodevelopment. For women of childbearing age with either genetic generalized epilepsy or focal epilepsy, lamotrigine and levetiracetam are the drugs of choice. In the case of childhood absence epilepsy, ethosuximide was proven to have similar efficacy to valproate but better tolerability. For juvenile myoclonic epilepsy,

valproate and topiramate are potentially efficacious, according to one study, and lamotrigine may exacerbate seizures, especially myoclonus, but levetiracetam seems to be the AED preferred in practice. Regarding focal seizures, levetiracetam and zonisamide have now joined carbamazepine and phenytoin, with adequate evidence supporting their use as initial monotherapy for adults with focal epilepsy. According to a panel of selected experts, however, the drugs of choice for focal epilepsies are lamotrigine, levetiracetam, and oxcarbazepine in the current practice. For new onset

**TABLE 95.2** Clinical Guidelines for the Use of Current Antiepileptic Medications<sup>a</sup>

Drug (Abbreviation)	Indication (Epilepsy Type/Syndrome)	Daily Dosage (mg/kg/d)	Usual Maintenance Doses (mg/d)	Suggested Titration Rate (Initial Dose + mg/d/wk up to Desired Dose or Adequate Response)	Common Adverse Effects	Idiosyncratic Effects
<b>First-Generation AEDs</b>						
Phenobarbital (PB)	Focal epilepsy Generalized epilepsy Status epilepticus N.B. Not effective against absence seizures	1.5–3	50–200	30 mg at bedtime + 30–50 mg/d every 1–2 wk	Sedation (in adults), hyperactivity (in children), behavior changes (depression), cognitive dysfunction, lethargy, osteopenia, connective tissue disorders (Dupuytren contractures), teratogenicity N.B. Reduces OCP efficacy	Stevens-Johnson syndrome/toxic epidermal necrolysis (SJS/TEN), hepatic failure, granulocyte suppression
Primidone (PRM)	Focal epilepsy Generalized epilepsy N.B. Not effective against absence seizures	5–12	500–1500	125–250 mg daily + 125 mg/d/wk	Sedation, dizziness, nausea and GI irritability, ataxia, loss of libido, cognitive changes N.B. Reduces OCP efficacy	Same as for phenobarbital
Phenytoin (PHT)	Focal epilepsy Generalized epilepsy Status epilepticus	3–8	200–800	200–300 mg (100 mg tid) + 100 mg/d/wk	Drowsiness, cognitive changes, dyskinesias, hirsutism, ataxia, coarse facial features, gingival hyperplasia, osteopenia, lymphadenopathy, anemia (megaloblastic), teratogenicity N.B. Reduces OCP efficacy	SJS/TEN, hepatic failure, agranulocytosis, aplastic anemia, lupus-like reactions, hyperglycemia

TABLE  
95.2Clinical Guidelines for the Use of Current Antiepileptic Medications<sup>a</sup>—cont'd

Drug (Abbreviation)	Indication (Epilepsy Type/Syndrome)	Daily Dosage (mg/kg/d)	Usual Maintenance Doses (mg/d)	Suggested Titration Rate (Initial Dose + mg/d/wk up to Desired Dose or Adequate Response)	Common Adverse Effects	Idiosyncratic Effects
Carbamazepine (CBZ)	Focal epilepsy	10–15	400–1600	400 mg daily (200 mg bid) + 200 mg/d/wk	Diplopia, dizziness, lethargy, behavior changes, cognitive changes, dyskinesias, conduction blocks N.B. Reduces OCP efficacy	Agranulocytosis, aplastic anemia, SJS/TEN, angioedema, hepatic and renal failure, hyponatremia
Clonazepam (CZP)	Focal epilepsy Generalized epilepsy N.B. Used as adjunctive agent	0.05–0.1	1–8	0.5–1 mg/d + 0.5–1 mg/d/wk	Drowsiness, ataxia, behavior disorder	Dependence, withdrawal syndrome/seizures with discontinuation
Valproate (VPA)	Focal epilepsy Generalized epilepsy Status epilepticus	20–30	500–2500	500–1000 mg per day + 250 mg/d/wk	GI upset, hepatic toxicity, hyperammonemia, behavior changes, tremor, weight gain, hair loss, significant teratogenicity/negative neurodevelopmental impact for exposed fetuses	Pancreatitis, hepatic failure, coma
Ethosuximide (ESM, ESX, ETS)	Generalized epilepsy (absence seizures only)	10–20	500–1500	250–500 mg + 250 mg/d/wk	Nausea, anorexia, vomiting and diarrhea, drowsiness, insomnia, ataxia, aggressive behavior, psychosis, depression	Skin rash, SJS/TEN, agranulocytosis, aplastic anemia, thrombocytopenia, DRESS syndrome
<b>Second-Generation AEDs</b>						
Gabapentin (GBP)	Focal epilepsy N.B. May aggravate myoclonic seizures	15–60	900–3600	300–900 mg + 300–900 mg/d/1–2 wk	Drowsiness, fatigue, dizziness	None
Lamotrigine (LTG)	Focal epilepsy Generalized epilepsy Status epilepticus N.B. May aggravate myoclonic seizures	1.7–8.3	100–400	Start with 25 mg/d for 2 weeks, then 50 mg/d for 2 weeks, + 50 mg/d/1–2 wk (faster with enzymes inducers, slower with inhibitors)	Dizziness, double vision, drowsiness, insomnia, headaches	Skin rash, SJS/TEN

TABLE  
95.2Clinical Guidelines for the Use of Current Antiepileptic Medications<sup>a</sup>—cont'd

Drug (Abbreviation)	Indication (Epilepsy Type/Syndrome)	Daily Dosage (mg/kg/d)	Usual Maintenance Doses (mg/d)	Suggested Titration Rate (Initial Dose + mg/d/wk up to Desired Dose or Adequate Response)	Common Adverse Effects	Idiosyncratic Effects
Topiramate (TPM)	Focal epilepsy Generalized epilepsy	3.3–10	100–400	250–50 mg/d + 25/50 mg/d/wk	Drowsiness, cognitive difficulties, kidney stones, glaucoma, teratogenicity and increased risk for SGA N.B. Reduces OCP efficacy at high doses	Oligohydrosis/hyperthermia, metabolic acidosis
Tiagabine (TGB)	Focal epilepsy	0.5–1.0	16–56	4 mg/d + 4–8 mg/d/wk	Drowsiness, fatigue, dizziness, cognitive difficulty, tremor	Nonconvulsive status epilepticus/encephalopathy
Oxcarbazepine (OXC)	Focal epilepsy Generalized epilepsy	3.3–30	600–2400	600 mg/d + 600 mg/d/wk	Drowsiness, fatigue, dizziness, headache N.B. Reduces OCP efficacy at high doses	Hyponatremia, skin rash, Stevens-Johnson syndrome
Levetiracetam (LEV)	Focal epilepsy Generalized epilepsy	16.7–50	1000–4000	750–1000 mg + 500 mg/d/wk	Drowsiness, fatigue, dizziness, headache, psychiatric disturbance	Psychosis
Zonisamide (ZNS)	Focal epilepsy Generalized epilepsy	3.3–10	200–600	100 mg/d + 100 mg/d/wk	Drowsiness, dizziness, anorexia, weight loss, headache, cognitive difficulties, kidney stones	Hepatotoxicity, SJS/TEN, oligohydrosis/hyperthermia, metabolic acidosis
Felbamate (FLB, FBM)	Focal epilepsy Generalized epilepsy (LGS)	15–40	1800–3600	600 mg + 600 mg/d/1–2 wk	decreased appetite, nausea, insomnia, dizziness, somnolence, and headache N.B. Potentially reduces OCP efficacy	Aplastic anemia, liver failure
Pregabalin (PGB)	Focal epilepsy N.B. May aggravate myoclonic seizures	—	150–600	50–75 mg/d + 50–75 mg/d/wk	Somnolence, dizziness, ataxia, blurred vision, increased appetite, peripheral edema, myoclonus	None

TABLE  
95.2Clinical Guidelines for the Use of Current Antiepileptic Medications<sup>a</sup>—cont'd

Drug (Abbreviation)	Indication (Epilepsy Type/Syndrome)	Daily Dosage (mg/kg/d)	Usual Maintenance Doses (mg/d)	Suggested Titration Rate (Initial Dose + mg/d/wk up to Desired Dose or Adequate Response)	Common Adverse Effects	Idiosyncratic Effects
<b>Third-Generation AEDs</b>						
Rufinamide (RFM)	Generalized epilepsy (LGS)	5.0–47.0	400–3200	200–400 mg/d + 200–400 mg/d/wk	Fatigue, nausea, decreased appetite, dizziness, tremor N.B. Potentially reduces OCP efficacy	Hypersensitivity, leukopenia, status epilepticus
Vigabatrin (VGB)	Focal epilepsy (also infantile spasms)	40–60	1000–3000	250–500 mg/d + 500 mg/d/wk	Sedation, fatigue, weight gain, headaches, dizziness, depression	Bilateral concentric visual field constriction (progressive in permanent), MRI changes in infants (asymptomatic and reversible)
Eslicarbazepine (ESL)	Focal epilepsy	—	800–1200	400 mg + 200–400 mg/d/wk	Dizziness, drowsiness, nausea, ataxia, depression	Skin rash, Stevens-Johnson syndrome, DRESS syndrome
Lacosamide (LCM, LCS)	Focal epilepsy Status epilepticus	—	200–400	100 mg + 50–100 mg/d/wk	Dizziness, headache, nausea, diplopia, syncope, atrial arrhythmias	PR prolongation on EKG
Clobazam (CLB)	Focal epilepsy Generalized epilepsy	0.1–0.5	10–40	10 mg + 5 mg/d/wk	Drowsiness, fatigue, ataxia, dizziness, memory disturbance, aggressiveness N.B. Reduces OCP efficacy	Angioedema, depression, SJS/TEN
Perampanel (PER, PRP)	Focal epilepsy Generalized epilepsy	—	8–12	2 mg/d + 2 mg/d/wk	Dizziness, somnolence, headache, fatigue, ataxia, blurred vision, aggression, homicidal ideation	Acute psychosis, DRESS syndrome
Brivaracetam (BRV)	Focal epilepsy Generalized epilepsy	—	50–200	50–100 mg/d + 50 mg/d/wk	Drowsiness, fatigue, dizziness, nausea and vomiting, psychiatric disturbance	Angioedema, bronchospasm, decreased neutrophils

<sup>a</sup>Information in this table reflects the authors' practice and may be different from the commercial guidelines for these medications.

AEDs, Antiepileptic drugs; *bid*, twice a day; EKG, electrocardiogram; GI, gastrointestinal; OCP, oral contraceptive; SGA, small for gestational age; *tid*, three times per day.

**TABLE 95.3 Mechanism of Action, Basic Pharmacokinetic Data (Half-Life, Time to Steady State, Percent Bound to Proteins), and Target Therapeutic Concentration Range for Current Antiepileptic Medications**

Drug (Abbreviation)	Mechanism of Action	Half-Life in Adults (h)	Time to Steady State (days)	Protein Binding (%)	Therapeutic Range of Serum Concentration ( $\mu\text{g/mL}$ )
<b>First-Generation AEDs</b>					
Phenobarbital (PB)	Potentiates GABA <sub>A</sub> receptor-mediated postsynaptic chloride channel	45–136	14–21	40–60	15–40
Primidone	Potentiates GABA <sub>A</sub> receptor	6–18	4–7	0	5–12
Phenytoin	Enhancement of the fast inactivation of the voltage-gated sodium channel	10–34	7–8	69–96	10–20
Carbamazepine	Enhancement of the fast inactivation of the voltage-gated sodium channel	14–27 (auto-induction)	3–4	66–89	4–12
Clonazepam	Potentiates the activity of GABA	20–40	14–21	47	>0.03
Valproate	Enhancement of the fast inactivation of the voltage-gated sodium channel; upregulates glutamate transport; downregulates GABA transport	6–15	1–2	80–95	50–100
Ethosuximide	Blockade of T-type calcium currents in thalamus	30–60	2–10	<10	40–100
<b>Second-Generation AEDs</b>					
Gabapentin	No interaction with GABA, binds to voltage-gated calcium channels	5–7	1–2	<5	2–20
Lamotrigine	Interferes with the fast-inactivated state of the voltage-gated sodium channel	24–50	3–15	55	2.5–15
Topiramate	Multiple mechanisms, including weak inhibition of carbonic anhydrase activity	19–24	4–5	9–17	5–20
Tiagabine	Inhibition of GABA uptake at the synapse	7–13	1–2	95	No target concentration
Oxcarbazepine	Interferes with the fast-inactivated state of the voltage-gated sodium channel	8–10	2	40	10–35
Levetiracetam	Nonspecific decrease in neurotransmitter release by binding to the synaptic vesicle protein SV2A	6–8	2	<10	5–45
Zonisamide	Weak inhibition of carbonic anhydrase activity and reducing T-type calcium currents	50–70	7–14	40	10–40
Felbamate	Positive modulator of GABA <sub>A</sub> receptors and antagonist of NMDA receptors	20–23	3–5	25	40–100
Pregabalin	No interaction with GABA, binds to voltage-gated calcium channels	6	1–2	0	2.8–8.2

**TABLE 95.3 Mechanism of Action, Basic Pharmacokinetic Data (Half-Life, Time to Steady State, Percent Bound to Proteins), and Target Therapeutic Concentration Range for Current Antiepileptic Medications—cont'd**

Drug (Abbreviation)	Mechanism of Action	Half-Life in Adults (h)	Time to Steady State (days)	Protein Binding (%)	Therapeutic Range of Serum Concentration (µg/mL)
<b>Third-Generation AEDs</b>					
Rufinamide	Interferes with the activity of the voltage-gated sodium channels, at higher doses may inhibit glutamate receptors	6–8	1–2	34	No target concentration Usually 3–30
Vigabatrin	Irreversibly inhibits GABA-T	5–10.5	2	0	No target concentration Usually 20–60
Eslicarbazepine	Competitive interaction with the inactivated state of the voltage-gated sodium channel	13–20	4–5	<40	No target concentration Usually <0.05
Lacosamide	Enhancement of the slow inactivation of the voltage-gated sodium channel	13	3	<15	2.5–18
Clobazam	Enhancement of the inhibitory effect of GABA, by binding to the GABA receptor at postsynaptic site	10–30	5–9	85	No target concentration Usually 100–300
Perampanel	Noncompetitive antagonism of AMPA glutamate receptor	105	14–21	95	No target concentration
Brivaracetam	Selective binding affinity for synaptic vesicle protein 2A (SV2A) in the brain and nonspecific decrease in neurotransmitter release	~9	2	≤20	No target concentration

epilepsy in the elderly, levetiracetam and lamotrigine should be the first-line AEDs.

AEDs should be administered in the simplest possible schedule, to help with compliance. Most of them are now available in extended-release formulations, which allows for once or twice a day dosing regimen, and may improve tolerability, likely by reducing the degree of level fluctuation. In some patients who experience an acute dose-related sedation, a large single dose can be taken in the evening, or a smaller dose can be used in the morning and a larger dose at bedtime.

Patients taking AEDs should be monitored closely, at least initially, to ensure adequate blood levels of the drug. There is individual variability, both in the rapidity with which drugs are absorbed and metabolized and in the degree to which concurrent administration of other drugs alters the rate of metabolism of the drug in question. With some AEDs (e.g., carbamazepine), autoinduction needs to be factored in the initial uptitration regimen and plan for repeated level checks. Moreover, the relationship between

the blood level of an agent and the dose administered is not always linear, and saturation kinetics need to be taken into consideration (e.g., phenytoin); once binding sites, renal excretory capacity, or metabolic enzymes become saturated, the blood level tends to rise more markedly with smaller increments in dosage.

Blood levels should be checked at intervals of 7 to 10 half-lives after an alteration in dosage. Several studies have demonstrated that serum levels of the first-generation AEDs correlate well in a group of patients with therapeutic efficacy and with the presence of side effects, whereas high levels for many of the second- and third-generation AEDs are less frequently triggering toxicity. It should be emphasized, however, that for any given patient, the proper blood level depends on individual factors; absence of seizures and freedom from side effects are the goals of treatment; and blood levels are only a guide, albeit an important one, toward achieving those goals. Although individual laboratories differ in the precise range accepted as therapeutic for a given AED, the levels given in [Table 95.3](#) are close to those found in most institutions.

In summary, blood levels may be useful in any of the following situations: (1) checking the adequacy of the dosage and establishing an individual therapeutic concentration once the desired clinical outcome is attained; (2) ensuring patient compliance with the medication regimen; (3) confirming the diagnosis of AED toxicity (frequent symptoms include drowsiness, ataxia, dizziness, diplopia, and dysarthria); (4) to guide dosage adjustment in situations associated with increased pharmacokinetic variability (pregnancy, children, elderly, comorbidities or changing formulations); and (5) assessing the effect of newly added drugs on the levels of previously administered ones.

Finally, patients treated with AEDs should undergo periodic physical examinations to spot early idiosyncratic side effects and to ensure that no lesion missed in the initial evaluation has now become evident. EEGs should be performed every few years to assess the nature of the abnormal activity and to monitor the appearance of new focal abnormalities. However, frequent use of EEGs in the management of patients with seizures not yet controlled by medication is not likely to prove helpful in deciding the next therapeutic step and may cause unnecessary alarm because of drug-induced slowing.

### Refractory and Recurrent Seizures

In patients with refractory seizures, a systematic trial of a wide spectrum of suitable drugs should be made, each drug being pushed to tolerance or high therapeutic levels before another is tried. Drugs that do not appreciably reduce the seizure frequency should be discontinued. It is rarely necessary to have the patient taking more than three drugs at a time. In discontinuing medication, even of an auxiliary drug, dosage should be gradually tapered over several weeks. The most common cause of status epilepticus is sudden withdrawal of medication.

Failure to control seizures despite therapeutic levels of two or more drugs may result from numerous factors: (1) noncompliance; (2) incorrect diagnosis (seizure mimics, including PNES or a mixed epileptic and nonepileptic disorder); (3) wrong choice of medication, although the choice, as explained previously, remains largely empiric (e.g., paradoxical increase in seizures with starting on an AED; sodium-channel blocker in generalized epilepsies); (4) progression of an underlying neurologic disorder that may require discovery or further definition (e.g., autoimmune encephalitis/epilepsy); and (5) drug-resistant epilepsy.

In general, failure to control seizures despite use of additional drugs at higher dosages should lead to a reassessment of the whole regimen and gradual simplification of the regimen. Shifts from one drug to another or discontinuation of a major drug should be undertaken gradually; in those with a serious potential for frequent generalized seizures, this may have to be accomplished in the hospital.

The recurrence of seizures after a period of good control should prompt a diligent search for complicating factors. Most commonly, these include inadequate dosage to

maintain therapeutic levels (e.g., pregnancy, drug-drug interactions), lapses in patient compliance, or intercurrent illness (e.g., electrolyte abnormalities, infection, liver or kidney disease). Worsening of the condition that led to the seizure disorder may be evaluated by repeating the EEG and MRI or CT scan. A patient whose results on initial neurologic evaluation for central nervous system pathology were negative may experience a reappearance of seizures as the sole manifestation of a slowly growing tumor, especially a glioma or oligodendroglioma.

A patient's epilepsy is deemed to be pharmacoresistant if sustained seizure freedom is not achieved after adequate trials of at least two appropriate AEDs, given alone or in combination. Another AED trial is thought to have low chances of success (3%–20%) and, if the patient has been managed by an internist/general neurologist up to this point, a referral to an epileptologist should be made for diagnostic reassessment, including presurgical evaluation for either resection surgery (if one resectable focus is identified) or a stimulation device (either RNS if the identified focus is nonresectable/eloquent cortex, or if two foci are identified, or VNS or DBS [deep brain stimulator] if more than two foci or no focus are identified).

### Stopping Antiepileptic Medications

In many patients, complete control of seizures for a period of years leads to the inevitable question, "When can I stop the medicine?" Unfortunately, a recent Cochrane review concluded that there is evidence in children that discontinuing medications before at least two seizure-free years is associated with a higher recurrence risk than waiting for two or more seizure-free years, particularly if individuals have an abnormal EEG and focal seizures; the same authors concluded that there is no definite evidence to guide AED withdrawal in adults. A 2004 review of 28 studies, some included and some excluded from the Cochrane review, reported that the cumulative probability of remaining seizure free after AED withdrawal was 66% to 96% at 1 year and 61% to 91% at 2 years for children and 39% to 74% at 1 year and 35% to 57% at 2 years for adults.

Certain factors in the history raise the risk of discontinuing therapy. More severe seizure disorder, as measured by frequency of seizures before medication is instituted or by frequency of seizures while taking medication, is associated with increased risk of recurrence. A long history of seizures, even if infrequent, should suggest an ongoing seizure diathesis as opposed to the patient with a similar number of seizures over a short period. Onset of seizures after age 30 years has a higher incidence of recurrence when no medication is being taken. EEG abnormalities, such as focal slowing or bilateral paroxysmal spike-wave or sharp-wave activity, either before the institution of therapy, during therapy, or after withdrawal of medication, are usually associated with an increased risk of recurrence. Most investigators agree that the risk of further seizures is greater in those with

focal seizures than in those with generalized seizures. Also, patients with juvenile myoclonic epilepsy, those with prior withdrawal attempts, and those with late remission have a higher risk of relapse.

Even though discontinuation of drug treatment does not seem to affect the long-term prognosis, patients should be informed that there is a transient 2-fold risk of seizures for the first 2 years after stopping AEDs. Moreover, 20% of patients who were seizure free for years do not become seizure free immediately after restarting AED treatment after relapse.

Practice varies in different clinics, but a seizure-free period of at least 2 years and possibly longer (e.g., in the patient with a longer history of seizures) should be achieved before drug withdrawal is considered. In suitable candidates, an EEG before tapering the medication over several months and a satisfactory EEG result (absence of focal slowing or bilateral paroxysmal changes) after the cessation of all drugs are necessary conditions for the further withholding of anticonvulsants. However, a normal or mildly abnormal EEG result is no guarantee of a sustained remission. Patients should avoid driving during the period of tapering and for several months thereafter. In many cases, a frank discussion of the risks and potential difficulties involved will lead to a mutual decision to continue the medication indefinitely.

### Management of Epilepsy During Pregnancy

Pregnancy in a woman undergoing treatment for seizures raises important questions regarding the efficacy and safety of AEDs both for the mother and the developing fetus. Preconception counseling for women of childbearing age on an AED should be done routinely, and the regimen should be adjusted to the fewer number of AEDs possible, with a preference for the AEDs with known safe profiles during pregnancy, if the patient's epilepsy permits, months if not years before conception. The recommendation for daily folic acid should also be made for all women of childbearing age and a higher dose (1–4 mg daily) should be chosen, as periconception folic acid use was associated with decreased risk for major congenital malformations (MCMs) and improved developmental outcomes.

It was shown that antiepileptic medications may impact the risk for MCMs (neural tube defects, cardiac, urogenital, cleft lip/palate that require surgery at or soon after birth), neonatal outcomes (e.g., birth weight, head circumference, Apgar score, need for neonatal intensive care unit), and obstetric outcomes (e.g., preterm delivery and C-section rates) as well as long-term neurodevelopmental impact (IQ, verbal and nonverbal abilities, memory, behavior and any predisposition for autism spectrum disorders). Similarly, although epilepsy per se does not increase the risk for MCM, uncontrolled seizures may have a detrimental effect on the mother (injury, sudden unexpected death in epilepsy) and on the developing fetus (injury/miscarriage, evidence for prolonged fetal distress even with brief convulsive seizures, increased risk for neurodevelopmental delay with five or

more convulsive seizures, and potential risk for small for gestational age associated with uncontrolled nonconvulsive seizures). Based on clinical evidence so far, levetiracetam and lamotrigine seem to have the safest profile, followed by carbamazepine and oxcarbazepine, and potentially zonisamide and lacosamide, but less data are available for these last two AEDs. Topiramate should be avoided given growing evidence of increased risk for MCM and small for gestational age. Valproate is the AED with the highest MCM rates and the most detrimental impact on long-term neurodevelopment, including increased risk for autism; thus, it should only be used as a last resort. In addition, monotherapy is preferred, and if polytherapy is necessary, it should exclude valproate or topiramate.

Review of relevant literature revealed large variations in the percentage of patients with unchanged seizure frequency ranging from 54% to 80%; the percentage of women with a decrease in seizure frequency ranged from 3% to 24%, and the percentage of women with an increase in seizure frequency ranged from 14% to 32%. Good predictors for sustained seizure control during pregnancy are generalized (73.6%) versus focal epilepsy (59.5%) and seizure control in the 9 months to 1 year before pregnancy (approximately 90% of women with epilepsy [WWE] remain seizure free during pregnancy if seizure free for at least 9 months to 1 year before pregnancy, whereas WWE who had seizures in the prepregnancy month had 15 times higher risk for seizures during pregnancy).

One of the major factors that may lead to impaired seizure control during pregnancy is the fluctuation in the AED clearance, which can be controlled for by monthly AED level checks and adequate dose adjustments to maintain an individualized target concentration, determined on the preconception level that offered the best seizure control.

### Social and Legal Issues

There are considerable social and legal implications of the diagnosis of epilepsy. Each state differs in its precise requirements, but most states impose obligations on both the physician and the patient in regard to driving. Every physician who treats seizure disorders should become familiar with the laws of his or her state. Most states require a period of abstinence from driving after the diagnosis of a seizure disorder and a minimum period of seizure-free status before the resumption of driving. These requirements are generally binding on patients with an element of impaired consciousness during their seizures; the strictures may be less severe in the case of focal seizures without loss of consciousness.

Engaging in sports or occupations in which a sudden impairment of consciousness would lead to almost certain injury should be discouraged. Skiing, bobsledding, mountain climbing, and swimming without a companion pose hazards that are often unacceptable; operating milling machines, lathes, saws, or other dangerous equipment is in the same class.

Further restrictions usually depend on the nature of the seizures (rate of onset and degree of impairment) and their frequency. Finally, it is essential that patients receive a thorough explanation of the nature of epilepsy or seizures and that efforts be

made to dispel the mistaken but nonetheless prevalent popular notions regarding this illness. Family members are entitled to the same complete explanation and often require instruction in the proper steps to take if a seizure should occur.

## Board Simulation: Neurology

TRACEY A. MILLIGAN

### Questions

1. A 22-year-old man is evaluated in the emergency department (ED) 2 hours after sudden onset of moderate neck pain followed by vertigo, ataxia, slurred speech, and difficulty swallowing. His medical history is unremarkable, and he is not taking any medications. Physical examination shows left ptosis, anisocoria with the left pupil smaller than the right, nystagmus, left-sided dysmetria, and decreased pain and temperature sensation on the left side of the face and right side of the body. CT scan of the brain is normal.  
What is the most appropriate test?
  - A. Repeat CT of the brain in 24 hours
  - B. Carotid ultrasound
  - C. MRI, MR angiography of the brain and neck
  - D. Lumbar puncture
  - E. CT of the skull base and neck
2. A 32-year-old man is evaluated for what he calls a “sinus headache.” The headache occurs 2 or 3 times per month and is accompanied by facial pressure and occasional rhinorrhea. Resting in a dark quiet room gives some relief. The symptoms resolve in 1 or 2 days regardless of treatment. He has tried multiple varieties of decongestants and antihistamines without success. Acetaminophen-aspirin-caffeine preparations provide minimal relief. He is currently symptomatic. The patient is pale and moderately distressed. Temperature is 37.1°C, pulse rate is 84 beats per minute, respiration rate 16 breaths per minute, and blood pressure is 132/75 mm Hg. His face is tender on palpation.  
What is his most likely diagnosis?
  - A. Cluster headache
  - B. Migraine without aura
  - C. Sinus headache
  - D. Tension headache
  - E. Trigeminal neuralgia
3. A 70-year-old man is evaluated for a 9-month history of progressive gait disturbance. For the same period of time, he has noticed numbness and tingling in his hands and an occasional “electric shock” sensation into his arms and down his spine when he bends his neck. He has a normal mental status and cranial nerve examination. Upper extremity strength is normal except for mild 4/5 weakness of the intrinsic muscles of his hands. Lower extremity strength is 4/5. There is vibratory loss in the hands and from the knees down. Reflexes are 2+ in the biceps bilaterally, with 3+ in the triceps and knee jerks, and sustained clonus in the ankles. An extensor planar response is present bilaterally. Gait is very stiff and narrow based, and his legs tend to “scissor” over each other as he walks forward.  
Which of the following is the most likely diagnosis?
  - A. Parkinson disease
  - B. Lumbar spinal stenosis
  - C. Normal-pressure hydrocephalus
  - D. Cervical spondylotic myelopathy
  - E. Paraneoplastic syndrome
4. A 70-year-old woman with a history of diabetes mellitus is admitted to the intensive care unit (ICU) after surgical repair of a small bowel perforation associated with peritonitis. After treatment of the sepsis, she cannot be weaned from the ventilator. Physical examination reveals severe generalized weakness with sparing of cranial nerve function. Reflexes are absent, and the sensation is decreased to light touch in the distal upper and lower extremities. Cerebrospinal fluid (CSF) protein concentration is normal.  
What is the most likely diagnosis?
  - A. Vasculitic neuropathy
  - B. Guillain-Barré syndrome
  - C. Diabetic lumbosacral polyradiculopathy
  - D. Critical illness polyneuropathy
  - E. Myasthenia gravis
5. A 32-year-old woman is evaluated for a 2-week history of weakness of the right arm and left leg. The initial symptom was acute right wrist drop associated with sensory loss in a radial nerve distribution and severe pain. One week later, she developed similar symptoms in the left peroneal nerve distribution. The patient has systemic lupus erythematosus, and her medications include prednisone and hydroxychloroquine.  
Which of the following is the most likely diagnosis?
  - A. Guillain-Barré syndrome
  - B. Toxic neuropathy
  - C. Motor neuron disease

- D.** Vasculitic neuropathy  
**E.** Lyme disease
6. A 59-year-old man has been incontinent of urine eight times in the past 3 months. He complains of urgency and cannot inhibit micturition. His family notes that his gait has become hesitant and his thinking has slowed. He had a single episode of subarachnoid hemorrhage 2 years ago treated by clipping of an aneurysm. Medical history is otherwise unremarkable. Neurologic examination shows decreased spontaneity but good memory and normal use of language; a small-stepped, shuffling gait; and bilateral extensor plantar reflexes. The most likely diagnosis is:  
**A.** Normal-pressure hydrocephalus  
**B.** Alzheimer disease  
**C.** Cervical spondylitic myelopathy  
**D.** Diabetic neuropathy  
**E.** Parkinson disease
7. Ten days ago, a 22-year-old man had an inoculation of tetanus toxoid in his right arm after removal of a splinter. He now has severe pain in the right shoulder and right arm and paresthesias in the right hand. Physical examination shows severe weakness of muscles around the right shoulder girdle and absence of the right biceps reflex. Passive range of movement of the shoulder is normal. Sensory examination is normal, and other reflexes in the arms and legs are normal. The most likely diagnosis is:  
**A.** Brachial neuritis  
**B.** Herniated C7 disk  
**C.** Epidural cervical spinal abscess  
**D.** Cervical spinal cord tumor  
**E.** Rotator cuff injury
8. A 60-year-old man with a long history of back pain recently began feeling weakness and tingling in his legs when he walks more than a half a block. The symptoms disappear when he sits. He has no symptoms when doing bicycling-like exercises supine on his bed even after 30 minutes. Except for an absent left ankle reflex, neurologic examination is normal. Foot and femoral pulses are normal. The most likely diagnosis is:  
**A.** Aortic atherosclerosis with claudication  
**B.** Polyneuropathy  
**C.** Herniated lumbar L5 disk  
**D.** Lumbar spinal stenosis  
**E.** Cervical spondylitic myelopathy
9. A 25-year-old previously healthy man is found unconscious in his apartment. There is no evidence of trauma. On examination, he is responsive to voice and painful stimulation. There is no evidence of meningeal irritation. The pupils are 3 mm and unreactive. There are no inducible eye movements by the doll's eye maneuver or irrigation of a tympanic membrane with ice water, but he is able to look up when asked to do so. The blood pressure is 90/70 mm Hg, and the pulse rate is 54 beats per minute. Respiratory function is depressed. The most likely diagnosis is:  
**A.** Sedative drug overdose  
**B.** Subarachnoid hemorrhage  
**C.** Intracranial mass  
**D.** Brainstem stroke  
**E.** Narcotic overdose
10. A 35-year-old woman who had a renal transplant 4 years ago for renal failure caused by membranous glomerulonephritis is hospitalized because of progressive right homonymous hemianopia. She has been treated with prednisone and cyclosporine. A test for HIV is negative. CT scan of the brain shows a large low-density lesion in the left occipital lobe that spares the cortical gray matter. There is no mass effect and no contrast enhancement. There are also similar smaller lesions throughout the white matter. The most likely diagnosis is:  
**A.** Multiple sclerosis  
**B.** Glioma  
**C.** Embolic stroke  
**D.** Progressive multifocal leukoencephalopathy  
**E.** Primary central nervous system (CNS) lymphoma
11. A 70-year-old woman is hospitalized with aspiration pneumonia. She has had difficulty walking over the past 3 to 4 years. She now frequently falls and has been using a walker for 1 year. Her speech is unintelligible, and she has poor vision. She was briefly treated with carbidopa-levodopa without improvement. On physical examination, she looks anguished, has difficulty with down gaze, and is severely dysarthric. She is rigid throughout but more so in the neck and has moderate bradykinesia and impaired gait and postural reflexes. What is the most likely diagnosis?  
**A.** Parkinson disease  
**B.** Progressive supranuclear palsy  
**C.** Normal-pressure hydrocephalus  
**D.** Amyotrophic lateral sclerosis  
**E.** Vascular dementia
12. A 50-year-old woman is evaluated for a 2-day history of headache and progressive sleepiness. She was diagnosed with breast adenocarcinoma 5 years ago and has received lumpectomy, breast radiation therapy, and chemotherapy with cyclophosphamide, methotrexate, and doxorubicin. The tumor recurred 1 year ago, and she has metastases to the liver, lung, and bone. Her medications include morphine sulfate and tamoxifen. On examination, she is afebrile and drowsy but can follow simple commands symmetrically with all four extremities. The pupils are 4 mm, symmetric, and reactive. She has mild bilateral papilledema. There is mild neck stiffness. CT of the head with and without contrast shows communicating hydrocephalus with no abnormal enhancement. What is the most likely diagnosis?  
**A.** Pseudotumor cerebri  
**B.** Leptomeningeal carcinomatosis

- C. Superior sagittal sinus thrombosis  
 D. Fungal meningitis  
 E. Methotrexate toxicity
13. Four years after having lumpectomy and radiation treatment for breast carcinoma, a 45-year-old woman develops pain and weakness of the left leg that spreads over a period of 1 week to involve the right leg. She also has local back pain in the midthorax and a circumferential band-like sensation. In the past day, she has become incontinent of urine after brief urgency, and her genitalia are numb. Reflexes are 3+ with unsustained ankle and knee clonus; toes are extensor, and the legs occasionally jerk into a flexed posture. The most likely diagnosis is:  
 A. Intramedullary metastasis  
 B. Epidural metastasis  
 C. Carcinomatous meningitis  
 D. Metastasis to the sagittal sinus  
 E. Radiation necrosis of the spinal cord
14. A 55-year-old man is evaluated in the ED after awakening with vertigo, ataxia, and headache. He has hypertension and stable angina, and his medications are aspirin, a beta-blocker, and a statin. On examination, his blood pressure is 170/90 mm Hg. Physical examination reveals bidirectional nystagmus and gait ataxia. CT scan of the brain is normal. Examination on the following day reveals intractable hiccups, bidirectional horizontal nystagmus, normal strength, and dysmetria of the right upper and lower extremities. Which of the following is the most likely diagnosis?  
 A. Ménière disease  
 B. Cerebellar infarction  
 C. Vestibular migraine  
 D. Benign positional vertigo  
 E. Vestibular neuronitis
15. A 23-year-old mechanic caught his hand in a vise. Two weeks later he developed a severe, constant ache in his hand. The hand becomes pale with some cyanotic mottling and feels cold and sweaty, and movement is limited. The most likely diagnosis is:  
 A. Carpal tunnel syndrome  
 B. Occlusion of the ulnar artery  
 C. Psychophysiologic disorder  
 D. Complex regional pain syndrome  
 E. Acute brachial plexus neuritis (Parsonage-Turner syndrome)
16. A 30-year-old man is evaluated for a 1-month history of episodes during which he is suddenly unable to speak. He has had five episodes; the last three were during the past week. There are no warnings preceding episodes, and they last 20 to 30 seconds. During the episodes, the patient has twitching of the right side of his face; on one occasion, the twitching progressed to involve the right arm. The patient states that he is fully aware of his surroundings during the episodes and has no other symptoms. He has no significant medical history and takes no medications. Physical examination is normal. Which of the following is the most likely diagnosis?  
 A. Transient ischemic attack  
 B. Frontal lobe seizure  
 C. Hemiplegic migraine  
 D. Hypoglycemia  
 E. Amyloid angiopathy
17. A 60-year-old woman is transferred to a chronic care facility 8 weeks after a cardiac arrest. The arrest occurred when she was at a restaurant and suddenly lost consciousness. When emergency medical services arrived minutes later, she was found to be in Vfib arrest and was successfully cardioverted to normal sinus rhythm. Since her cardiac arrest, she has remained unresponsive, without any response to commands; 3 weeks after the arrest, she began to have the return of normal sleep-wake cycles. On examination, she has a tracheostomy in place but is not on the ventilator and breathes well spontaneously. She occasionally yawns. Pupils are equal and reactive to light. Her eyes are open; she has spontaneous conjugate movements of her eyes to either side but does not appear to track objects or look at the examiner. She flexes her arms to noxious stimuli but has no evidence of any purposeful or voluntary response to visual, auditory, or tactile stimulation. Which of the following is the most appropriate description of this patient's condition?  
 A. Coma  
 B. Vegetative state  
 C. Minimally consciousness state  
 D. Locked-in syndrome  
 E. Brain dead
18. A 75-year-old man is evaluated for dizziness. He feels light headed when he stands and has fainted twice in the last year. He has a sense of imbalance with occasional falls that has developed insidiously over the past 3 years. He also has urinary incontinence, constipation, and impotence. On examination, blood pressure is 130/80 mm Hg with a pulse rate of 80 beats per minute while lying down and a blood pressure of 80/50 mm Hg with no change in pulse rate standing up. There is impairment in fine motor movements bilaterally and in gait and balance. There is mild rigidity but no tremor. Deep tendon reflexes are brisk and symmetric, and extensor plantar response is present bilaterally. What is the most likely diagnosis?  
 A. Systemic amyloidosis  
 B. Progressive supranuclear palsy  
 C. Multiple system atrophy  
 D. Vitamin B<sub>12</sub> deficiency  
 E. Parkinson disease
19. A 55-year-old man is evaluated for a 5-month history of progressive right foot drop and slurred speech. Physical examination reveals tongue weakness associated with tongue fasciculations and atrophy and

a positive jaw jerk. The right leg is weak and atrophic with fasciculations. He has ankle clonus and an extensor plantar response. The sensory examination is normal.

What is the most likely diagnosis?

- A. Cervical spondylosis
  - B. Myasthenia gravis
  - C. Spinal muscular atrophy
  - D. Amyotrophic lateral sclerosis
  - E. Transverse myelitis
20. A 50-year-old man is evaluated for a 6-month history of progressive proximal muscle weakness, myalgias, fatigue, and distal paresthesias. He also has constipation and mild hoarseness. He has a history of obesity, hyperlipidemia, and hypertension. Medications include lovastatin and lisinopril. Physical examination confirms the presence of hip and shoulder girdle weakness. Reflexes are normal, although the relaxation phase is delayed. Creatine kinase level is 12,000 U/L. Which of the following is the most appropriate for this patient?
- A. Remove the statin
  - B. Muscle biopsy
  - C. Thyroid-stimulating hormone assay
  - D. Electromyography
  - E. Acetylcholine receptor antibody titer

### Answers

1. C. This patient has had an ischemic stroke. The symptoms and signs involve multiple cranial nerves and crossed sensory deficits and cerebellar ataxia, which all localize to the left lateral medulla and cerebellum. The vascular territory is the posterior inferior cerebellar artery, which is the major branch of the vertebral artery. The normal CT rules out a cerebral hemorrhage and may not be sensitive enough to visualize an early stroke in the posterior fossa. Because the patient is young, the most likely etiology is that he has had an arterial dissection of the vertebral artery, which usually causes pain in the posterior head or neck, Horner syndrome (miosis and ptosis), dysarthria, dysphagia, and decreased pain and temperature sensation of the face and contralateral body, dysmetria, ataxia, and vertigo. Carotid ultrasounds are rarely helpful in the evaluation of patients with posterior circulation syndromes. Lumbar puncture is used to evaluate suspected subarachnoid hemorrhage in the patient who has a severe headache and normal CT scan. These localized signs would be atypical for a subarachnoid hemorrhage. CT scan of the skull base and neck will not show the stroke and may miss a vertebral artery dissection. (van der Worp HB, van Gijn J. Clinical practice. Acute ischemic stroke. *N Engl J Med*. 2007;357(6):572–579.)  
Key points: Vertebral artery dissections typically present with neck or head pain, Horner syndrome, dysarthria, dysphagia, decreased pain and temperature sensation, dysmetria, and ataxia and vertigo.
2. B. This patient presents with typical symptoms of migraine headache. Those symptoms include worsening of the headache with movement, limitation of activities, and requiring absence of light and sound. Although some autonomic features are present (congestion/rhinorrhea), the headache is not a cluster type because it lasts longer than 180 minutes. In addition, although not part of the absolute criteria for cluster headache, patients with cluster headache prefer to be mobile because resting causes worsening of the pain. The patient does not have the secondary headache of sinus infection because of the lack of fever or discolored nasal discharge. Although sinus symptoms are not formal criteria for migraine, they are quite common and can complicate the diagnosis. Tension-type headache can be ruled out because of the disabling characteristic of the headache and the presence of both phonophobia and photophobia. Trigeminal neuralgia causes severe facial pain and typically lasts seconds to minutes. Pain may be triggered by chewing or touching the face and can occur many times throughout the day. (Charles A. Migraine. *N Engl J Med*. 2017;377(6):553–561.)  
Key point: Migraine headache without aura criteria includes worsening of headache with movement, limitation of activities, phonophobia, and/or photophobia or nausea.
3. D. The patient has bilateral weakness and vibratory loss in the hands and legs as well as bilateral upper motor neuron findings including spastic gait. These findings are most consistent with a cervical spinal cord process. The historical finding of a Lhermitte sign, an electric shock-like sensation that occurs with neck flexion, is a helpful clue to the presence of a cervical spinal cord problem. The progressive nature of the symptoms suggests a compressive lesion, which can occur in this age group because of cervical spondylosis. Lumbar spinal stenosis would not explain the upper extremity symptoms or the spasticity seen in the patient. Multiple sclerosis can present as a progressive spinal cord syndrome but would be unusual in this age group. Normal-pressure hydrocephalus presents as a shuffling “magnetic” gait as if the feet are glued to the floor, unlike the spastic gait of this patient. Amyotrophic lateral sclerosis is a purely motor syndrome that affects both the lower and upper motor neurons. The condition can cause weakness and spasticity but would not explain the sensory symptoms or signs in this patient. A paraneoplastic syndrome is much less likely, but an example syndrome causing a gait disorder would be paraneoplastic cerebellar degeneration and is most commonly associated with anti-Yo antibodies. In this syndrome, the gait is wide-based. (Alli S, Anderson I, Khan S. Cervical spondylotic myelopathy. *Br J Hosp Med (Lond)*. 2017;78(3):C34–C37.)

Key points: Lhermitte sign, an “electric shock” sensation down the neck, back, or extremities with flexion of the neck, is a helpful clue to cervical spinal cord disease. Cervical spondylosis is a chronic disorder of degenerative changes of the vertebrae, ligaments, and disks that may narrow the spinal canal and can cause cervical spinal cord compression.

4. D. Critical illness polyneuropathy is characterized by generalized or distal flaccid paralysis, depressed or absent reflexes, and distal sensory loss with relative sparing of cranial nerve function. The cause is unknown, but it usually occurs after admission to the ICU, and the predisposing risk factors are sepsis and/or multiorgan failure or the use of paralytics. Cerebral spinal fluid protein is normal in this disorder. (Kress JP, Hall JB. ICU-acquired weakness and recovery from critical illness. *N Engl J Med*. 2014;370(17):1626–1635.)

Guillain-Barré syndrome is associated with weakness and respiratory failure that normally begins before admission to the ICU and is usually preceded by a viral infection. Cranial nerves are frequently affected, and CSF protein concentration is often elevated within 1 week and can be useful in distinguishing this disorder from critical illness polyneuropathy. Vasculitic and lumbosacral diabetic neuropathy are not associated with respiratory failure. Myasthenia gravis is a cause of failure to wean from a ventilator but is often associated with facial weakness, and sensory examination is normal.

Key points: Critical illness polyneuropathy is a common cause of failure to wean from a ventilator in a patient with associated multiorgan failure and sepsis. Critical illness polyneuropathy is characterized by generalized distal flaccid paralysis, depressed or absent reflexes, and distal sensory loss with sparing of cranial nerve functions.

5. D. Vasculitic neuropathy, also called mononeuritis multiplex, involves at least two mononeuropathies and is associated with pain, weakness, or sensory loss. Diseases such as polyarteritis nodosa, rheumatoid arthritis, systemic lupus erythematosus, or diabetes mellitus place patients at higher risk of developing the disease. Toxic neuropathies, Guillain-Barré syndrome, and motor neuron disease usually do not present as individual mononeuropathies and are not associated with pain. (Gwathmey KG, Burns TM, Collins MP, Dyck PJ. Vasculitic neuropathies. *Lancet Neurol*. 2014;13(1):67–82.)

Key points: Mononeuritis multiplex, vasculitic neuropathy, is a painful asymmetric asynchronous sensory and motor peripheral neuropathy involving isolated damage to at least two separate nerve areas. Mononeuropathy multiplex syndromes can be distributed bilaterally, distally, and proximally throughout the body.

6. A. Patients with normal-pressure hydrocephalus exhibit the classic triad of gait difficulties, urinary incontinence, and cognitive decline. It can be misdiagnosed as Parkinson disease (parkinsonism, tremor,

rigidity) or Alzheimer disease (primary cognitive disorder with memory disorders). Although the exact mechanism is unknown, normal-pressure hydrocephalus is thought to be a form of communicating hydrocephalus with impaired CSF reabsorption at the arachnoid villi. Cervical spondylitic myelopathy usually affects arms and legs, and the patient may have a spastic gait. Diabetic neuropathy is a length-dependent neuropathy that predominantly affects the longest nerves; therefore the distal lower extremities are affected first. (Leinonen V, Vanninen R, Rauramaa T. Cerebrospinal fluid circulation and hydrocephalus. *Handb Clin Neurol*. 2017;145:39–50.)

Key point: Normal-pressure hydrocephalus exhibits the classic triad of gait difficulties, urinary incontinence, and cognitive decline.

7. A. Brachial neuritis is characterized by severe shoulder and upper arm pain followed by marked upper arm weakness. The temporal profile of pain preceding weakness is important in establishing a prompt diagnosis and differentiating acute brachial plexus neuritis from cervical radiculopathy. MRI of the shoulder and upper arm musculature may reveal denervation within days, allowing prompt diagnosis. Electromyography conducted 3 to 4 weeks after the onset of symptoms can localize the lesion and help confirm the diagnosis. Treatment includes analgesics and physical therapy, with resolution of symptoms usually occurring in 3 to 4 months. Patients with cervical radiculopathy present with simultaneous pain and neurologic deficits that fit a nerve root pattern. This differentiation is important to avoid unnecessary surgery for cervical spondylotic changes in a patient with a plexitis. (Van Eijk JJ, Groothuis JT, Van Alfen N. Neuralgic amyotrophy: an update on diagnosis, pathophysiology, and treatment. *Muscle Nerve*. 2016;53(3):337–350.)

Key point: Brachial neuritis is characterized by severe shoulder and upper arm pain followed by marked upper arm weakness.

8. D. Lumbar stenosis (spinal stenosis) is a condition whereby either the spinal canal (central stenosis) or vertebral foramen (foraminal stenosis) becomes narrowed. If the narrowing is substantial, it causes compression of the nerves, which causes the painful symptoms of lumbar spinal stenosis. The most common cause of lumbar spinal stenosis is degenerative arthritis. Patients with spinal stenosis may or may not have back pain, depending on the degree of arthritis that has developed. Pressure on spinal nerves can result in pain in the areas that the nerves supply. The pain may be described as an ache or a burning feeling. It typically starts in the area of the buttocks and radiates down the leg. The pain down the leg is often called “sciatica.” As it progresses, it can result in pain in the foot. As pressure on the nerve increases, numbness and tingling often accompany the burning pain, although not all patients will have both burning pain and numbness and tingling. Studies of the lumbar spine show that leaning forward

can actually increase the space available for the nerves. Many patients may note relief when leaning forward and especially with sitting. Pain is usually made worse by standing up straight and walking. Some patients note that they can ride a stationary bike or walk leaning on a shopping cart. Walking more than one or two blocks, however, may bring on severe sciatica or weakness. With aortic atherosclerosis with claudication, leaning forward will not make a difference. (Gandhi J, Shah J, Joshi G, et al. Neuro-urological sequelae of lumbar spinal stenosis. *Int J Neurosci*. 2017;1–28.)

Key point: Lumbar spinal stenosis is secondary to degenerative joint disease. Pressure on spinal nerves can result in pain in the areas that the nerves supply and can be relieved by leaning forward, as in leaning against a cart or riding a bicycle.

9. D. Patient is responsive to voice and stimulation and has no eye movements with the cold caloric examination. This localizes to the brainstem and is consistent with a locked-in syndrome. Patients with the locked-in syndrome are conscious because of intact cortical and upper brainstem function but are quadriplegic and can communicate only by moving their eyes vertically or blinking. The locked-in syndrome is caused by lesions of the base of the pons. Sedative drug overdose or narcotic would not give such a focal examination. Key point: Vascular lesions in the pons may cause the patient to be “locked-in” (intact consciousness, quadriparesis with abnormal caloric responses and vertical gaze intact).
10. D. Progressive multifocal leukoencephalopathy is characterized by progressive damage to the white matter of the brain at multiple locations. It occurs almost exclusively in people with severe immune deficiency, such as transplant patients on immunosuppressive medications, patients receiving certain kinds of chemotherapy, or patients with AIDS. There is generally no enhancement with CT or MRI imaging of the brain. For primary CNS lymphoma, neuroimaging reveals solitary lesions that are most commonly located supratentorially in the white matter of the frontal or parietal lobes or in the subependymal regions, but the lesions may also involve the deep gray matter. CT scans usually show high attenuation, probably because of high cellularity, and virtually all lesions show homogeneous contrast enhancement. On MRI, B-cell primary CNS lymphoma lesions are clearly delineated masses that appear isointense to hypointense on T1-weighted images and mostly iso- or hyperintense on T2-weighted images. Nearly all lesions show homogeneous enhancement with contrast material. A classic presentation is the lesion that crosses the corpus callosum in a butterfly pattern. The time course is not appropriate for a brain tumor or stroke. Both the imaging and time course are not consistent with multiple sclerosis. (Tan CS, Koralnik IJ. Progressive multifocal leukoencephalopathy and other disorders

caused by JC virus: clinical features and pathogenesis. *Lancet Neurol*. 2010;9(4):425–437; Bohra C, Sokol L, Dalia S. Progressive multifocal leukoencephalopathy and monoclonal antibodies: a review. *Cancer Control*. 2017;24(4):1073274817729901.)

Key point: Progressive multifocal leukoencephalopathy is characterized by progressive damage to the white matter of the brain at multiple locations in patients with severe immune deficiency/suppression medication and does enhance on CT/MRI imaging of the brain.

11. B. Parkinsonism with early gait and balance involvement, vertical gaze palsy, severe dysarthria, and dysphagia suggests progressive supranuclear palsy. Lack of responsiveness of early gait and balance impairment to dopaminergic medications and lack of asymmetry make Parkinson disease unlikely. The lack of the classic triad of gait impairment, cognitive decline, and urinary incontinence makes normal-pressure hydrocephalus unlikely. Amyotrophic lateral sclerosis presents with weakness, muscle atrophy, and fasciculations, which are not present in this case. Vascular dementia is unlikely to cause vertical gaze palsy.

Key points: Progressive supranuclear palsy is characterized by parkinsonism with early gait and balance involvement, vertical gaze palsy, and severe dysarthria and dysphagia. Normal-pressure hydrocephalus is characterized by the classic triad of gait impairment, cognitive decline, and urinary incontinence.

12. B. Leptomeningeal spread occurs in 5% to 15% of systemic carcinomas. It may present as a cranial neuropathy or spinal polyradiculopathy. Occasionally, it can present with confusion because of seizures, diffuse brain infiltration, or communicating hydrocephalus from obstruction of the arachnoid granulations. A chronic infectious meningitis could present in a similar fashion but is less likely because the patient is not severely immunocompromised.

Neither superior sagittal sinus thrombosis nor pseudotumor cerebri is associated with hydrocephalus. Methotrexate toxicity can lead to optic neuropathy, but this is typically at the time of intrathecal administration. In this patient, the most appropriate next step to establish the diagnosis is a lumbar puncture to evaluate for malignant cells. Sometimes several lumbar punctures are required before a positive cytologic diagnosis is documented. MRI of the neuronal axis with contrast would be more likely to document leptomeningeal enhancement but is not a sensitive tool. (Nayar G, Ejikeme T, Chongsathidkiet P, et al. Leptomeningeal disease: current diagnostic and therapeutic strategies. *Oncotarget*. 2017;8(42):73312–73328.)

Key point: Leptomeningeal spread of the systemic carcinoma manifests as cranial neuropathy or spinal polyradiculopathy or as encephalopathy diffuse brain infiltration or communicating hydrocephalus.

13. B. Epidural metastases are very common in patients with advanced cancer. The tumor reaches the epidural space via contiguous spread from adjacent vertebral body metastases or, less commonly, from direct extension of tumor through the intervertebral foramina from adjacent tissue. Back pain is the herald symptom of epidural metastases, occurring, on average, many weeks to months before any neurologic damage; that is, pain occurs long before there is any direct compression of the spinal cord. Carcinomatous meningitis usually presents with either confusion or cranial neuropathies and tends not to be painful. Lesions of the sagittal sinus will cause headache, papilledema, and, in severe cases, cerebral hemorrhage and cerebral edema. Radiation necrosis of the spinal cord will tend to be a painless myelopathy and affect both extremities equally. Intramedullary spinal cord metastases are extremely rare and typically present with weakness rather than pain. (Yáñez ML, Miller JJ, Batchelor TT. Diagnosis and treatment of epidural metastases. *Cancer*. 2017;123(7):1106–1114.)  
Key point: Epidural metastases are seen in patients with advanced cancer from direct extension of tumor through the intervertebral foramina from adjacent tissue. Back pain is the herald symptom of epidural metastases.
14. B. This patient presents with the classic signs of an ischemic or hemorrhagic cerebellar stroke, which are vertigo, headache, and ataxia. Although a CT scan can exclude hemorrhage, infarcts in the posterior fossa may not be well visualized early. His deterioration the following day with signs of brainstem compression (altered level of consciousness and intractable hiccups) indicates a dire situation, and urgent neurosurgical decompression is required. Peripheral vertigo may be the result of many disorders of the ear including vestibular neuronitis, benign positional vertigo, and vestibular migraine acoustic neuroma and Ménière disease, but none of these causes unilateral limb ataxia, dysarthria, or hiccups. Headache may accompany vestibular migraine but is not a feature of the other peripheral disorders. (Kim JS, Caplan LR. Clinical stroke syndromes. *Front Neurol Neurosci*. 2016;40:72–92.)  
Key point: Classic symptoms of cerebellar stroke are headache, vertigo, and ataxia.
15. D. Complex regional pain syndrome (CRPS) is a chronic pain condition. The key symptom of CRPS is continuous, intense pain out of proportion to the severity of the injury that gets worse rather than better over time. CRPS most often affects one of the arms, legs, hands, or feet. Often the pain spreads to include the entire arm or leg. Typical features include dramatic changes in the color and temperature of the skin over the affected limb or body part, accompanied by intense burning pain, skin sensitivity, sweating, and swelling. The etiology of CRPS is not clear. In some cases, the sympathetic nervous system plays an important role in sustaining the pain. Another theory is that CRPS is caused by a triggering of the immune response, which leads to the characteristic inflammatory symptoms of redness, warmth, and swelling in the affected area. Carpal tunnel syndrome causes pain in the palm of the hand and weakness in the distribution of the median nerve. Occlusion of the ulnar artery usually will not cause our patient's symptoms because of the vascular compensation provided by the radial artery. Psychophysiologic disorders would not explain the color change and change in temperature of the skin over the affected limb. Acute brachial plexus neuritis presents as pain and weakness of the upper shoulder or upper back. Distal hand function and sensation are usually not affected. (Marinus J, Moseley GL, Birklein F, et al. Clinical features and pathophysiology of complex regional pain syndrome. *Lancet Neurol*. 2011;10(7):637–648.)  
Key points: CRPS is a chronic pain condition that is continuous, intense pain out of proportion to the severity of the injury, which gets worse rather than better over time, and the extremity has changes in skin color and temperature over the affected area.
16. B. The patient most likely has focal seizures of the frontal lobe. The clinical presentation of focal seizures depends on their neuroanatomic location. In this case, the seizures originate in Broca's language area and spread to the primary motor cortex. Frontal seizures are usually brief and without aura or postictal confusion. With the recent onset of seizures, brain scanning with an MRI should be done to rule out space-occupying lesions or other pathology. Transient attack, hemiplegic migraine, amyloid angiopathy, and hypoglycemia can cause focal neurologic deficits but would not cause twitching of the arm and face. This patient is also too young to have cerebral amyloid angiopathy. (Gold JA, Sher Y, Maldonado JR. Frontal lobe epilepsy: a primer for psychiatrists and a systematic review of psychiatric manifestations. *Psychosomatics*. 2016;57(5):445–464.)  
Key points: Frontal seizures are brief and are usually not associated with an aura or postictal confusion. The manifestation of partial seizures depends on their neuroanatomic location.
17. B. In this patient, severe cerebral anoxia from her cardiac arrest caused severe diffuse hemispheric cortical injury with relative preservation of brainstem function, leading to the development of a vegetative state. A vegetative state is a clinical condition of complete unawareness of self or the environment, accompanied by sleep-wake cycles and preservation of brainstem and hypothalamic functions. The diagnosis of a vegetative state should be made only after careful observation of the patient for any signs of awareness or purposeful responsiveness. In contrast to a vegetative state, in which there is no evidence of consciousness, in the minimally conscious state there is severely altered consciousness with minimal but definite behavioral evidence of awareness of the self or the

environment. Patients with the locked-in syndrome are conscious because of intact cortical and upper brainstem function but are quadriplegic and can communicate only by moving their eyes vertically or blinking. The locked-in syndrome is caused by lesions of the base of the pons. Coma is a profound state of unconsciousness; the patient has no response to stimuli and does not have a normal sleep–wake cycle. Brain death is the complete absence of all hemispheric or brainstem function including absence of respiratory drive. (Vella MA, Crandall ML, Patel MB. Acute management of traumatic brain injury. *Surg Clin North Am*. 2017;97(5):1015–1030.)

Key points: Severe cerebral anoxia from cardiac arrest can cause severe diffuse cerebral hemispheric cortical injury with relative preservation of brainstem function, leading to the development of a vegetative state. A vegetative state is a condition of no awareness of self or the environment, accompanied by sleep–wake cycles and preservation of brainstem and hypothalamic function. It is also referred to as the unresponsive wakefulness syndrome.

18. C. This patient has evidence of dysautonomia (orthostatic hypotension, neurogenic bladder, constipation, and impotence), gait-predominant parkinsonism, and corticospinal tract signs. This constellation of symptoms is consistent with multiple system atrophy. Multiple system atrophy with prominent dysautonomia is referred to as Shy-Drager syndrome. Parkinson disease is usually asymmetric at onset, more commonly associated with tremor, and does not have prominent gait and balance involvement in the beginning of the disease. Parkinson disease can be associated with dysautonomia, but this usually occurs late in the disease and is not as pronounced. Vitamin B<sub>12</sub> deficiency can present with cognitive impairment, corticospinal tract signs, and peripheral neuropathy, but dysautonomia is not part of the clinical presentation. Progressive supranuclear palsy manifests itself with parkinsonism, vertical gaze palsy, and corticospinal signs but not dysautonomia. Parkinsonism is not part of the presentation of systemic amyloidosis. (Stefanova N, Bücke P, Duerr S, Wenning GK. Multiple system atrophy: an update. *Lancet Neurol*. 2009;8(12):1172–1178.)

Key point: Multiple system atrophy is characterized by orthostatic hypotension, neurogenic bladder, constipation, and impotence, with gait-predominant parkinsonism and corticospinal tract signs.

19. D. Amyotrophic lateral sclerosis is an acquired neurodegenerative disorder involving the cortical motor neurons in the frontal lobe, resulting in upper motor neuron sign (hyperreflexia, spasticity, extensor plantar responses) and the anterior horn cells in the spinal cord causing lower motor neuron signs/symptoms (atrophy, fasciculations, and weakness). Affected patients typically present with slowly progressive distal asymmetric muscle weakness associated with muscle

atrophy and fasciculations. As a result of upper motor neuron degeneration in the frontal lobe, extensor plantar responses and pathologic hyperreflexia (ankle clonus) are also present.

Spinal muscular atrophy is a genetic disorder of children or young adults affecting only the anterior horn cells and therefore is not characterized by the pathologic hyperreflexia or extensor plantar response. Myasthenia gravis is a neuromuscular junction disorder that can cause dysarthria and dysphagia. The treatment is with acetylcholinesterase inhibitors, which may cause fasciculations. Myasthenia gravis, however, does not cause upper motor neuron signs, and weakness is typically proximal and symmetric. Cervical spondylosis can cause a combination of upper motor neuron signs because of spinal cord compression and lower motor neuron signs caused by nerve root compression; however, it is not associated with dysarthria and tongue weakness/fasciculations. Transverse myelitis is demyelination of the spinal cord and does not cause dysarthria and tongue weakness/fasciculations. (Hardiman O, Al-Chalabi A, Chio A, et al. Amyotrophic lateral sclerosis. *Nat Rev Dis Primers*. 2017;3:17071.)

Key points: Amyotrophic lateral sclerosis is characterized by pathologic hyperreflexia, spasticity, and extensor plantar responses along with atrophy, fasciculation, and weakness. Muscle weakness in amyotrophic lateral sclerosis usually begins distally and asymmetrically in the upper or lower extremities and may be limited initially to the bulbar muscles, resulting in dysarthria and dysphagia.

20. B. Hypothyroid myopathy is characterized by proximal muscle weakness, muscle hypertrophy, myalgias, and paresthesias. The physical examination is remarkable for the phenomenon of “myoedema,” which can be elicited by percussion of the muscle with the reflex hammer as well as a delay in the relaxation phase of the muscle stretch reflex. Hypothyroid myopathy is usually associated with creatine kinase levels 10 to 100 times the upper limit of normal limits. Therefore many patients with hypothyroid myopathy are inappropriately referred for electromyography or muscle biopsy before obtaining thyroid function tests. (Sindoni A, Rodolico C, Pappalardo MA, Portaro S, Benvenga S. Hypothyroid myopathy: a peculiar clinical presentation of thyroid failure. Review of the literature. *Rev Endocr Metab Disord*. 2016;17(4):499–519.)

Although myasthenia gravis can cause proximal muscle weakness and fatigue, it is not associated with myalgias, paresthesias, or muscle enzyme elevations.

Key points: Hypothyroid myopathy is characterized by muscle pain, cramps, stiffness, fatigue, and paresthesias. In hypothyroid myopathy, creatine kinase levels may be 10 to 100 times normal levels, but thyroid function tests should be performed before electromyography or muscle biopsy.

## Neurology Summary

EMILY CHOI DECROOS, TRACEY A. CHO, JAMES D. BERRY, AND ANEESH B. SINGHAL

**D**iseases of the brain, spinal cord, nerve, and muscle pose unique diagnostic and management challenges. The signs and symptoms of different neurologic diseases often overlap, can mimic nonneurologic diseases, can be transient in nature yet portend ominous outcome, and sometimes do not localize to a particular anatomic location. The diagnosis may not be apparent even with advanced imaging or other investigations. Brain imaging frequently reveals incidental abnormalities that further complicate management decisions. The frequent lack of a firm diagnosis, the relative paucity of established treatment options, and the chronic nature of many neurologic diseases make management especially difficult. Nevertheless, careful history taking that focuses on establishing the anatomic location and the temporal nature of the disease process, combined with knowledge of the basic anatomy of the nervous system, makes it possible in most instances to decipher the various nervous system diseases. In this chapter, we provide a general approach to diagnosis and briefly summarize the evaluation and management of specific neurologic diseases and neurologic emergencies that are more relevant to the practicing general physician or medical internist.

### Evaluation of Weakness

Weakness has a dizzying array of causes, including neurologic (e.g., diseases of the brain or spinal cord involving the corticospinal tract or supplemental motor pathways, diseases of the neuromuscular junction, motor nerves, and muscle) to nonneurologic (e.g., asthenia from endocrine disturbances, electrolyte imbalance, and depression). As a first step, patients should be asked to distinguish loss of muscle power (generally neurologic) from generalized fatigue or malaise (often nonneurologic). Recognition of the four major types and patterns of neurologic weakness (upper motor neuron, lower motor neuron, neuromuscular junction, and myopathic weakness; [Table 97.1](#)) can simplify history taking and help direct the examination toward localizing the anatomic site of the lesion. The patient should be asked about the circumstances during which the weakness is noted, the onset, duration, and fluctuant nature of symptoms, associated neurologic symptoms (e.g., sensory change, weight

loss, bowel/bladder dysfunction, visual changes), and the types of movements that are most impaired. Difficulty rising from squatting position or lifting objects over the head suggests proximal muscle weakness; inability to open jars or stand on toes can suggest a distal process; highly variable weakness could suggest neuromuscular junction disease; unilateral weakness suggests a central nervous system (CNS) lesion; leg weakness (paraparesis) could suggest a spinal cord lesion. Difficulty swallowing and dysarthria suggest a brain or brainstem lesion. Sudden-onset unilateral weakness suggests a vascular lesion (stroke) affecting the corticospinal tract. Acute onset or rapidly progressive weakness should be worked up acutely (with particular regard for the 3–4.5 hour window for administration of intravenous [IV] tissue plasminogen activator [tPA] in the case of stroke and the 12-hour to 24-hour window for surgery in spinal cord compression), weakness with subacute onset should be worked up efficiently, and weakness with a chronic course should be worked up in due time provided respiratory muscle weakness is not apparent, and there is no pharyngeal weakness that may increase the risk for aspiration pneumonia.

### Evaluation of Sensory Symptoms

Sensory symptoms may arise from lesions in the peripheral nerve, or in central sensory pathways, from the dorsal columns and spinothalamic tracts as they traverse the spinal cord and brainstem to the thalamus, internal capsule, and cortical regions of the brain. The sensory system is notoriously difficult to evaluate because the physician needs to rely on patient perceptions for both the history and examination. Examination should focus on both primary sensory change (touch, pinprick, joint position, and vibratory sense) and “cortical” sensory changes such as agraphesthesia (inability to recognize an object by touch) and loss of two-point discrimination. The neurologic history should focus on defining the type of sensory symptom (paresthesia, pain, allodynia, numbness, etc.) and the pattern of sensory loss, which depends on the onset, location, duration, progression, and associated symptoms. Common patterns of sensory loss include hemisensory change (brain or brainstem pathology or cervical spine disease if face is spared), spinal level

**TABLE 97.1** Key Features of Weakness

Feature	Upper Motor Neuron	Lower Motor Neuron	Neuromuscular Junction	Myopathic
Muscle bulk	Normal (disuse atrophy may develop later)	Decreased	Normal	Variable
Muscle tone	Increased (except during the acute phase of central lesions)	Decreased	Normal	Decreased
Pattern of weakness	Upper extremity: extensor > flexor Lower extremity: flexor > extensor	Distal > proximal Segmental	Variable; often proximal, frequently bulbar	Proximal
Deep tendon reflexes	Brisk ± clonus	Diminished or absent	Normal; may become diminished over time	Normal or diminished
Fasciculations	None	Present	Absent (treatment with pyridostigmine can cause fasciculations)	Absent
Plantar reflex	Extensor	Flexor	Flexor	Flexor

(myelopathy), dermatomal (radiculopathy), length-dependent, often called *stocking-glove* (peripheral neuropathy), nerve distribution (mononeuropathy), and confluent nerve distributions (mononeuropathy multiplex). Recent medication and habit changes should be investigated (e.g., habitual leg crossing can cause peroneal neuropathy). Accompanying weakness and changes in deep tendon reflexes may help to localize the lesion; for example, distal symmetric sensory loss, associated with distal weakness, loss of muscle tone, and decreased tendon reflexes would suggest a peripheral motor-sensory neuropathy.

## Evaluation of Visual Symptoms

The most common visual symptoms resulting from neurologic disorders include double vision (diplopia) and loss of vision, which could be localized to one or both eyes. For diplopia, it is important to ascertain whether the double vision disappears with closure of either eye (monocular diplopia usually results from nonneurologic causes such as lens dislocation) and the effect of horizontal and vertical eye movements on the degree of double vision. The examination should include observation of smooth pursuit to each of the cardinal directions of gaze, watching for misalignment of the eyes and noting the position in which it is most prominent. Associated features such as retroorbital pain should raise suspicion of inflammation or a compressing brain aneurysm; associated hemiparesis would suggest a central lesion such as midbrain or pontine stroke; associated pain, eye redness, and chemosis suggest a local inflammatory lesion secondarily affecting the extraocular nerves or muscles that control eye movement; and associated ptosis or proximal muscular weakness would raise the question of a neuromuscular junction disorder such as myasthenia gravis.

Similarly, for visual loss it is essential to inquire whether the symptoms are localized to one eye or both eyes and to distinguish visual hemifield defects from unilateral loss of vision. Unilateral loss of vision suggests a prechiasmal lesion such as demyelinating diseases of the optic nerve (multiple sclerosis [MS]) or retinal or ocular ischemia (internal carotid artery stenosis, giant cell arteritis). Bilateral acute loss of vision usually localizes to the occipital-parietal lobes and can result from ischemia (cardiac arrest, top-of-the-basilar embolus, cerebral vasoconstriction syndromes), brain edema (hypertensive encephalopathy), or demyelinating diseases. Hemivisual field loss (hemianopia) usually implicates postchiasmal lesions localizing to the lateral geniculate nucleus or occipital or temporal lobe from diseases such as stroke or brain tumor. Other visual symptoms include mild ptosis with miosis (components of the Horner syndrome, commonly resulting from carotid artery dissection) and positive visual phenomena such as scintillations and fortification spectra associated with unilateral headaches in patients with migraine.

## Common Neurologic Conditions

### Seizures

A seizure is defined as “a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.” Seizures can be primary or idiopathic or secondary to head trauma, infection, stroke, metabolic insults, brain tumors, and other etiologies. Epilepsy is a brain disorder characterized by recurrent seizures caused by underlying genetic abnormalities or acquired injury and by the neurobiologic, cognitive, psychologic,

**TABLE 97.2** Classification of Seizures (International League Against Epilepsy)

Seizure Subtype	Definition
Generalized	Involve both hemispheres from onset
Tonic	Generalized stiffening of the body with loss of consciousness
Tonic-clonic (grand mal)	Stiffening of the body followed by alternating flexion and extension with loss of consciousness
Clonic	Alternating flexion and extension without initial tonic phase with loss of consciousness
Myoclonic	Sudden onset, brief muscle activation often described as a “body jerk”; consciousness may be preserved
Atonic	Sudden onset loss of tone, causing the clinical entity called “drop attacks,” typically with a loss of consciousness
Absence (petit mal)	Staring episodes without loss of consciousness but with loss of attention and lack of responsiveness lasting seconds, often associated with eye fluttering
Partial	Begin focally
Simple partial	Limited area of cortex involved causing no change in consciousness and provoking signs and symptoms correlating to the area of cortex involved including alterations in sensation, language, or psyche or localized movements, often tonic or clonic in nature
Complex partial	Semiology is similar to simple partial seizures but with impairment of consciousness either from onset or in the course of the event (suggesting a larger area of cortex is involved)
Complex partial with secondary generalization	Semiology is similar to complex partial seizures, but during the event, there is spread to involve both hemispheres, causing bilateral symptoms

and social consequences of recurrent seizures. In patients with epilepsy, seizures can be precipitated by minor factors (viral infection, lack of sleep, etc.) but are not referred to as provoked or secondary seizures. Seizures will affect about 5% of people at least once during their lifetime.

Among these, a smaller percentage will develop epilepsy. The prevalence of epilepsy in developed countries is about 5 per 1000.

Seizures can be classified as partial or generalized, with subtypes within each group (Table 97.2). Focal seizures may spread to involve the entire brain (secondary generalization), whereas generalized seizures involve the entire brain from their onset and may have their genesis in the thalamus.

The most common differential diagnoses for seizures include syncope, nonepileptic seizures (also referred to as pseudoseizures or psychogenic seizures), panic attacks, migraine, transient ischemic attack, dystonia, cataplexy, and nonepileptic myoclonus (e.g., after cardiac arrest). History taking should focus on distinguishing seizures from their mimics and, further, on characterizing the type of seizures because medical treatment is dependent on the subtype. Features more typical of seizure include the presence of urinary incontinence, tongue biting, loss of awareness, adventitious movements (synchronized when diffuse), vocalizations, preceding aura, and a prolonged postictal confusional state. Although more common in seizures, convulsions and even urinary incontinence and tongue biting may occur in syncope, but patients usually return to baseline more rapidly. The examiner should

carefully assess for possible provoking factors (drug intoxication or withdrawal, head trauma, meningitis/encephalitis, severe metabolic disturbance) and inquire about similar prior events, including febrile seizures in childhood and any personal or family history of seizure. For patients with a known seizure disorder, a full medication history should be obtained, including current medications and their doses, recent compliance, past antiepileptic medications and any allergies or adverse reactions, and recent emotional and physical stressors such as lack of sleep, change in eating patterns, illness, or surgery. In addition, it is important to know if the semiology of the current event is similar to or distinct from that of prior seizures and if the patient has ever suffered from status epilepticus in the past. Medical and neurologic physical exam should be performed to rule out ongoing or intermittent seizure, to uncover any signs of infection, trauma, drug intoxication, or other concurrent illness, and to rule out any neurocutaneous syndrome with a thorough skin exam. Vital signs, emergent blood glucose measurement, and clinical status should be observed carefully until the patient has returned to a baseline mental status.

Diagnostic evaluation after a first seizure should be directed at uncovering precipitating factors. Blood glucose, complete serum chemistries, liver function tests, complete blood count, arterial blood gas when appropriate, serum and urine toxicology, levels of any antiepileptic drugs being taken for psychiatric or pain disorders, urinalysis and culture, chest x-ray, electrocardiogram (EKG), and lumbar puncture, when indicated, to rule out inflammation or

• **Fig. 97.1** Brain MRI. Axial contrast-enhanced T1-weighted image showing an extraaxial enhancing mass consistent with a benign meningioma (*arrow*), in a patient with seizures. The role of electroencephalogram (EEG) in the acute diagnosis of seizure is limited to the diagnosis of status epilepticus. However, in patients with a first unprovoked seizure, a follow-up EEG will reveal a significant abnormality in approximately 30% of cases. This is helpful to confirm the diagnosis of seizure and may help to predict recurrence. Patients with an abnormal EEG have a 50% chance of recurrence, about twice as likely as those with a normal EEG. In patients with no interictal epileptiform abnormalities, multiple EEGs can increase the negative predictive value for further seizure episodes to over 90%. Finally, the EEG can help distinguish among seizure subtypes, thus guiding specific treatment and prognosis.

infection of the CNS should be performed. Serum prolactin may help differentiate nonepileptic seizure from an epileptic seizure if drawn within 30 minutes of the event and compared to the patient's baseline. Prolactin can rise after syncope and cannot be used to differentiate seizure from syncope. It is rarely used in practice because of its temporal and diagnostic limitations. Electroencephalogram (EEG) is an essential study in the evaluation of possible seizure but is rarely indicated in the emergency setting, except for the evaluation for status epilepticus. In the absence of persistent neurologic deficit, focal features, history of trauma, or clinical suspicion for intracranial abnormality, acute imaging of the brain with CT or MRI is not required and can be arranged on an outpatient basis. Otherwise, it should be done as a part of the acute evaluation. The yield of CT or MRI after a first unprovoked seizure is about 10%, identifying disorders such as stroke, tumor (Fig. 97.1), or neurocysticercosis. MRI is more sensitive than CT and is the preferred imaging modality if available. The workup for epileptic patients presenting

with seizures of their typical semiology but increased duration or frequency is similar, although lumbar puncture is not indicated without compelling evidence for a CNS infection. It is not uncommon for a patient to be brought to the emergency department for a typical seizure that has occurred in public, and if reliable, these patients need not be reinvestigated for etiology.

The first decision in treatment of epilepsy is whether an antiepileptic drug (AED) is necessary. For many causes of provoked seizures such as alcohol withdrawal or other metabolic disturbances, treatment should be directed at the underlying process, and an AED is not necessary. In the case of symptomatic etiologies with possible structural changes (such as tumor, stroke, or head trauma) an AED is usually initiated and continued for at least 1 year. For those patients with recurrent seizures or a seizure in the setting of a clear irreversible cause, AED treatment should be initiated. In patients with a single unprovoked seizure of unknown cause, other factors may weigh in the decision to start treatment. The presence of risk factors such as an abnormal EEG, family history, abnormal neurologic exam, presentation with status epilepticus, and postictal Todd's paralysis argues for treatment. Social factors such as the ability to drive or work may also contribute to the decision. Apart from AED treatment, patients should be instructed to avoid any factors that clearly precipitate their seizures, such as sleep deprivation, alcohol, or stress. They should also be advised to refrain from activities during which a seizure could lead to injury of themselves or others, including driving, operating heavy machinery, working at a height, or swimming or bathing alone. Each state has different regulations regarding driving, and the patient should be directed to the appropriate governing body.

In terms of choosing an AED, many factors contribute to the first-line choice for each patient, including the subtype of seizure, age of the patient, side effects, comorbid illnesses, and drug interactions (Table 97.3). In general, certain agents have been shown to be effective in controlling partial or secondarily generalized seizures, including carbamazepine, valproic acid, phenytoin, and many of the newer agents, especially lamotrigine and oxcarbazepine. For primarily generalized epilepsies, a number of agents may be used, including valproic acid, lamotrigine, topiramate, levetiracetam, and zonisamide. Ethosuximide has efficacy specific to absence seizures. Several newer agents were more recently approved by the US Food and Drug Administration (FDA). Clobazam and rufinamide are approved as adjunctive therapy in Lennox-Gastaut syndrome. Lacosamide, eslicarbazepine, and perampanel are approved as adjunctive therapy for treatment of partial onset seizures.

Pregnancy poses a particular problem for epilepsy treatment because all AEDs are at least potentially teratogenic. Valproic acid, phenytoin, phenobarbital, primidone, and carbamazepine should be avoided. This must be balanced with the adverse effects on the fetus of hypoxia from severe seizures. In women who require AED treatment for seizure

**TABLE 97.3** Categories of Anticonvulsants

Blockers of repetitive activation of sodium channel	Phenytoin, carbamazepine, oxcarbazepine, lamotrigine, topiramate
Enhancers of slow inactivation of voltage-gated sodium channel	Lacosamide, rufinamide
GABA-A receptor enhancers	Phenobarbital, benzodiazepines, vigabatrin, tiagabine, gabapentin, and topiramate
Glutamate modulators	Topiramate, lamotrigine, felbamate
T-type calcium-channel blockers (voltage-gated calcium channel)	Ethosuximide, valproate
N-type and L-type calcium-channel blockers	Lamotrigine, topiramate, zonisamide, valproate
H-current modulators	Gabapentin, lamotrigine
Blockers of unique binding sites	Gabapentin, levetiracetam
Carbonic anhydrase inhibitors	Topiramate, zonisamide

control, monotherapy if possible at the lowest effective dose is preferred. Although lamotrigine and levetiracetam are believed to be associated with a lower teratogenic risk during pregnancy, both medications are pregnancy class C, and overall data on safety of the newer anticonvulsant drugs during pregnancy are limited. Folic acid supplementation should be administered to help protect against neural tube defects.

The risk of recurrence after a first seizure of any kind ranges from 25% to 80% depending on other risk factors. Prognosis depends on many factors, including age, specific epilepsy syndrome, underlying lesions, and response to AED treatment. In general, about 80% of patients will have a remission or good control with AED treatment. Most of the remaining 20% with poor control despite multiple AEDs and/or surgery are comprised of patients with infantile spasms or seizures related to a severe underlying lesion.

## Headache

Headache is the most common neurologic symptom in the outpatient setting. The international classification of headache disorders classifies headaches as either primary or secondary disorders. Primary headaches fit a recognized pattern with typical characteristics, and an underlying disease state is not the cause of the headache. Subcategories of primary headache disorders include migraine, tension headache, cluster and trigeminal autonomic type headaches, and other primary headaches. [Table 97.4](#) shows the

**TABLE 97.4** Common Primary Headache Disorders

Type	Characteristic	Management
Migraine – with aura – without aura – complicated	± visual, sensory aura; throbbing; usually unilateral; photophobia, phonophobia; onset over minutes to 1 hour; ± nausea/emesis; identifiable triggers; improves with sleep; duration up to 24 hours	Abortive: NSAIDs, acetaminophen, trigger avoidance, triptans, ± ergots as outpatient; IV antiemetics, IV ergots as inpatient Prophylactic: for headaches >1/wk First-line: propranolol, topiramate Second-line: tricyclic antidepressants, calcium-channel blockers, valproic acid (effective but limiting side effect profile) Third-line: gabapentin
Tension-type headache	Constant; occipital predominance radiating frontally; bilateral; worse with emotional stress; worse later in day; duration up to days; ± scalp tenderness	First-line: NSAIDs, acetaminophen, lifestyle change Second-line: occipital steroid injections, cervical muscle or frontalis botox injections
Primary thunderclap headache	Sudden onset; severe; maximal in severity at onset	Urgent CT/MR with vascular imaging to exclude secondary causes such as ruptured cerebral aneurysm
Cluster	Sudden onset; unilateral; stabbing; orbital/supraorbital/temporal; occur in clusters with periods of quiescence between; ± seasonal prevalence; at least one unilateral symptom of nasal congestion, sclera injection, tearing, facial/orbital edema, ptosis, myosis	Abortive: oxygen, ergotamine Prophylactic (used during a cluster): First-line: oral prednisone (60 mg × 3 days, then taper) Second-line: propranolol; lithium

*Continued*

**TABLE 97.4** Common Primary Headache Disorders—cont'd

Type	Characteristic	Management
Trigeminal neuralgia	Stabbing/lancinating paroxysms of pain to a trigeminal distribution; unilateral symptoms; identifiable triggers	First-line: carbamazepine (start 200 mg bid or lower to avoid side effects, titrate to max 600 mg bid); oxcarbazepine is likely equivalent Second-line: phenytoin, gabapentin, baclofen Surgical: if MRI reveals vascular loop, surgery or radiosurgery may resolve symptoms

*bid*, Twice a day; *IV*, intravenous; *NSAIDs*, nonsteroidal antiinflammatory drugs.

**TABLE 97.5** Common Secondary Headache Disorders

Emergent Causes of Headache	Characteristic Headache Features	Focal Neurologic Signs	Initial Diagnostic Workup
Subarachnoid hemorrhage	Sudden onset, maximal at onset, bilateral, ± throbbing, worst headache of life, ± nausea	Confusion, depressed arousal, seizures, ± focal motor/sensory/cranial nerve deficits	Noncontrast head CT, lumbar puncture, cerebral angiography (CT, MR, and/or catheter)
Intracranial hemorrhage	Worsening over hours, often with nausea, ± throbbing	Focal neurologic signs are present on examination, ± confusion, ± depressed arousal	Noncontrast head CT, ± brain MRI
Mass lesion	Gradual worsening over days or weeks, worst when recumbent, intermittent or constant, ± lateralizing pain	Focal neurologic signs are invariably present but may be subtle; frontal lesions produce less deficits	Brain MRI with and without contrast, ± CT initially (depending on availability of MRI)
Meningitis/encephalitis	Worsening over hours or days, often occipital with neck pain	Nuchal rigidity, fever; confusion/depressed arousal only in encephalitis	Lumbar puncture, noncontrast head CT prior if neurologic examination is not normal
Carotid or vertebral dissection	Sudden onset, vertex pain is classic for carotid, occipital pain for vertebral, ± preceding neck pain	Carotid: contralateral weakness, numbness, neglect, dysarthria Vertebral: visual field deficit, dysarthria, incoordination, gait difficulty, nausea	Noncontrast head CT, noninvasive angiography (MRA/CTA), brain MRI with T1 fat saturated images
Temporal arteritis	Lateralized frontal headache worse when chewing. May be retroorbital. Progressive over days to weeks. Patients age >50 years.	Jaw claudication, visual dimming or transient monocular blindness, temporal tenderness, weight loss, fever, optic disk pallor	ESR, brain CT, or MRI to rule out structural cause
Acute angle closure glaucoma	Onset over hours, may be precipitated by dilated pupil examination, retroorbital or orbital pain	Injected eye, decreased visual acuity in affected eye, often mydriasis	Ocular pressure measurement

*ESR*, Erythrocyte sedimentation rate; *MRA*, magnetic resonance angiography.

management of the common types of primary headache disorders. Secondary headache disorders are ones that result from an underlying process, which can be vascular, hemorrhagic, neoplastic, cerebrospinal fluid (CSF)-pressure related, substance use or withdrawal induced, inflammatory, or infectious. Table 97.5 shows the key features of the most common causes of secondary headaches and their initial management.

With a 10% to 18% prevalence of migraine, and 20% to 30% prevalence of tension-type headache in the general population, the vast majority of headaches are benign. However, headache can also be symptomatic of potentially ominous etiologies, leading to concern on the part of both the physician and the patient that a secondary etiology of headache may be overlooked without brain imaging. An informed physician can often allay

**TABLE 97.6** Guidelines for Brain Imaging in Patients With Headache

Emergent neurologic imaging recommended	“Thunderclap” headache with abnormal neurologic examination findings
Neurologic imaging recommended to determine safety of lumbar puncture	Headache accompanied by signs of increased intracranial pressure Headache accompanied by fever and nuchal rigidity
Neurologic imaging should be considered	Isolated “thunderclap” headache Headache radiating to neck Temporal headache in an older individual New-onset headache in patient who: <ul style="list-style-type: none"> <li>• Is HIV positive</li> <li>• Has a prior diagnosis of cancer</li> <li>• Is in a population at high risk for intracranial disease</li> </ul> Headache accompanied by abnormal neurologic examination findings, including papilledema or unilateral loss of sensation, weakness, or hyperreflexia
Neurologic imaging not usually warranted	Migraine and normal neurologic examination findings
No recommendation (some evidence for increased risk of intracranial abnormality)	Headache worsened by Valsalva maneuver, wakes patient from sleep, or is progressively worsening
No recommendation (insufficient data)	Tension-type headache and normal neurologic examination results

From the U.S. Headache Consortium, the American Academy of Neurology, the American College of Emergency Physicians, and the ACR.

these concerns with an appropriate medical history, thorough neurologic exam, and a basic understanding of the differential diagnosis for headache. Only then should imaging be considered, the guidelines for which are presented in [Table 97.6](#). Imaging is usually not indicated in patients with a primary headache disorder and normal neurologic examination.

### Ischemic Stroke

Stroke is defined as an acute neurologic event secondary to brain or retinal ischemia or hemorrhage. Ischemic stroke results from either arterial thrombosis or emboli to the cerebral vessels. Stroke ranks as the second leading cause of death worldwide and the fifth leading cause of death in the United States. Stroke is the leading cause of disability. Approximately 795,000 people have new or recurrent stroke each year in the United States. Approximately 610,000 of these are first attacks, and 185,000 are recurrent attacks. On average, every 40 seconds someone in the United States has a stroke. Risk factors for stroke include age, hypertension, hyperlipidemia, smoking, diabetes, hypercoagulable states, cardiac arrhythmias such as atrial fibrillation, cardiomyopathy, and presence of a cardiac thrombus, among many others. Primary ischemic stroke and transient ischemic attacks (TIAs) conveniently divide into five etiologic subtypes: (1) large artery atherothrombotic (15%); (2) embolic (57%; cardiac, ascending aorta, or unknown source); (3) small vessel lacunar (25%); (4) other (3%), such as arterial dissection, venous sinus occlusion, and arteritis; and (5) unknown cause, either because of two or more competing causes, or

an incomplete evaluation, or a thorough but unrevealing evaluation. Stroke etiology varies by age, with cerebral arteriopathies such as dissection and other so-called uncommon causes being more prevalent at younger ages and atherosclerosis, atrial fibrillation, and small-vessel lacunar disease being more prevalent at older ages.

The ABCD2 score (A, age; B, blood pressure; C, clinical symptoms; D, duration; and D, diabetes) is a risk assessment tool designed to improve the prediction of short-term stroke risk after a TIA. The score is optimized to predict the risk of stroke within 2 days after a TIA but also predicts stroke risk within 90 days.

The symptoms of stroke are variable, depending on the vascular territory affected ([Table 97.7](#)). Patients presenting with symptoms of stroke should be admitted or referred to the nearest hospital for emergent care. Emergency management should include evaluation of the hemodynamic and respiratory stability of the patient with vital signs and brief clinical history and neurologic exam including an assessment of the National Institutes of Health stroke scale score. Brain imaging should be performed as soon as possible to determine the extent of the infarction and exclude mimics such as brain hemorrhage ([Fig. 97.2](#)).

The time of onset should be determined, and a neurologist should be consulted emergently for evaluation and to determine eligibility for IV tPA, which is FDA-approved for administration within 3 hours after stroke symptom onset. Based on the results of clinical trials showing efficacy until 4.5 hours, some centers administer IV tPA until 4.5 hours after stroke symptom onset. The dose of tPA is

Distribution	Symptoms
Middle cerebral artery	Weakness and sensory loss of contralateral face, arm, and leg, dysarthria, global aphasia in dominant hemisphere, apraxia and neglect in nondominant hemisphere, homonymous hemianopia, gaze deviation toward the lesion
Anterior cerebral artery	Contralateral leg weakness and sensory loss. If both ACAs involved, may have bilateral paraparesis, abulia, and urinary incontinence.
Anterior choroidal	Contralateral hemiplegia, hemihypesthesia, homonymous hemianopia
Posterior cerebral artery	P1: Precommunal PCA. Infarction often involves P1 perforators to the midbrain, subthalamic, and thalamic signs. Midbrain syndromes: Claude syndrome: 3rd nerve palsy + contralateral ataxia Weber syndrome: 3rd nerve palsy + contralateral hemiplegia Benedict syndrome: 3rd nerve palsy, contralateral ataxia, hemiplegia Thalamic syndromes: Dejerine-Roussy syndrome: contralateral hemisensory loss Artery of Percheron: paresis of upward gaze and drowsiness and abulia; coma, unreactive pupils, bilateral pyramidal signs P2: Postcommunal PCA. Cortical temporal and occipital lobe signs. Hemianopia with macular sparing. Visual agnosia for faces, objects, mathematical symbols, and colors. Medial temporal lobe and hippocampal involvement can cause a disturbance in memory. Patients can also develop recognizable syndromes such as alexia without agraphia, peduncular hallucinosis (visual hallucinations of brightly colored scenes and objects), Balint syndrome (optic ataxia, ocular apraxia, visual inattention, and similtagnosia), Anton syndrome (denial of blindness), and palinopsia (persistence of the visual image).
Basilar	Somnolence, ptosis, disorders of ocular movement, paralysis of vertical gaze, convergence retraction nystagmus; pseudoabducens palsy, skew deviation, lid retraction, facial weakness, hearing loss, nystagmus, hemiplegia
SCA	Ipsilateral cerebellar ataxia, unstable gait, vertigo
AICA	Horizontal and vertical nystagmus, vertigo, nausea, vomiting; ipsilateral facial paralysis; paralysis of conjugate gaze to the side of the lesion; ipsilateral deafness, tinnitus, cerebellar ataxia, Horner syndrome, impaired facial sensation; contralateral pain and temperature sensation in the body
PICA	Ipsilateral facial numbness, numbness to pain in the contralateral body; ipsilateral ataxia, gait instability, nausea, vertigo, Horner syndrome
Lacunar infarcts	Hemisensory loss and hemiparesis: thalamocapsular Pure hemisensory loss: thalamus Pure motor hemiparesis: internal capsule, corona radiata, basis pontis Dysarthria/clumsy hand: genu of the internal capsule, basis pontis Ataxic hemiparesis: pons, midbrain, internal capsule

ACA, Anterior cerebral artery; AICA, anterior inferior cerebellar artery; PCA, posterior cerebral artery; PICA, posterior inferior cerebellar artery; SCA, superior cerebellar artery.

• **Fig. 97.2** Brain MRI in ischemic stroke. Head MR angiography (left panel, axial three-dimensional time-of-flight image) shows an abrupt cutoff of the left middle cerebral artery (*arrow*). Fluid-attenuated inversion recovery sequence axial image (middle panel) shows hyperintensity in the middle cerebral artery (*arrow*), consistent with acute thrombus or slow flow within this artery; the surrounding brain parenchyma is hyperintense from early ischemic change. Axial diffusion-weighted image (right panel) shows hyperintense signal consistent with infarction.

0.9 mg/kg, with 10% administered as a bolus and the remaining 90% by IV infusion over 1 hour. Contraindications to IV tPA include a stroke greater than one-third of the middle cerebral artery territory on noncontrast head CT, evidence for brain hemorrhage, head trauma, prior history of intracerebral hemorrhage, rapidly resolving or minimal focal neurologic deficits, suspicion of subarachnoid hemorrhage, recent trauma or surgery within the prior 15 days, active internal bleeding or recent gastrointestinal bleeding, recent lumbar puncture or noncompressive arterial site puncture within 7 days, bleeding diathesis (international normalized ratio >1.7, prothrombin time >15, partial thromboplastin time >40, platelets <100, or known bleeding diathesis), uncontrolled hypertension (systolic blood pressure >185 mm Hg or diastolic blood pressure >110 mm Hg despite medications), and seizures at onset. Patients receiving IV tPA should ideally be admitted to an intensive care unit for at least 24 hours for close monitoring of neurologic status and blood pressure. Anticoagulation, arterial puncture, and antiplatelet agents should be avoided for 24 hours. A follow-up head CT scan should be obtained at 24 hours or earlier if there is a change in neurologic examination. If the patient remains stable, he or she may be transferred to the floor for further diagnostic evaluation and management.

The results of several recent clinical trials have shown impressive benefit with intraarterial clot retrieval strategies in patients with ischemic stroke from embolus or occlusion of major cerebral arteries. The FDA has granted approval for several devices (e.g., Trevo, Solitaire) as initial therapy for stroke to remove clot until 6 hours after onset, when used in conjunction with IV tPA. Hence rapid brain and vascular imaging should be performed, and patients potentially eligible for intraarterial therapy should be transferred to comprehensive stroke centers as soon as possible.

Brain MRI using diffusion-weighted imaging has high sensitivity and specificity (over 95%) for ischemic stroke. The further diagnostic evaluation should be based on the suspected underlying pathophysiology. For example, vascular imaging should be performed using CT angiography, MR angiography, catheter angiography, or vascular ultrasound (carotid duplex imaging) for suspected artery-to-artery stroke from carotid artery atherosclerosis or dissection. Cardiac evaluation using EKG, transthoracic or transesophageal ultrasound, and Holter monitoring is indicated for suspected cardioembolic stroke. Blood tests such as protein C, protein S, antithrombin III levels, and antiphospholipid antibodies may be indicated in young individuals with cryptogenic stroke. Erythrocyte sedimentation rate and C-reactive protein levels may be obtained on suspicion of underlying malignancy, bacterial endocarditis, or cerebral vasculitis, with additional infectious or inflammatory workup as indicated. Furthermore, a lipid panel should be considered to assess vascular risk.

Treatment with an antiplatelet agent (aspirin, clopidogrel, aspirin-dipyridamole combination) or an anticoagulant agent such as warfarin, if indicated, should

be initiated within 24 hours after admission. Prophylaxis against deep vein thrombosis with subcutaneous low-molecular-weight heparin and the prompt evaluation of swallow function with implementation of measures to prevent aspiration pneumonia are important. Patients should be evaluated by physical, occupational, and speech therapy if they have persistent deficits. If there is significant carotid stenosis (either moderate or severe) on vessel imaging, the patient may be considered for carotid endarterectomy or stenting depending on the surgical risk. The decision to use antiplatelets or anticoagulants for stroke prevention depends on the underlying pathophysiology; in general, warfarin is used only for high-risk cardiac sources such as atrial fibrillation, left ventricular thrombus, cardiomyopathy, and prosthetic heart valves. Stroke prevention therapy with cholesterol-lowering agents (statins), antihypertensive medications (preferably thiazide diuretics and angiotensin-converting enzyme inhibitors), or antidiabetic agents may be initiated if indicated as per the latest national treatment guidelines. After patients have been medically stabilized, if they exhibit persistent deficits and cannot be cared for at home, they should be considered for inpatient rehabilitation or a nursing facility. Stroke unit care, prevention of acute poststroke complications, appropriate stroke preventive medications, and rehabilitation constitute the mainstay of therapy for ischemic stroke. With these measures, from 2004 to 2014, stroke death rate decreased 28.7%, and the actual number of stroke deaths declined 11.3%.

### Intracerebral Hemorrhage

Intracerebral hemorrhages (ICHs) can be classified based on location (parenchymal, subdural, epidural, subarachnoid) or underlying etiology (primary hypertensive or secondary to ruptured berry aneurysms, vascular malformations, neoplasms, cerebral venous sinus thrombosis, blood dyscrasias, coagulopathies, etc.). Symptoms can vary depending on the location within the brain or spinal cord and may include coma or altered sensorium, weakness, sensory loss, aphasia, visual field deficits, headache, vomiting, and ataxia. The onset is typically acute, although symptom onset may be subacute—for example, with subdural hematomas or in patients with underlying brain tumor.

Hypertensive ICHs are commonly located in the basal ganglia, thalamus (Fig. 97.3), pons, and cerebellum. Chronic hypertension results in lipohyalinosis of small blood vessels, vessel wall weakening, and eventual rupture. Clinical examination may reveal clues to the location—for example, downward eye deviation with thalamic hemorrhage, deep coma with pinpoint pupils in pontine ICH, and severe headache, vomiting, nystagmus, and ataxia with cerebellar ICH. Space-occupying effects lead to raised intracranial pressure with consequent signs of brain herniation.

Lobar ICH (Fig. 97.4) can be hypertensive, although the most common cause is cerebral amyloid angiopathy (CAA),

• **Fig. 97.3** Hypertensive left thalamic hemorrhage with intraventricular extension.

• **Fig. 97.4** Parenchymal brain hemorrhage in the right frontal lobe. Lobar hemorrhages in the elderly usually result from underlying congophilic amyloid angiopathy.

which is frequently associated with Alzheimer dementia. A sensitive antemortem marker of CAA is the presence of multiple cerebral microhemorrhages on advanced MRI techniques (gradient-echo or susceptibility-weighted imaging). Location of these MRI lesions in the cortical-subcortical junction favors the diagnosis of CAA; deep lesions in the basal ganglia and thalamus favor a diagnosis of hypertensive vasculopathy. Because of their superficial location in the sensorimotor cortex, CAA-associated hemorrhages frequently manifest as a spell of numbness “marching” across the limb. In patients with severe CAA and prior ICH, it is reasonable to avoid antiplatelet agents and anticoagulants to reduce the risk of hemorrhage.

Subarachnoid hemorrhage (SAH) can be spontaneous, such as from ruptured berry aneurysms, or induced by head trauma. Aneurysmal SAH carries a high morbidity and mortality; it affects younger individuals, and of those who arrive to the hospital alive, the mortality rate within the first month is 45%. Among survivors, more than half are left with major deficits. Saccular aneurysms commonly occur at the terminal internal carotid artery, the middle cerebral artery bifurcation, top of the basilar artery, anterior communicating artery, and posterior communicating artery (Fig. 97.5). Mycotic aneurysms occur more distally. The rupture risk is higher with larger aneurysms (greater than 6–7 mm) and certain locations (e.g., top of the basilar). Common symptoms include sudden, severe headache, loss of consciousness, and neck stiffness. Delayed neurologic consequences of SAH include rerupture, hydrocephalus, stroke

• **Fig. 97.5** Cerebral angiogram. Lateral projection, showing a saccular aneurysm in the posterior communicating artery (arrow).

from vasospasm, and hyponatremia from cerebral salt-wasting. Treatment of aneurysmal SAH includes prompt surgical clipping or endovascular coiling, treatment of raised intracranial pressure, and “triple H” (hypertension, hemodilution, and hypervolemic) therapy for cerebral vasospasm.

Nimodipine, a centrally acting calcium-channel blocker, has been shown to improve outcome.

ICH may result from ruptured vascular malformations such as cavernous angiomas, arteriovenous malformations, and dural arteriovenous fistulas. Treatment of the underlying vascular malformation using surgical, neurointerventional, or radiation approaches are warranted to reduce the risk for rebleeding and, in certain situations, to prevent initial hemorrhage. The most common neoplasms associated with ICH include cerebral metastases from melanoma, thyroid, renal cell, lung, and breast carcinomas, choriocarcinoma, and primary brain tumors—glioblastoma multiforme (adults) and medulloblastoma (children).

If an ICH is suspected, a plain head CT scan should be acquired urgently. Many centers perform acute arterial imaging with CT angiography, MR angiography, or catheter angiography to assess for underlying vascular lesions. Venous studies should be considered because cerebral venous sinus thrombosis can manifest with hemorrhage and brain edema. The goals of medical therapy are to control blood pressure to normal levels, reverse coagulopathy by administering vitamin K or fresh frozen plasma, and reduce elevated intracranial pressure using mannitol or hypertonic saline. A neurosurgical consultation should be obtained for consideration of surgical evacuation, treatment of the underlying condition, or managing intracranial pressure by placing an intracranial bolt or ventricular drain. Surgical evacuation is controversial in hemispheric ICH; however, cerebellar ICHs are typically evacuated if there is risk for hydrocephalus or brainstem compression. At least in the initial stages, ICH patients are best managed in specialized neuro-intensive care units. Once they are medically stable, such tests should be performed to evaluate for underlying causes. The presence of acute blood sometimes makes it difficult to exclude underlying causes such as brain tumors, in which case a brain MRI should be repeated after a few weeks.

### Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is an acute polyradiculopathy often characterized by areflexia, rapidly progressive ascending motor weakness, and, to a lesser degree, sensory loss and paresthesias of the extremities. Autonomic instability and diffuse back pain are common. GBS has several variants including the axonal, demyelinating, and the Miller-Fisher variant with ophthalmoplegia, ataxia, and areflexia. Symptoms typically progress over days, peak at 3 to 4 weeks, and in most cases regress over a few weeks. Up to 30% develop respiratory weakness requiring mechanical ventilation, and 70% develop autonomic involvement leading to fluctuations in heart rate and blood pressure, loss of sweating, and urinary retention. Such patients should be admitted to an intensive care unit for monitoring or respiratory and hemodynamic support. Forced vital capacities (FVCs) and negative inspiratory force (NIF) should be checked at least three times a day until the patient clearly shows no signs of progression.

GBS has been associated with *Campylobacter jejuni*, HIV, *Mycoplasma pneumoniae*, *Haemophilus influenzae*, Epstein-Barr, Zika, and hepatitis virus infections. The differential diagnosis is broad and includes chronic inflammatory demyelinating neuropathy (CIDP), porphyria, diphtheria, heavy metal toxicity (arsenic, thallium, organophosphates, lead), vasculitis, myopathy, neuromuscular diseases such as myasthenia or botulism, Lyme disease, polio, tick paralysis, West Nile virus, and even basilar artery thrombosis. A workup should be undertaken to evaluate for infections and to rule out mimics. Electromyography (EMG) and nerve conduction studies are often normal in the initial stages but show typical findings of demyelinating radiculopathy after 8 to 10 days. Characteristic findings on CSF examination are albuminocytologic dissociation (elevated protein levels with mild pleocytosis).

Treatment options include a course of IV immune globulins or plasmapheresis. The benefit is greatest if the treatment is initiated earlier in the course of the disease, particularly within 2 weeks of symptom onset. In patients with facial and eye closure weakness, corneal dryness should be prevented. General measures such as narcotics for pain control and prophylaxis against deep vein thrombosis and pressure ulcers are important. GBS has an incidence of 1 to 2 per 100,000 per year. Ultimately, 2% to 5% of individuals die from complications, 70% to 80% will have a complete recovery by 1 to 2 years, and 20% will be left with residual weakness. There is a 3% incidence of recurrence. Factors associated with poor outcome include a fulminant course with maximum symptoms within 7 days, respiratory failure, autonomic imbalance, axonal involvement, and age >60 years.

### Myasthenia Gravis

Myasthenia gravis (MG) is an adult-onset autoimmune disease of the neuromuscular junction. It is the most common of a group of neuromuscular junction disorders, all of which cause fluctuating weakness. MG is caused by antibodies against the postsynaptic acetylcholine receptor (AChR). It has an incidence rate of 10 to 20 per million per year affecting all age groups and a bimodal age distribution with peaks in the second to third and sixth to eighth decades. There is a non-mendelian genetic predilection with first-degree relatives of patients having a 1000-fold greater risk of developing MG. Approximately 65% of cases are associated with thymic hyperplasia, and 10% of myasthenics have a thymoma. Congenital myasthenic syndromes are less common, frequently affect children, and are caused by genetic mutations affecting components of the neuromuscular junction rather than autoimmunity.

Symptoms of MG include ptosis, diplopia, dysarthria, dysphagia, weakness of the neck, shoulder, or facial muscles, overall fatigue, weakness of the extremities, and respiratory failure in severe cases. Essentially any muscle may be affected, but sensory function is spared. Symptoms

often fluctuate and are usually worse in the evening or after significant use. Muscle weakness can worsen with infection, stress, surgery, trauma, and several common medications including beta-blockers, procainamide, lidocaine, quinidine, aminoglycosides, tetracycline, ciprofloxacin, clindamycin, phenytoin, lithium, trimethadione, chloroquine, d-penicillamine, and magnesium. Myasthenic crisis develops in 20% of patients and has a mortality of 4% to 8%. The differential diagnosis includes Lambert-Eaton syndrome (a disease of the presynaptic neuromuscular junction), GBS, CIDP, botulism, cholinergic toxicity, motor neuron disease, thyroid disease, vasculitis, organophosphate poisoning, mitochondrial myopathy, muscular dystrophy, and skull-base tumors.

The diagnostic workup should include serum electrolytes, creatinine kinase, antinuclear antibodies, thyroid panel, antithyroid antibodies, and levels of acetylcholine receptor (AChR) and MuSK (muscle-specific kinase) antibodies (if AChR negative). AChR antibodies are detectable in approximately 85% of myasthenia patients with generalized disease but in only 50% with weakness of ocular muscles only. MuSK antibodies are present in approximately 40% of patients with generalized myasthenia who are AChR-antibody negative. Edrophonium (Tensilon), a short-acting anticholinesterase, may be administered to look for signs of rapid improvement. Side effects of edrophonium include salivation, nausea, diarrhea, fasciculations, syncope, and bradycardia; thus atropine should be ready for IV administration. EMG with repetitive nerve stimulation should be obtained, looking for a decremental response. Single-fiber EMG is more sensitive and may reveal the diagnosis by demonstrating instability of the neuromuscular junction (increased jitter and blocking). Chest CT should be obtained to evaluate for thymoma.

Outpatient management typically includes a combination of acetylcholinesterase inhibitors, such as pyridostigmine, and steroid therapy. Weakness may worsen with initiation of steroid therapy; thus steroids should be titrated slowly. Other immunosuppressive medications, such as azathioprine, mycophenolate mofetil, cyclophosphamide, cyclosporine, rituximab, and tacrolimus, are sometimes used in more refractory cases. Thymectomy has been proven to be effective in patients with thymoma or those without thymoma with generalized myasthenia and positive AChR antibodies. It should be considered in patients age <60 years. Myasthenia crisis, or worsening weakness with the risk of respiratory failure or death, is cause for admission to the intensive care unit for close respiratory and hemodynamic monitoring. Intubation should be considered for FVC below 15 cc/kg and NIF less than -20. Peripheral oxygen saturations are not sensitive markers for impending respiratory failure because patients with neuromuscular weakness develop hypercarbia before hypoxia. Medical therapy should be initiated with the assistance of a neurologist and typically includes plasma exchange or IV immune

globulins, steroids, and pyridostigmine. Precipitants such as specific medications should be removed and infections promptly treated.

## Peripheral Neuropathies

Peripheral neuropathy affects up to 10% of the general population, with incidence increasing with age. Peripheral nerves include both afferent (sensory input traveling to the CNS) and efferent (motor and autonomic output from the CNS) nerve fibers. Afferent fibers consist of large myelinated fibers (vibration and position sense, tendon reflexes) and small unmyelinated fibers (pain and temperature sense). Efferent fibers also include large myelinated axons (motor information to muscles) and small unmyelinated nerves (autonomic output). As such, neuropathy can cause sensory symptoms, both positive and negative, and/or muscle weakness and autonomic dysfunction.

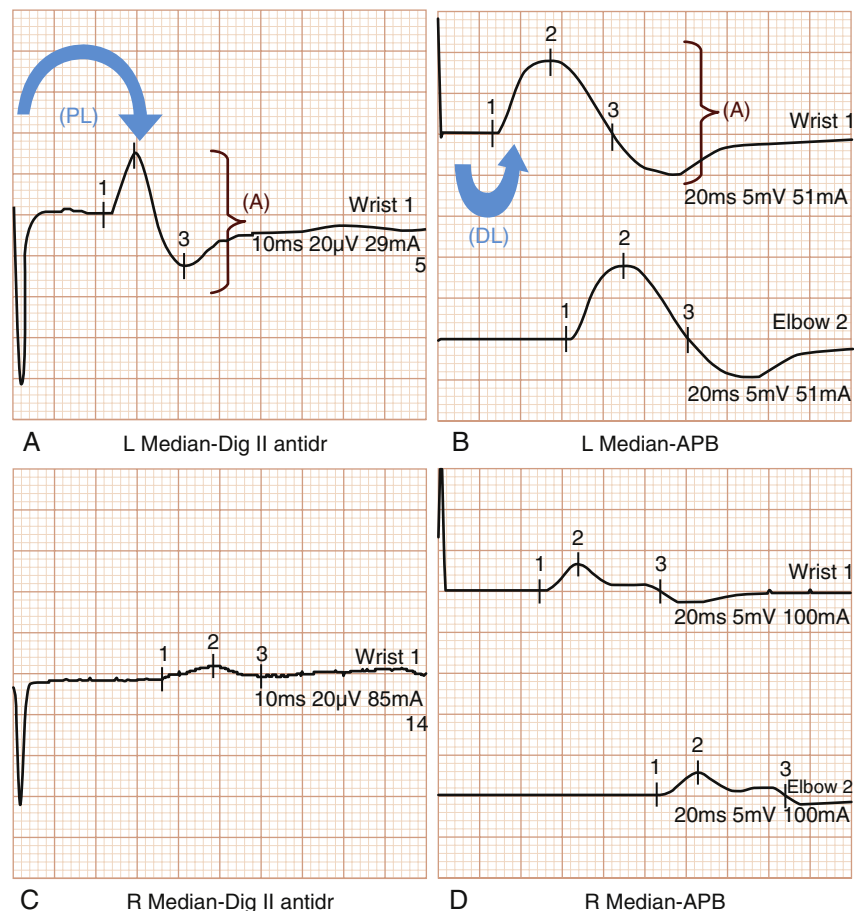

Peripheral neuropathies follow common patterns including mononeuropathy, mononeuropathy multiplex, and polyneuropathy. Polyneuropathies can be divided into small and large fiber disease. Small fiber neuropathies affect the axons of pain and temperature sensory fibers and/or autonomic fibers. Symptoms of small fiber neuropathy include dysesthesia, painful paresthesia, and numbness (usually in a stocking-glove distribution). Large fiber neuropathies can be primarily motor, sensory, or mixed and might cause weakness numbness and/or paresthesias. Large fiber neuropathies can be further subdivided into axonal and demyelinating forms. The peripheral nerve is vulnerable to a multitude of toxic, vascular, and metabolic insults, and the nerve fibers are dependent on the cell body for nutritional support and regeneration. The longest fibers are often the first and most severely affected by axonal injuries. Thus axonal degeneration typically results in a symmetric length-dependent deficit. Diabetes mellitus is the most common risk factor for length-dependent peripheral neuropathy, followed by alcoholism, nonalcoholic liver disease, malignancy, chronic renal disease, and family history. Demyelination typically affects the large-diameter sensory (vibration and position sense, tendon reflexes) and motor fibers. Demyelinating neuropathies can cause a non-length-dependent deficit reminiscent of mononeuropathy multiplex. Chronic and acute inflammatory demyelinating polyneuropathy (CIDP and AIDP) and their variants and inherited demyelinating polyneuropathy are the most common causes of demyelinating neuropathy.

Carpal tunnel syndrome (CTS) is the most common mononeuropathy caused by compression of the median nerve by the flexor retinaculum in the wrist. It affects 0.1% to 4% of the population, with a female-to-male ratio of 3:1. Symptoms include forearm pain, paresthesias in the lateral three and a half fingers on the palmar aspect of the hand, and weakness with thumb abduction, opposition, and flexion. Symptoms are often worse at night. On examination there may be weakness, sensory loss in the distribution described earlier, atrophy of the thenar eminence, and a positive Tinel

sign (symptoms elicited by tapping on the wrist) or Phalen sign (flexion of the wrist for at least 30 s reproduces symptoms). Nerve conduction studies can establish the diagnosis (Fig. 97.6). In mild or early cases of CTS, conservative therapy may be initiated with wrist splints to be worn at night and avoiding repetitive movements, typing, or treating other predisposing conditions. Physical therapy and anti-inflammatory medications may be helpful. Steroid injections may be considered but typically offer only temporary relief. For refractory cases despite conservative therapy or if there is weakness or atrophy of muscles, the patient may benefit from carpal tunnel release surgery. Meralgia paresthetica is a sensory mononeuropathy caused by compression of the lateral femoral cutaneous nerve at the inguinal ligament or in the pelvis. Predisposing factors include obesity, tight belts, pregnancy, diabetes, abdominal or pelvic masses, or prolonged sitting. Symptoms include numbness, burning, or paresthesias in the anterolateral thigh. Treatment is aimed at relieving the compression, such as wearing looser clothing, belts, or holsters to modify compressive forces, weight loss, injection of local anesthetics, and steroids. Tricyclics, other medications targeted at relieving neuropathic pain such

as gabapentin or pregabalin, and topical anesthetics may be considered as well. Peroneal neuropathy at the fibular neck is the most common lower extremity mononeuropathy. Lumbosacral and cervical radiculopathy are common, with incidence increasing with age. Brachial and lumbosacral plexopathy are rare but important causes of sensory and motor symptoms in the upper and lower extremity, respectively.

On examination, it is important to look for lymphadenopathy, organomegaly, musculoskeletal changes, or joint abnormalities such as atrophy, pes cavus, or hammer toes, abnormalities of the tonsils or oropharynx, skin, hair, and nail changes, and rash. As with all neurologic disorders, a careful history and focused examination are essential in narrowing the differential diagnosis. The initial laboratory workup should include complete blood counts, erythrocyte sedimentation rate, serum electrolytes, liver and renal function tests, hemoglobin A1c, thyroid studies, vitamin B<sub>12</sub> and folate levels, antinuclear antibody, serum and urine protein electrophoresis with immunofixation, and tests for infections such as Lyme, syphilis, or HIV as appropriate. Genetic tests may be indicated for suspected hereditary

• **Fig. 97.6** Nerve conduction studies of the median nerve. (A and B) Normal and (C and D) median neuropathy at the wrist as seen in carpal tunnel syndrome. (A) Sensory nerve action potential (SNAP) to digit 2 with normal amplitude (A) and peak latency (PL). (B) Compound muscle action potential (CMAP) to abductor pollicis brevis with normal amplitude (A) and distal latency (DL). (C) SNAP amplitude and peak latency prolongation. (D) CMAP amplitude reduction and distal latency prolongation.

neuropathies. Further evaluation with electrophysiologic studies, including EMG and nerve conduction studies, is indicated to confirm the presence of a neuropathy, provide precise localization, and distinguish axonal from demyelinating polyneuropathies. In cases where a diagnosis is unclear, and particularly if there is suspicion for vasculitis or amyloidosis, a sural nerve biopsy may be useful. Small fiber neuropathy is not seen on EMG, which only evaluates large fiber nerves and might be demonstrated on skin biopsy or with autonomic testing.

Treatment of peripheral neuropathy is directed at the underlying cause, when possible. This may include tight glucose control in diabetes, removal of toxins or offending drugs, thyroid or vitamin B<sub>12</sub> replacement, or treatment of systemic inflammatory or infectious conditions. Symptomatic treatment is typically directed at controlling neuropathic pain. Several antiepileptic and antidepressant medications have shown benefit in this regard, particularly gabapentin, pregabalin, amitriptyline, and duloxetine. Other options include opiate medications such as tramadol and nonpharmacologic treatment such as acupuncture. The prognosis for peripheral neuropathy depends on the underlying cause, severity, and chronicity. In general, axonal neuropathies have a poorer prognosis for recovery than demyelinating. If an offending agent is removed early enough, permanent neuropathy may sometimes be avoided. In many cases, however, the damage is permanent, and treatment must focus on symptom control and prevention of complications such as ulcers.

### Dementia, Delirium, and Other Cognitive Impairments

Dementia is defined as an acquired and persistent impairment in memory, plus at least one other cognitive domain (reasoning, spatial processing, language, or executive function), to an extent that daily functioning is compromised. In general, dementing illnesses are subacute to chronic, associated with underlying structural changes in the brain, and irreversible. Mild cognitive impairment (MCI) is used to denote patients with abnormal cognition and presumed early stage of dementia, with otherwise preserved daily functioning. It should be noted that dementia and MCI do not cause alteration in level of consciousness (LOC) and do not fluctuate rapidly (these are the hallmarks of encephalopathy). Distinguishing dementia or MCI from subacute encephalopathy in the acute hospital setting can be challenging. Furthermore, the two often coexist because of the increased susceptibility of patients with dementia to encephalopathy. For this reason, the evaluation of dementia should generally be deferred to the outpatient setting in an otherwise healthy patient.

The dementias can be classified by their predominant anatomic localization (subcortical vs. cortical), by their potential reversibility, by the rapidity of progression, or by etiology. For the internist, it is most useful to consider several broad categories based on etiology.

Neurodegenerative disorders involve pathologic processes that are specific to the brain, including Alzheimer disease (AD), dementia with Lewy bodies (DLB), other parkinsonian syndromes such as progressive supranuclear palsy (PSP) and corticobasal ganglionic degeneration (CBD), and the frontotemporal dementias (FTDs). Vascular dementia (VaD) occurs in patients with cerebrovascular disease and clinical or subclinical infarcts. These groups comprise the major irreversible dementias. Reversible or treatable causes of cognitive decline include chronic alcoholism, vitamin B<sub>1</sub> or B<sub>12</sub> deficiency, hypothyroidism, renal or liver failure, infections such as HIV, chronic meningitis, and neurosyphilis, chronic subdural hematoma, normal-pressure hydrocephalus, brain tumors, paraneoplastic limbic encephalitis, toxic exposure to various drugs and heavy metals, depression (pseudodementia), and recurrent nonconvulsive seizures. Rapidly progressive dementias (RPDs) have a distinct differential, although there is some overlap with unusually rapid neurodegenerative causes. In these cases, symptoms progress over weeks to months rather than months to years as is typical for most dementias. The prototypical RPD is Creutzfeldt-Jakob disease, in which abnormally folded prion protein causes aggregation and propagation in brain tissue leading to rapid global cognitive decline and death. Probable diagnosis can be made on the basis of symptoms and signs, MRI with typical pattern (cortical ribbon of restricted diffusion and/or T2 hyperintensity, symmetric basal ganglia T2 changes), CSF 14-3-3 protein, and/or typical EEG pattern (periodic synchronous biphasic or triphasic sharp waves). Other causes of RPD are important because some are treatable. These include atypical FTD, DLB, PSP, and CBD; autoimmune and paraneoplastic disorders such as Hashimoto encephalopathy and autoimmune encephalitis associated with N-methyl-D-aspartate or voltage-gated potassium channel antibodies; infections such as HIV, syphilis, and Whipple; and toxic-metabolic causes such as Wilson disease and vitamin B<sub>12</sub> deficiency.

Delirium, encephalopathy, or acute confusional state is a syndrome characterized by a fluctuating alteration in LOC and cognition. Cognition can be altered in a variety of ways, including the presence of illusions, hallucinations, delusions, and/or the loss of orientation, memory, language skills, ability to perform calculations, or reason. A feature that distinguishes encephalopathy from psychosis is that the latter does not affect the LOC. Much encephalopathy can be explained by acute medical illness, seizure, encephalitis, acute demyelination, stroke, recent surgery, systemic infection, electrolyte imbalances, hypoglycemia, pain, or medication effects or withdrawal, particularly in the elderly population.

Encephalitis denotes the presence of brain inflammation and may cause an acute confusional state or more focal symptoms. Herpes simplex virus (HSV) is the most common cause of sporadic infectious encephalitis. It tends to cause a prodrome of subtle behavioral changes, high-grade

fever, and finally acute mental status changes, alteration in consciousness, focal neurologic deficits, and seizures. Initial CSF examination will typically reveal pleocytosis, and the diagnosis of herpes simplex encephalitis rests on the detection of viral DNA in the CSF. Brain imaging usually shows changes in the inferior frontal and anterior temporal lobes (Fig. 97.7). Hemorrhage is a late-occurring event in HSV encephalitis, and its absence should not be relied on to exclude the diagnosis. Antiviral therapy (IV acyclovir) is the mainstay of treatment.

The workup of dementia begins with a complete history, during which corroborative information from close friends or family is critical because the patient may not

be able to provide an accurate history. Defining the onset, duration, and severity of symptoms, family history, and social habits including alcohol, tobacco, and drug use can often point to the correct diagnosis (Table 97.8). Gradual progressive memory impairment as the initial presenting symptom is suggestive of AD. Prominent behavioral changes, such as inappropriate social conduct, point to FTD. Stepwise worsening in a patient with vascular risk factors typifies VaD. Early visual hallucinations and fluctuations in alertness are often associated with DLB. Early falls are characteristic of parkinsonian syndromes PSP and CBD. Physical exam may reveal other important clues to the correct diagnosis. Whereas AD typically involves

• **Fig. 97.7** Herpes simplex virus-1 (HSV-1) encephalitis on MRI. (A) Fluid-attenuated inversion recovery and (B) diffusion-weighted imaging MRI sequences demonstrating abnormal signal in the right medial temporal lobe in a patient with HSV-1 encephalitis.

**TABLE 97.8** Characteristics of Major Dementias

Disease	Early Symptoms	Early Signs	Typical Test Results	Underlying Disorder
Alzheimer disease	Short-term memory loss precedes language difficulty (word searching often discovered only on direct questioning of family)	Delayed recall affected first. Later, word generation, spatial orientation, long-term memory.	MRI/CT: atrophy in the temporal > parietal lobes	Amyloid precursor protein is cleaved aberrantly, leading to accumulation of amyloid plaques Hyperphosphorylated tau causes tangles
Dementia with Lewy bodies	Visual hallucinations and sleep disorder often precede bradykinesia and tremor	Waxing/waning signs of loss of executive function; parkinsonism (bradykinesia, tremor, cogwheel rigidity); REM sleep disorder	MRI/CT: posterior parietal and occipital atrophy	Synuclein accumulation into cytoplasmic inclusions known as Lewy bodies appears to be the etiology of DLB
Other parkinsonian syndromes progressive supranuclear palsy, corticobasal ganglionic degeneration	Falls, irritability, apathy, bulbar symptoms such as dysarthria, dysphagia (PSP)	Parkinsonism (bradykinesia, tremor, cogwheel rigidity), gaze palsy (PSP), limb apraxia/alien hand (CBD)	MRI/CT with midbrain atrophy (PSP) or asymmetric cortical atrophy (CBD)	Hyperphosphorylated tau accumulation

*Continued*

**TABLE 97.8** Characteristics of Major Dementias—cont'd

Disease	Early Symptoms	Early Signs	Typical Test Results	Underlying Disorder
Vascular dementia	Stepwise progression of memory deficits and focal neurologic signs	Slowed cognition, stepwise deterioration with plateaus between. Focal neurologic deficits are typically present because of symptomatic ischemic strokes.	MRI/CT: marked white matter disease, evidence of prior strokes (cortical and/or subcortical). Stroke workup may reveal cause of ischemic strokes	Evaluate for stroke risk factors including hypertension, hyperlipidemia, diabetes, atrial fibrillation, malignancy, inflammatory disease
Frontotemporal dementia	Behavioral changes include apathy, depression, disinhibition, poor social demeanor, reduced executive functioning, and aphasia. Primary progressive aphasia may reveal expressive language deficits only.	Frontal release signs (grasp, suck, snout, glabellar, palmo-mental reflexes), Luria testing deficits, poor social skills, abulia, aphasia	MRI/CT: atrophy of the frontal and temporal lobes	Typical inclusions consisting of either tau (Pick bodies) or ubiquitin and TDP43 (or rarely FUS). TDP43 associated with FTD-ALS combination.

*CBD*, Corticobasal ganglionic degeneration; *CT*, computed tomography; *DLB*, dementia with Lewy bodies; *FTD-ALS*, frontotemporal dementia–amyotrophic lateral sclerosis; *MRI*, magnetic resonance imaging; *PSP*, progressive supranuclear palsy; *REM*, rapid eye movement.

• **Fig. 97.8** Alzheimer disease on MRI. (A) Fluid-attenuated inversion recovery and (B) magnetization-prepared rapid gradient echo MRI sequences demonstrating prominent medial temporal lobe atrophy with enlargement of ventricles in a patient with moderate Alzheimer disease.

motor symptoms only later in the disease process, FTD is associated with rigidity and possibly amyotrophic lateral sclerosis. DLB, PSP, and CBD feature prominent parkinsonian signs, such as tremor, rigidity, bradykinesia, and shuffling gait. Patients with VaD may have focal signs from stroke. Diagnostic testing in dementia is aimed at uncovering a reversible etiology. Investigations should include a thyroid function test, a vitamin B<sub>12</sub> level, possibly HIV and RPR depending on the clinical history, and neuroimaging (preferably MRI; Fig. 97.8) to assess for structural causes such as chronic subdural hematoma, normal pressure hydrocephalus, or brain tumor. Lumbar puncture and EEG could be considered. Patients should be screened

for depression, which can accompany or mimic dementia (pseudodementia). Formal neuropsychologic testing can sometimes help to differentiate specific dementias.

Although different dementias can vary in presentation and progression, supportive care is critical and largely similar. Patient safety should be emphasized, as should that of the caretaker. Violent outbursts can be embarrassing to relatives. Support services in the home, adult care services, and finally placement in appropriate care settings should be actively arranged for caregivers by the treating physicians. As in pediatrics, guidance should be a mainstay of visits so that caregivers will anticipate potential challenges. Services that might be helpful to families include occupational and

**TABLE 97.9** Common Types of Abnormal Movements

Movement	Description
Tremor	Involuntary, rhythmic movement at a joint with oscillation of a specific frequency and amplitude. Description should include frequency, amplitude, and subtype. Subtypes include: Rest tremor (prominent in repose) Action tremor (prominent with use or positioning of limb) Intention tremor (an action tremor that worsens as the limb nears its target) Rubral tremor (near continuous, with action > rest tremor)
Bradykinesia	Slowness of movement causing hypophonia, reduced eye blink and arm swing, micrographia, festination of gait
Chorea	Involuntary, irregular, arrhythmic, complex movements flowing from one muscle group to another. Often incorporated by patient into a voluntary movement.
Athetosis	Slow, sinuous movements, typically of the distal extremities
Dystonia	Sustained muscle contraction. Examples include torticollis and writer's cramp.
Myoclonus	Brief, asymmetric, arrhythmic muscle contraction. Often referred to as a jerk. Can be single, multiple, or continuous. Can be focal or generalized.
Asterixis	Sudden loss of sustained tone in muscle
Tic	Brief, stereotyped, repetitive movement, can be suppressed voluntarily, often associated with Tourette disease

physical therapy, social work, financial planners, homemakers, visiting nurses, adult day care providers, and, eventually, chronic nursing facilities or palliative care and home hospice providers.

### Parkinsonism, Tremor, and Other Movement Disorders

Movement disorders are motor syndromes characterized by a paucity or slowness of movement or abnormal involuntary movement. A major challenge is to correctly classify the abnormal movement (Table 97.9). The examination of movement disorders is largely observational: watch the patient in repose, while performing prespecified actions including limb positioning, writing, moving rapidly and repetitively, standing from a chair, walking, and performing actions that will elicit symptoms. Determine whether the movement can be voluntarily suppressed. A thorough exam of muscle tone, strength, reflexes, cranial nerves (especially eye movements), sensation, and gait should follow. Essential tremor and parkinsonism, including idiopathic Parkinson

disease (PD), are by far the most common movement disorders seen in the outpatient clinic.

Parkinsonism is a syndrome consisting of all or some of the following cardinal features: resting tremor, bradykinesia (slowed movements), rigidity (increased tone on passive movements), and postural instability (imbalance and tendency to fall). The term includes idiopathic PD and the so-called Parkinson-plus syndromes such as DLB, multiple systems atrophy, PSP, and CBD. After AD, idiopathic PD is the second most common neurodegenerative disease. It has a prevalence of 0.3% of the population and an incidence rate of approximately 15 new cases per 100,000 person-years, with rates in men two to three times that for women. As for AD, the risk increases with age, with prevalence of 1% among those age >60 years and 3.5% in those age >85 years; only 4% are diagnosed age <50 years. Although most cases are sporadic, 25% of patients with PD have a first-degree relative with PD, and earlier age of onset is associated with genetic causes.

Distinguishing PD from other forms of parkinsonism can be challenging, especially early in the course when cardinal signs may be lacking. A definite diagnosis of PD requires the presence of at least two cardinal features (rest tremor, bradykinesia, rigidity). Other features that are more typical for PD include unilateral onset, rest tremor, and persistence of asymmetry throughout the course. Supportive evidence may also be found in a positive response to treatment with dopamine replacement therapy: PD patients usually show a response to levodopa at a dose of 300 to 600 mg total daily dose, whereas a lack of response to levodopa, symmetrical onset, and lack of tremor should raise suspicion for an alternate diagnosis. Other red flags include early falls, prominent dysautonomia, and rapid progression. In atypical cases, MRI is useful to exclude structural causes of symptoms such as infarcts, tumor, or normal-pressure hydrocephalus. Routine MRI is typically normal in PD. Newer imaging modalities such as positron emission tomography and dopamine transporter imaging using single photon emission photography (DaTscan) show promise for distinguishing specific parkinsonian syndromes, but they are currently used primarily by specialists at research centers.

Essential tremor is distinguished from PD by symmetrical intention tremor, although less commonly it may be unilateral or present at rest. Bradykinesia and rigidity are lacking, and essential tremor is often improved by alcohol. Because it may be inherited in an autosomal dominant pattern, family history is helpful. Involvement of the head is atypical for PD but may be seen in essential tremor in isolation or in conjunction with a hand tremor.

The foundation of treatment for PD is symptomatic management. There are no proven disease-modifying (neuroprotective) treatments for PD, therefore the timing of initiating symptomatic treatment depends on the disease burden and patient preference. The most effective medication remains levodopa, especially for bradykinesia and rigidity. It is typically administered with carbidopa in the form of Sinemet to reduce systemic metabolism.

The most common side effects early on include nausea and drowsiness. These may sometimes be avoided by starting with a low dose and gradually escalating, as well as taking the medication with meals. Most patients taking levodopa will eventually develop dyskinesias (unwanted involuntary movements) or motor fluctuations (wearing off between doses). These can sometimes be delayed by initiating treatment with a dopamine agonist, either ropinirole (Requip) or pramipexole (Mirapex). Although they are associated with fewer dyskinesias and motor fluctuations, they are also less effective and more prone to side effects of somnolence, hallucinations, and leg edema. In general, dopamine agonists should be considered in younger patients (age <65 years) to prolong time to levodopa initiation, and older patients should receive levodopa to avoid the cognitive side effects of dopamine agonists. For younger patients with tremor predominance, anticholinergic agents such as trihexyphenidyl (Artane) and benzotropine (Cogentin) may be useful, but they should be avoided in older patients or those with cognitive deficits. Management should also address nonmotor symptoms such as rapid eye movement–sleep behavior disorder, depression, fatigue, and autonomic symptoms such as constipation, sexual dysfunction, and orthostatic hypotension. Essential tremor can be effectively treated with propranolol or primidone. For both PD and essential tremor, advanced refractory disease may improve with implantation of a deep brain stimulator in the subthalamic nucleus or globus pallidus in select patients (Fig. 97.9).

Life expectancy is not altered in patients with essential tremor. The life expectancy of patients with PD depends on the age of onset but generally ranges between 9 and 11 years shorter than the normal population. Prominence of bradykinesia and rigidity at onset, as well as older age of onset, are associated with more rapid progression of motor symptoms. Conversely, tremor predominance is associated with a slower progression. Dementia occurs in 30% to 40% of patients with PD and is more common in those without tremor predominance. It is associated with earlier nursing home

placement and decreased survival. It should be emphasized that most patients progress slowly and remain functional for many years with appropriate symptomatic treatment.

### Multiple Sclerosis and Other Demyelinating Diseases

MS is an autoimmune disease of unknown etiology that results in destruction of central myelin. The hallmarks of MS are demyelinating brain or spinal cord lesions that are separated in space and time and the exclusion of other potential causes of similar symptoms. The mean age of onset is 30 years of age. Onset before age 10 years or after age 50 years should raise suspicion for an alternate diagnosis. There are apparent geographic disparities in MS prevalence, with rates highest in Europe, Australia, New Zealand, Canada, and the northern United States. This may be explained in part by racial differences in susceptibility, with the highest incidence rates among Caucasian populations. Prevalence rates also increase from southern to northern latitudes. Evidence suggests that increased sun exposure and supplemental vitamin D reduce the risk of developing MS. In the United States, the prevalence of MS is 1 per 1000. As with other autoimmune diseases, women are affected more than men (2:1 to 3:1). Genetic factors also play a role in the risks for MS. Approximately 20% of patients with MS have a relative also affected. Siblings of MS patients have a 3% to 5% risk of developing MS.

There are several patterns of disease in MS. In relapsing remitting MS (RRMS), patients have distinct attacks without progression between relapses. Approximately 85% to 90% of cases present with this course, with onset typically in the late 20s. Most patients with RRMS will eventually develop disease progression with or without relapses, constituting secondary progressive MS. In the small percentage of patients with primary progressive MS, disease begins with a progressive course, typically at an older age than RRMS.

Less common forms of CNS demyelination include acute disseminated encephalomyelitis (ADEM) and neuromyelitis optica (NMO). ADEM is typically preceded by a viral

• **Fig. 97.9** Deep brain stimulation for Parkinson disease. (A) Axial T1 and (B) coronal spoiled gradient recalled acquisition (SPGR) sequences demonstrating deep brain stimulator electrodes terminating in the bilateral subthalamic nuclei in a patient with advanced idiopathic Parkinson disease.

infection or other immune stimulus such as vaccination and results in a typically monophasic illness of variable severity. It is more common in children but may occur in adults as well. NMO, also called Devic disease, is characterized by optic neuritis and transverse myelitis simultaneously or in close succession. Typically, the brain has no or only mild clinical or radiographic involvement. The spinal lesions tend to be more severe than in MS, and optic neuritis is often bilateral. The presence of a specific marker of NMO, the serum IgG antibody against the aquaporin 4 water channel (NMO-IgG), allows for diagnosis when present and has expanded the clinical spectrum of disease described when defined by antibody positivity, denoted by the term *NMO-spectrum disorders*.

In the absence of any definitive test for MS short of brain biopsy, the diagnosis is based on clinical criteria, including symptoms, signs, and ancillary testing. Definite diagnosis requires two or more attacks and objective clinical evidence of two or more lesions. Attacks may be any clinical syndrome likely to result from CNS white matter inflammation and lasting at least 24 hours, including optic neuritis, transverse myelitis, and brainstem syndromes (Table 97.10). MRI has become an essential tool in making the diagnosis. Brain MRI sequences should include axial and sagittal fluid attenuated inversion recovery (FLAIR), T2, and axial T1 precontrast and postcontrast. Imaging the entire spinal cord

with T2 and T1 precontrast and postcontrast sequences may also reveal a subclinical lesion. MRI typically reveals multifocal T2 hyperintensities, most commonly located in the periventricular white matter, corpus callosum, and centrum semiovale (Fig. 97.10). The lesions are usually ovoid and situated perpendicular to the ventricles or corpus callosum. In the spinal cord, MS lesions are characteristically incomplete and rarely extend more than one or two spinal levels. Acutely, brain or spinal lesions may be enhancing on T1 postcontrast sequences. Later in the disease course, these lesions may become prominently hypointense on T1 images, and cortical atrophy may become apparent.

Because many other processes can lead to T2 hyperintensities on MRI, these changes must be interpreted in the setting of consistent clinical data and typical patterns.

When patients present with an initial demyelinating event but do not meet criteria for MS (so-called clinically isolated syndrome or CIS), MRI can help predict the risk for progression to clinically definite MS. Those with an abnormal MRI have a risk for developing MS anywhere from 56% to 88%, whereas those with a normal MRI have a 20% risk. Adjunct studies include CSF studies, which may reveal intrathecal production of oligoclonal immune globulins, and visual evoked potential studies, which may reveal slowed conduction suggestive of prior optic neuritis. Although these tests may be suggestive of MS, they are far less predictive than MRI.

Several agents currently used as first-line treatment in RRMS include glatiramer acetate (Copaxone, SC daily or three times a week [tiw]; Glatopa, SC daily), interferon- $\beta$ 1a (Avonex, intramuscularly weekly), interferon- $\beta$ 1a (Rebif, subcutaneously [SC] tiw), interferon- $\beta$ 1b (Betaseron, SC every other day [qod]), pegylated interferon- $\beta$ 1b (Plegridy SC q2weeks), dimethyl fumarate (Tecfidera, orally [po] twice a day), and teriflunomide (Aubagio po every day [qd]). All have been shown to reduce the frequency and severity of attacks in RRMS, as well as progression of disability and MRI lesions.

**TABLE 97.10** Typical Presenting Symptoms in Multiple Sclerosis

Sensory symptoms in limbs	Diplopia
Visual loss	Gait ataxia
Motor weakness	Sensory symptoms in face
Lhermitte sign (radiating electrical sensation with neck flexion)	Uhthoff phenomenon (worsening in hot ambient temperature)
Vertigo	Fatigue

• **Fig. 97.10** MRI in relapsing remitting multiple sclerosis. (A) Axial and (B) sagittal fluid-attenuated inversion recovery MRI sequences demonstrating multiple foci of increased T2 signal, including lesions arranged perpendicular to the ventricles, in a patient with relapsing remitting multiple sclerosis.

Because of reports of deaths caused by cardiac or unexplained causes, and several cases of severe herpes zoster infection, fingolimod (Gilenya, po qd) is typically reserved for patients who cannot tolerate or fail to respond to the injection therapies. For patients with severe onset or refractory RRMS, natalizumab (Tysabri) may be considered for its potent effects at controlling and preventing severe inflammation. Natalizumab must be prescribed through a registry and patients monitored for John Cunningham virus seroconversion caused by the small but real risk of progressive multifocal encephalopathy. A humanized monoclonal antibody against CD20 B cells has shown benefit in randomized controlled clinical trials and was FDA approved for use in primary progressive and RRMS in March 2017. Other options with limited evidence include pulse methylprednisolone, mitoxantrone, cyclophosphamide, azathioprine, and methotrexate. For acute exacerbations, there is some evidence that high-dose methylprednisolone (1 g IV daily for 3–5 days) may shorten the course of an attack without changing the overall course of the disease. Thus for minor symptoms such as nonpainful paresthesias or mild weakness, steroid treatment is not indicated. Although a small percentage of patients with MS will have disease characterized as benign (i.e., no subsequent relapse) or malignant (rapid progression to disability), the usual course is slowly progressive. The median time from diagnosis to requiring a cane for ambulation is about 30 years. Life expectancy is on average approximately 7 years less than the normal population but varies with disease severity.

### Dizziness and Vertigo

Dizziness refers to impairment in spatial perception and stability. The terms *unsteadiness*, *faintness*, *light-headedness*, *motion intolerance*, *imbalance*, *floating*, or *tilting* are often used interchangeably to describe dizziness. Vertigo is a common subtype of dizziness and reflects an illusion of movement, a sense that the patient or the patient's surroundings are spinning or moving. The estimated overall incidence of dizziness, vertigo, and imbalance is 5% to 10% and is estimated to be much higher (at 40%) for those patients age >40 years.

The causes of dizziness can be divided into four broad categories: vestibular dysfunction, brain hypoperfusion, ataxia, and psychogenic. Approximately 40% of all cases of vertigo are from peripheral vestibular dysfunction, 10% from CNS lesions, 15% reflect a psychiatric disorder, 25% presyncope/dysequilibrium, and 10% nonspecific dizziness. Hypotension related to vagal hyperactivity, low blood volume, or shock can lead to dizziness in the form of presyncope. Ataxia can be caused by central causes such as cerebellar or vestibular dysfunction or to peripheral sensory dysfunction. Psychogenic dizziness is a diagnosis of exclusion but is common in anxiety disorders.

Key clinical features of vertigo that suggest a peripheral cause (inner ear or vestibular nerve) include moderate or severe symptoms that are recurrent and worsened by changes in position. Positional nystagmus is typical. The

• **Fig. 97.11** Brain MRI, axial T2-weighted image, showing an acoustic neuroma (arrow).

nystagmus is characterized by a latent period before onset of approximately 2 to 20 seconds; the nystagmus usually lasts <1 minute and has fatigability. In contrast, central causes of dizziness are suggested by the presence of continuous mild nonpositional vertigo with vertical nystagmus with no latent period and that lasts >1 minute and is nonfatiguing. Because central causes are frequently secondary to brainstem or cerebellar ischemia, additional brainstem characteristics may be present, including diplopia, autonomic symptoms, nausea, dysarthria, dysphagia, or focal weakness. The most common cause of central dizziness is migraine, frequently referred to as vestibular migraine or migraine-associated dizziness. Other central causes include demyelination, acoustic tumors (Fig. 97.11), and brainstem or cerebellar vascular lesions (Boxes 97.1 through 97.4).

Workup for dizziness, especially with a goal of distinguishing peripheral from central causes, includes targeted physical examination techniques (head impulse, nystagmus, test of skew [HINTS examination]), standard blood tests, imaging (head CT, MRI/MR angiography), audiometry, and several specialist tests. Electronystagmography is performed by a neurologist or otolaryngologist. A standard battery consists of three parts: oculomotor evaluation, positioning/positional testing, and caloric stimulation of the vestibular system.

Most cases of dizziness do not require referral. Criteria for referral include (1) severe vertigo that is disabling; (2) ataxia out of proportion to vertigo; (3) vertigo lasting >4 weeks; (4) changes in hearing; (5) presence of vertical nystagmus; (6) presence of focal neurologic signs; and (7) systemic or psychiatric disease.

### • BOX 97.1 Causes of Dizziness

#### Peripheral

- Benign paroxysmal positional vertigo or canalithiasis—50%
- Vestibular neuronitis (labyrinthitis): 25%
- Ménière disease: 10%
- Trauma
- Drugs (e.g., aminoglycosides)

#### Central

- Vertebrobasilar insufficiency: 50%
- Multiple sclerosis
- Drugs (anticonvulsants, alcohol, hypnotics)

### • BOX 97.2 Causes of Vertigo

- Ear disease
- Toxic conditions (alcohol, food poisonings)
- Postural hypotension
- Infectious disease
- Cervicogenic
- Disease of the eye or brain
- Psychologic

### • BOX 97.3 Key Causes of Peripheral Dizziness

#### Benign Paroxysmal Positional Vertigo (BPPV)

- Brief moderate to severe recurrent episodes, lasts less than 1 minute, self-limited, responds poorly to antivertigo drugs
- Associated with head position
- Gradually diminishes over a month or two
- No hearing loss
- Latency or delayed onset of clinical presentation
- Positive test for positioning nystagmus (using Nylen-Barany maneuver, also known as the Dix-Hallpike test)
- Caused by canalithiasis (otoconia floating in the endolymph) or cupulolithiasis (otoconia adherent to cupula)
- Posterior canal most commonly affected (90% of cases)
- Most effective treatment is canalith repositioning from the affected canal to the vestibular (using maneuvers)
- Medications not effective in treatment of BPPV

#### Vestibular Neuronitis

- Paroxysmal, single attack of vertigo, a series of attacks, or a persistent condition that diminishes over 3–6 weeks
- May be associated with nausea, vomiting, and previous upper respiratory tract infections
- In general no auditory symptoms
- Associated with nystagmus
- May be secondary to a viral infection that affects the patient's vestibular ganglion and vestibular nerves (prodromal upper respiratory tract illness may or may not be present)

#### Cervicogenic Vertigo

- History of neck trauma and muscle spasm
- Limited cervical range of movement
- Positive chair rotation test (Fitz-Ritson)
- Patients may complain of dysequilibrium (tilt) more than rotational vertigo
- Overstimulation of upper cervical proprioceptors
- May overlap with BPPV or Ménière disease

#### Ménière Disease

- Sudden and recurrent (paroxysmal) attack of severe vertigo (fourth leading cause)
- Low-tone hearing loss, which may progress to severe hearing loss
- Low-tone tinnitus and sense of fullness in the ear
- Bilateral involvement in about 25% of patients
- Ménière disease etiology can be hereditary, autoimmune, infectious, or idiopathic
- >80% of patients respond to conservative therapy with salt restriction and diuretics. Other options: corticosteroids, given orally or intratympanically; intratympanic gentamicin (chemical labyrinthectomy), and surgery (shunting the endolymphatic sac)

### • BOX 97.4 Central Causes of Dizziness

#### Migraine

- Women > men
- Motion intolerance/sickness
- Vestibular symptoms usually dissociated from headaches but may occur as an aura or as part of headache
- Treatment of migraine-associated vestibulopathy is the same as treatment of migraine
- Eliminate trigger factors

#### Vertebrobasilar Insufficiency Transient Ischemic Attacks

- Sudden onset of dizziness with resolution of symptoms within 24 hours without residual subjective symptoms or objective signs
- Associated focal neurologic symptoms of isolated or combined brainstem symptoms such as dizziness, diplopia, or weakness, headache

- Presence of associated risk factors (e.g., hypertension, diabetes mellitus, coronary artery disease)

#### Multiple Sclerosis (MS)

- Vertigo as presenting feature occurs in <10% with MS; dizziness or vertigo occurs at some point in the course in a third of patients
- Onset is usually at age 20–40 years
- Episodes begin over hours to a few days and last weeks to months
- Associated typical symptoms include optic neuritis, ocular motor dysfunction, trigeminal neuralgia, sensorimotor deficits, myelopathy, ataxia, and bladder dysfunction
- Few patients present with hearing loss because of brainstem involvement
- Cause is recurrent, inflammatory central nervous system demyelination because of underlying autoimmune disorder

## Preoperative Evaluation and Management Before Major Noncardiac Surgery

ADAM C. SCHAFFER AND SYLVIA C.W. MCKEAN

There are more than 10 million major noncardiac surgical procedures performed in the United States per year, and this number is expected to grow as the population ages. The problem of perioperative cardiac events among patients undergoing noncardiac surgery is significant. The estimated risk of myocardial infarction (MI) in patients undergoing noncardiac surgery is 1.1% among unselected patients and 3.1% among patients at elevated risk of cardiac disease. The task of the internist providing preoperative evaluation of patients is not to provide medical “clearance.” Instead, the role of the internist is, in addition to answering any specific questions posed by the requesting physician, to provide a thorough assessment of the patient’s cardiovascular and other risks for the procedure. This risk assessment can assist in the balancing of risks and benefits that influences whether the surgeon decides to go forward with the procedure. The consulting internist must also provide specific suggestions regarding further testing that may be indicated for preoperative risk stratification and, most importantly, recommendations for measures that can be taken to mitigate the identified risks.

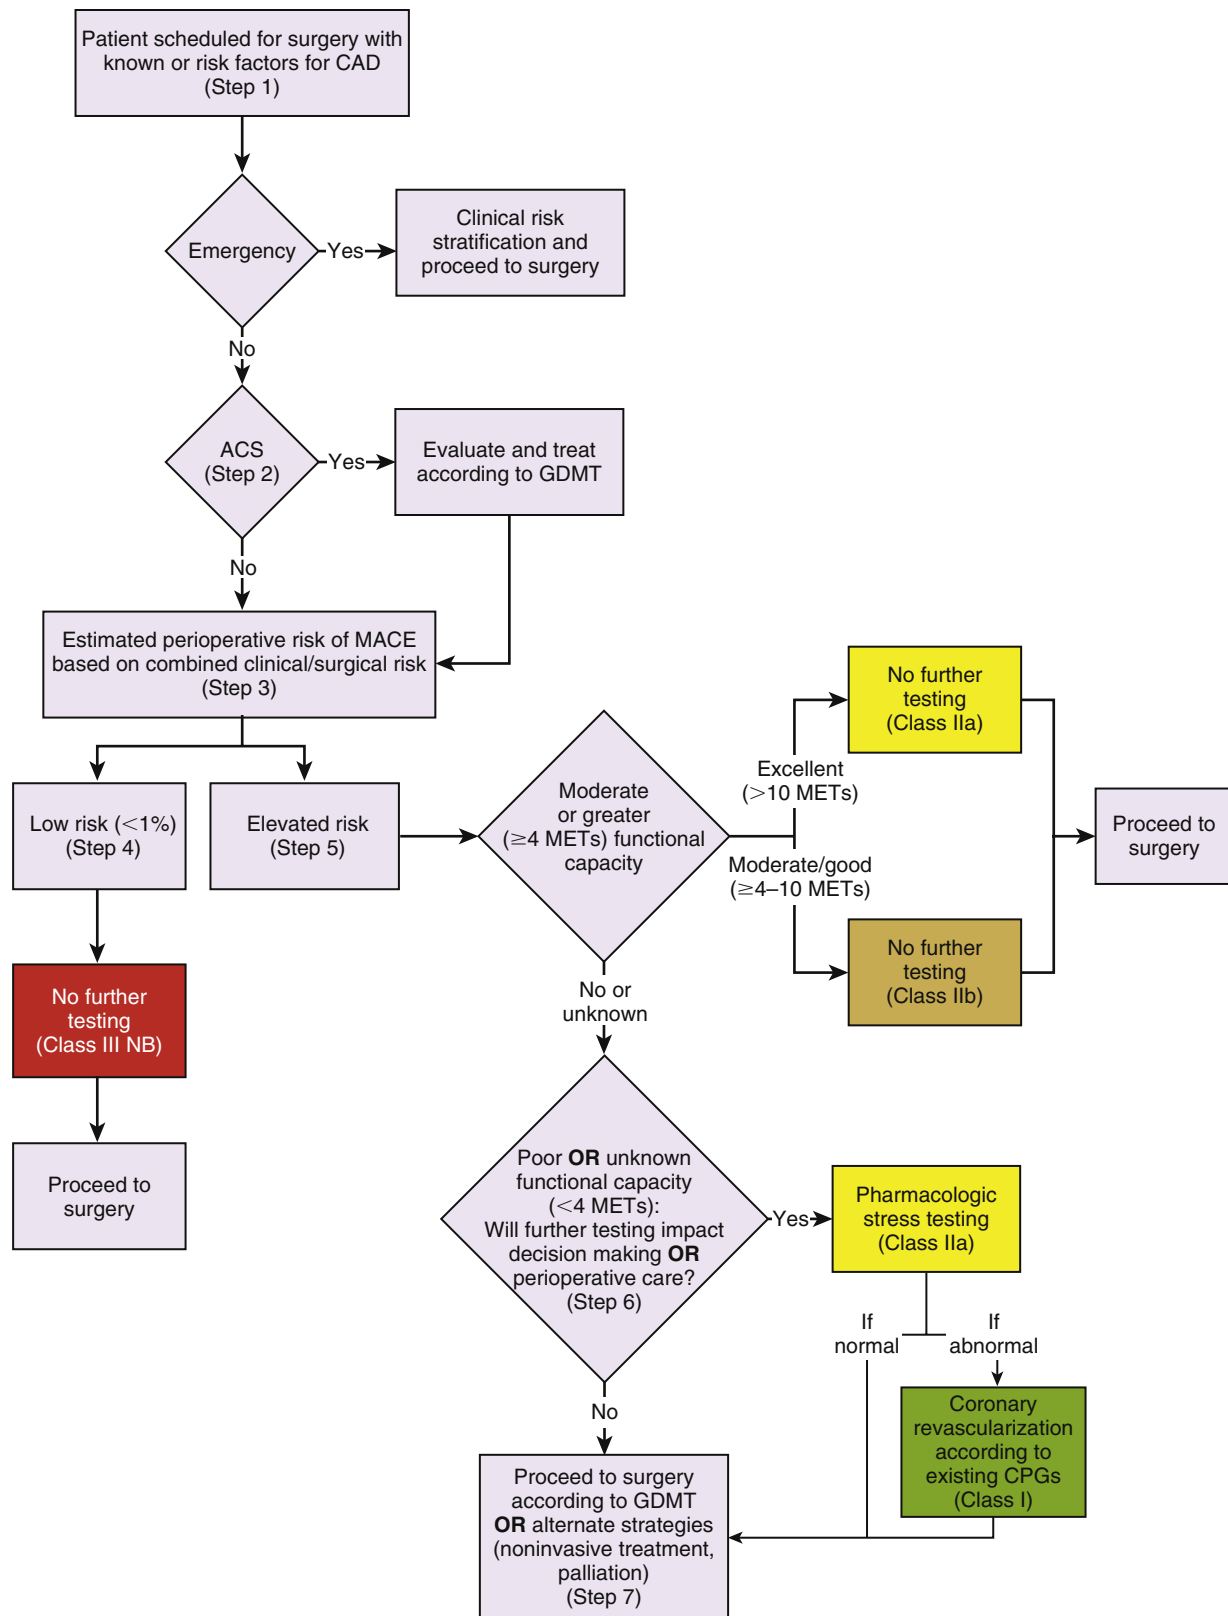

### American College of Cardiology/ American Heart Association Guidelines on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery

In 2014, new American College of Cardiology/American Heart Association (ACC/AHA) guidelines on perioperative evaluation and management were published, supplanting older guidelines from 2007. These 2014 guidelines serve as the cornerstone of preoperative evaluation. The guidelines provide an algorithmic approach to preoperative cardiac assessment, as shown in [Fig. 98.1](#).

As an initial step in the evaluation, the clinician should determine whether the patient is having an acute coronary syndrome (ACS), which, if present, should trigger cardiology consultation, a delay in surgery, and management as detailed in [Chapter 81](#). Absent the presence of ACS, the next step is cardiac risk assessment.

As the main measure of cardiac risk, the 2014 guidelines use the major adverse cardiac event (MACE), which is defined as death or MI. Methods for calculating the MACE risk are discussed subsequently. In patients who are determined to be at low risk, defined as a MACE risk <1%, it is appropriate to go forward with surgery. In patients with a MACE risk  $\geq 1\%$ , who are considered to be at elevated risk, the need for additional preoperative testing is determined by their functional capacity. A patient’s functional capacity is defined as the intensity of activity that the patient can engage in without any cardiac symptoms. The current threshold is being able to achieve  $\geq 4$  metabolic equivalents (METs) of activity without cardiac symptoms. A functional capacity of 4 METs corresponds to climbing the stairs at a slow pace, sweeping the sidewalk, or pushing a child in a stroller. Patients with a functional capacity of  $\geq 4$  METs can go to the operating room (OR) without the need for additional testing.

In patients with a MACE risk of  $\geq 1\%$  and a functional capacity <4 METs (or whose functional capacity cannot be determined, for example, because the patient is wheelchair bound), further preoperative testing, such as a pharmacologic stress test, should be considered. However, a preoperative stress test is appropriate only if it will alter management. Not all patients who have a MACE risk  $\geq 1\%$  and who do not make the 4 METs threshold should undergo a preoperative stress test. The risk of delaying the surgery for additional preoperative testing needs to be weighed against the benefits of determining whether the patient has cardiac ischemia. In general, if the patient could not afford the surgical delay that would be associated with cardiac revascularization, then a preoperative

• **Fig. 98.1** Algorithm for preoperative assessment as specified in the 2014 American College of Cardiology/American Heart Association guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery. ACS, Acute coronary syndrome; CAD, coronary artery disease; CPG, clinical practice guidelines; GDMT, guideline determined medical therapy; HF, heart failure; MACE, major adverse cardiac event; MET, metabolic equivalents; STEMI, ST-elevation myocardial infarction; UA/NSTEMI, unstable angina/non-ST-elevation myocardial infarction; VHD, valvular heart disease. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64(22):e77–e137.)

cardiac stress test is unlikely to change management. For example, patients with hip fractures have worse outcomes if surgery is delayed >72 hours, and so, in hip fracture patients, only in very uncommon circumstances would a preoperative stress be indicated, even if the patient has a MACE risk  $\geq 1\%$  and does not meet the 4 METs functional capacity.

Evaluating whether revascularization before surgery is beneficial in a population of patients undergoing vascular surgery, the CARP (Coronary Artery Visualization Prophylaxis) trial, by McFalls et al. 2004, enrolled 510 patients with documented coronary artery disease (CAD). In this trial, 510 patients who were considered at elevated cardiac risk, and who therefore had already undergone diagnostic cardiac catheterization, were eligible for enrollment only if their cardiac catheterization showed  $\geq 70\%$  coronary stenosis. Exclusion criteria included stenosis of the left main coronary artery, left ventricular ejection fraction  $< 20\%$ , or severe aortic stenosis. Enrolled patients were randomized to revascularization or no revascularization before surgery. Among the patients who were revascularized, 59% underwent percutaneous coronary intervention, and 41% underwent coronary artery bypass graft. There was no significant difference in the outcomes between the revascularization and no-revascularization groups, who had similar MI rates at 30 days (11.6% in the revascularization group vs. 14.3% in the no-revascularization group;  $P = .37$ ). The two groups also had similar 30-day death rates and long-term outcomes. In this group of patients undergoing vascular surgery, all of whom had angiographically proven CAD, preoperative revascularization did not improve outcomes.

## Risk Assessment

The older 2007 guidelines used the Revised Cardiac Risk Index (RCRI) developed by Lee et al. as the major risk assessment tool. The RCRI was designed to predict which patients were at elevated risk for major cardiac complications (defined as MI, pulmonary edema, ventricular fibrillation or primary cardiac arrest, and complete heart block) from nonemergent noncardiac surgery. Although the RCRI index has the advantage of simplicity, two online risk calculators are now the preferred methods of assessing cardiac risk and will provide the MACE risk for patients (Table 98.1).

A valuable feature of the ACS NSQIP (The American College of Surgeons National Surgical Quality Improvement Program) Surgical Risk Calculator is that, in addition to calculating the MACE risk, it also provides the perioperative risk in multiple other domains, such as the risk of death and various complications. These noncardiac risks should also be considered when balancing the risks and benefits of a given surgical procedure.

## Revascularization Before Surgery and Management After Revascularization

Revascularization before elective surgery requires careful consideration regarding the period between revascularization

and when the surgery is needed, given the requirement for dual antiplatelet therapy (DAPT; aspirin and clopidogrel) following revascularization. For patients who undergo balloon angioplasty without a stent, at least 14 days should elapse before surgery, because this is the minimum recommended duration of DAPT and so that the vessel may heal. In patients who receive bare-metal stents (BMS), at least 30 days should elapse before surgery, because this is the minimum duration for DAPT after placement of a BMS and to allow for some endothelialization of the stent. With drug-eluting stents (DES), the risk of stent thrombosis persists for a longer period than with BMS, and so a longer duration of DAPT is indicated. DAPT should be continued for at least 12 months after implantation of a DES. Depending on the risk of delaying surgery, surgery may be considered 6 months after placement of a DES.

Continued DAPT may be appropriate even after the minimum periods for DAPT following stent placement. If DAPT is discontinued after the minimum recommended period, aspirin should be continued. Of course, the surgeon's assessment of the bleeding risk from aspirin, or aspirin and clopidogrel, needs to be considered in deciding whether or not to continue these agents perioperatively after revascularization. However, given the potentially severe consequences of stent thrombosis, premature discontinuation of aspirin and clopidogrel should be avoided if possible. If it is felt to be absolutely necessary to prematurely discontinue clopidogrel because of the surgical bleeding risk, then aspirin should be continued perioperatively, and the clopidogrel should be restarted as soon as possible. In cases in which the surgeon is advocating discontinuing antiplatelet therapy during the minimum recommended period after stent placement, formal cardiology consultation is useful in helping to weigh the risks and benefits.

## Beta-Blockers

In the perioperative setting, the strongest (and only class I) indication for perioperative beta-blockers is that they should be continued in patients who are already on them for an appropriate indication (especially patients with a history of cardiac ischemia or MI) because beta-blocker withdrawal perioperatively can be harmful. Perioperative beta-blockade also appears to be of benefit among selected patients who are at elevated risk of perioperative cardiac events.

The largest randomized controlled trial of perioperative beta-blockers, the PeriOperative ISchemic Evaluation (POISE) trial, published in 2008, demonstrates the need for caution in the use of beta-blockers in the perioperative setting. This trial enrolled 8351 patients undergoing noncardiac surgery with at least one cardiac risk factor. Patients were randomized to either placebo or controlled-release metoprolol (CR metoprolol), 100 mg orally 2 to 4 hours before surgery, a postoperative dose of CR metoprolol based on heart rate and blood pressure, and then 200 mg of CR metoprolol orally daily for the next 30 days. Medication doses were omitted for hypotension or bradycardia, but there was no dose titration. The patients who received the CR metoprolol had a lower

**TABLE 98.1** Tools for Risk Assessment**The American College of Surgeons National Surgical Quality Improvement Program (ACS/NSQIP) Surgical Risk Calculator**Available at: <http://www.riskcalculator.facs.org/RiskCalculator/>

Input data: procedure, age group, sex. Functional status, emergency case, ASA class, steroid use for chronic condition, ascites within 30 days before surgery, systemic sepsis within 48 hours before surgery, ventilator dependent, disseminated cancer, diabetes, hypertension requiring medication, congestive heart failure in 30 days before surgery, dyspnea, current smoker within 1 year, history of severe COPD, dialysis, acute renal failure, body mass index.

Output data: risk for cardiac complications (MI or cardiac arrest). Also, risk for serious complication, any complication, pneumonia, surgical site infection, urinary tract infection, venous thromboembolism, renal failure, readmission, return to OR, death, discharge to nursing or rehabilitation facility, predicted length of hospital stay.

**NSQIP MICA Risk-Prediction Rule**Available at: <http://www.surgicalriskcalculator.com/miorcardiacarrest>

Input data: age, serum creatinine, ASA class, preoperative functional status, procedure site.

Output data: risk for perioperative myocardial infarction or cardiac arrest.

**Revised Cardiac Risk Index (RCRI)**

Risk factor:

1. High-risk type of surgery
2. Ischemic heart disease
3. History of congestive heart failure
4. History of cerebrovascular disease
5. Insulin therapy for diabetes
6. Preoperative serum creatinine >2.0 mg/dL

Intraperitoneal, intrathoracic, or suprainguinal vascular procedures

History of MI, positive stress test, current cardiac CP, nitrate usage, EKG with pathologic Q waves

History of CHF, pulmonary edema, or PND; rales or S3 on examination; chest x-ray with pulmonary edema

History of transient ischemic attack or stroke

An RCRI score of  $\geq 2$  corresponds to an elevated MACE risk as per the 2014 ACC/AHA guideline.

ASA, Acetylsalicylic acid; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CP, constrictive pericarditis; EKG, electrocardiogram, MI, myocardial infarction; OR, operating room; PND, paroxysmal nocturnal dyspnea.

From Cohen ME, Ko CY, Bilimoria KY, et al. Optimizing ACS NSQIP modeling for evaluation of surgical quality and risk: patient risk adjustment, procedure mix adjustment, shrinkage adjustment, and surgical focus. *J Am Coll Surg*. 2013;217(2):336–346; Gupta PK, Gupta H, Sundaram A, et al. Development and validation of a risk calculator for prediction of cardiac risk after surgery. *Circulation*. 2011;124(4):381–387; Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100(10):1043–1049.

rate of the primary outcome (a composite of cardiovascular death, nonfatal MI, and nonfatal cardiac arrest) than the placebo group (5.8% in the CR metoprolol group vs. 6.9% in the placebo group;  $P = .04$ ). However, the total mortality was higher in the CR metoprolol group (3.1%) than in the placebo group (2.3%;  $P = .03$ ). This higher mortality in the CR metoprolol group appears to have been driven by a higher rate of stroke in the CR metoprolol group (1%) than in the placebo group (0.5%;  $P = .005$ ).

Critics of the POISE trial point out that this trial involved administering high-dose beta-blockers to beta-blocker-naïve patients shortly before surgery and that this does not reflect typical clinical practice. Nonetheless, based largely on the POISE data, the 2014 ACC/AHA guidelines advised against starting beta-blockers on the day of surgery.

Two large retrospective studies (by Lindenauer et al. and London et al.) showed that the benefit of perioperative

beta-blockers appears to increase as the RCRI score increases. These studies showed that once the RCRI is above 2 to 3, the benefits of beta-blockers appeared to outweigh the risks. Nonetheless, 2014 ACC/AHA guidelines say only that “it may be reasonable” to start beta-blockers in patients with an RCRI score  $\geq 3$  (IIb recommendation), and, as noted earlier, beta-blockers should not be started for perioperative risk reduction on the day of surgery.

**Statins**

The most prominent prospective randomized controlled trials of statins for perioperative risk reduction, published in 2009 by Schouten et al. (with Don Poldermans as the senior author) showed a significant reduction in both perioperative myocardial ischemia and perioperative death from a cardiovascular cause in the statin arm compared with the placebo arm. However, this trial is now under a cloud because of the dismissal of

Dr. Poldermans as a result of alleged research impropriety, and so the 2014 ACC/AHA guidelines disregarded it in arriving at their recommendations. The benefits of statins in reducing perioperative cardiac events were demonstrated in a smaller clinical 2004 trial by Durazzo et al. and in a 2015 metaanalysis by Antoniou et al. Parallel to the recommendation for beta-blockers, the only class I recommendation for statins in the 2014 ACC/AHA guidelines is that patients who are already on statins should be continued on statins. In addition, as a class IIa recommendation, the 2014 ACC/AHA guidelines state that it is reasonable to put patients who are scheduled to undergo vascular surgery on statins perioperatively.

## Aspirin

Before the publication of the POISE-2 trial in 2014, the clinical data regarding the appropriate use of aspirin in the perioperative setting were quite limited. The POISE-2 trial randomized 10,010 patients who underwent noncardiac surgery to aspirin or placebo perioperatively. This randomization and administration of the acetylsalicylic acid (ASA) or placebo occurred approximately 2 to 4 hours before surgery. These patients, all of whom were at least moderate risk of perioperative cardiac events, were further stratified by whether or not they were taking aspirin at baseline. The aspirin dose was 200 mg orally daily before surgery and 100 mg orally after surgery. Among the patients who were not on aspirin at baseline, they took the aspirin or placebo for 30 days after surgery. Among the patients who were on aspirin at baseline, they took the aspirin or placebo for 7 days after surgery and then resumed their home aspirin regimen. Patients who had received a BMS less than 6 weeks before surgery and a DES less than 1 year before surgery were excluded from this trial.

The primary outcome was a composite of 30-day death or nonfatal MI. There was no significant difference in the rate of this primary outcome between the aspirin and placebo arms, with the primary outcome occurring in about 7% in each arm. In a subgroup analysis, continuation of aspirin perioperatively did not demonstrate a significant benefit in any of the subgroups presented, including patients undergoing vascular surgery and patients with high RCRI scores. Major bleeding was significantly more common in the aspirin arm, compared with the placebo arm. A notable practical finding from this study was that starting on postoperative day 8, there was no significant difference in the risk of major bleeding between the aspirin and placebo groups, suggesting a period after which aspirin can be safely started if the goal is to avoid postoperative bleeding.

Regarding the question of why aspirin did not confer a benefit in reducing 30-day death or nonfatal MI, the authors speculated that, although the antithrombotic effect of aspirin may have prevented some MIs, this beneficial effect may have been offset by the increased bleeding caused by aspirin, which could lead to acute anemia resulting in MIs. Overall, this study was unable to demonstrate a benefit

to perioperative aspirin in preventing 30-day death or nonfatal MI. Therefore when surgeons express a concern about the bleeding risk associated with continuing aspirin in the perioperative setting, consideration can be given to holding aspirin perioperatively and restarting the aspirin around postoperative day 8. Aspirin should not be held perioperatively among patients in the critical periods after coronary stent placement detailed previously.

A companion study as part of POISE-2 examined the perioperative effects of clonidine. Perioperative clonidine did not reduce the rate of 30-day death or nonfatal MI but did increase the risk of clinically important hypotension and bradycardia. There was also a significant increase in the risk of nonfatal cardiac arrest in the clonidine group. Therefore there is no role for the use of clonidine for perioperative cardiac risk reduction.

## Bridging Anticoagulation

In addition to perioperative aspirin, another important area of perioperative management that has recently (2015) been clarified by a large, well-designed trial is that of perioperative bridging anticoagulation for patients with atrial fibrillation. Douketis and the BRIDGE (Bridging Anticoagulation in Patients who Require Temporary Interruption of Warfarin Therapy for an Elective Invasive Procedure or Surgery) investigators enrolled 1884 patients who had atrial fibrillation for which they were taking warfarin and who were scheduled for elective surgery. All patients had to have a CHADS<sub>2</sub> score of at least 1. Patients were randomized to either bridging anticoagulation with the low-molecular-weight heparin (LMWH) dalteparin, at therapeutic doses, or to placebo. Those patients randomized to the bridging arm stopped their warfarin 5 days before surgery and were bridged with LMWH starting 3 days before surgery. In the bridging arm, the LMWH was held the day before surgery and then restarted 24 to 72 hours after surgery, depending on the surgical bleeding risk. Patients in the placebo arm had their warfarin held 5 days before surgery and received no LMWH. Warfarin was restarted within 24 hours after surgery in both arms. The primary outcomes were arterial thromboembolism and major bleeding within 30 days after surgery.

The rate of arterial thromboembolism was not significantly different between the two arms: 0.3% in the bridging arm and 0.4% in the placebo arm. The rate of major bleeding was significantly higher in the bridging arm, at 3.2%, compared with 1.3% in the placebo arm. Notable among the secondary outcomes was a trend ( $P = .10$ ) toward a higher rate of MI in the bridging arm, perhaps because of ischemia resulting from anemia caused by blood loss, given the higher rate of major bleeding in the bridging arm.

Therefore this trial was not able to demonstrate a benefit to bridging anticoagulation with LMWH in atrial fibrillation patients on warfarin. Although this is the definitive trial in this area, one major caveat exists. The mean

CHADS<sub>2</sub> score was 2.3, and only 38.3% of patients had a CHADS<sub>2</sub> score  $\geq 3$ . The question of whether patients with high CHADS<sub>2</sub> scores would benefit from bridging anticoagulation remains unresolved, and many clinicians would use bridging anticoagulation in patients with CHADS<sub>2</sub> scores of  $\geq 5$ . Furthermore, in the vast majority of cases, patients on direct oral anticoagulants (DOACs), such as dabigatran, for atrial fibrillation will not require bridging anticoagulation. Because the anticoagulant effect of these agents diminishes rapidly once they are discontinued, typically the DOACs are stopped approximately 2 days before a procedure without the use of bridging anticoagulation.

## Bacterial Endocarditis Prophylaxis

The applicable guidelines on antibiotic prophylaxis to prevent bacterial endocarditis peri-procedurally include a dedicated guideline published by the AHA in 2007 and the 2014 AHA/ACC guideline for the management of patients with valvular heart disease, which also addresses this issue. Both these sets of guidelines recommend providing antibiotic prophylaxis only to the highest-risk patients undergoing certain procedures. Patients considered at highest risk include those who have a prosthetic cardiac valve or prosthetic material used to repair a valve, previous infective endocarditis, certain types of congenital heart disease, or cardiac transplantation recipients with valvular abnormalities. The procedures for which these highest-risk patients should receive prophylaxis include high-risk dental procedures (i.e., those involving gingival manipulations, manipulation of deeper portion of the tooth above the gumline [periapical region], or a break of the oral mucosa), respiratory procedures involving any incision or biopsy, and procedures involving infected skin. It is no longer recommended that patients with mitral valve prolapse receive endocarditis prophylaxis. Moreover, endocarditis prophylaxis is no longer recommended for gastrointestinal or genitourinary procedures, in the absence of established infections at these sites. The recommended regimen for antibiotic prophylaxis for dental procedures is amoxicillin (or ampicillin in patients unable to take an oral medication). In penicillin-allergic patients, clindamycin, azithromycin, or clarithromycin are recommended.

## Glucocorticoids in Surgical Patients

Among patients taking exogenous glucocorticoids, who therefore may have adrenal suppression, the stress of surgery may lead to clinically significant adrenal insufficiency. This adrenal insufficiency may be manifested by hypotension and shock, although symptoms may be more nonspecific, such as abdominal pain. Laboratory abnormalities associated with adrenal insufficiency include hyponatremia and eosinophilia. Concern about the stress of surgery precipitating adrenal insufficiency has led to the use of perioperative glucocorticoid coverage, also referred to as stress-dose steroids. The incidence of perioperative adrenal insufficiency in surgical patients taking exogenous glucocorticoids is low, occurring  $<1\%$  of the time, with some estimates as low as 0.01%. However, given the potentially serious consequences of perioperative adrenal insufficiency, and the fact that it is preventable, internists providing perioperative consultation need to be attentive to this issue.

According to recommendations made by Axelrod, patients taking  $\leq 5$  mg of prednisone per day (or its equivalent), as long as the dosing was early in the day, are unlikely to have adrenal suppression and so generally do not need perioperative glucocorticoid coverage, although they should be continued on their usual dose of glucocorticoids. Patients taking  $\geq 20$  mg of prednisone (or its equivalent) are likely to have adrenal suppression and so should receive perioperative glucocorticoid coverage. Adrenal suppression from exogenous glucocorticoids may last as long as a year, so patients who previously have been on high-dose glucocorticoids should be considered for perioperative glucocorticoid coverage. Inhaled glucocorticoids and high-potency topical glucocorticoids may exert a systemic effect and cause adrenal suppression, and so patients taking these forms of steroids should also be considered for perioperative glucocorticoid coverage. Any patient who is taking exogenous glucocorticoids and who has a cushingoid appearance should be given perioperative glucocorticoid coverage.

The most widely cited regimen for perioperative glucocorticoid coverage is based on the recommendations of Salem et al. (Table 98.2).

In cases in which the likelihood of adrenal suppression is unclear (e.g., patients unsure of how much glucocorticoids they are taking), or if there is a desire to avoid perioperative glucocorticoid coverage because of concern about side effects,

**TABLE 98.2** Perioperative Glucocorticoid Coverage

Magnitude of Surgical Stress	Recommended Perioperative Glucocorticoid Coverage		
	Hydrocortisone	Methylprednisolone	Duration
Minor (e.g., inguinal herniorrhaphy)	25 mg/d	5 mg/d	1 d
Moderate (e.g., total joint replacement)	50–75 mg/d	10–15 mg/d	1–2 d
Major (e.g., involves cardiopulmonary bypass)	100–150 mg/d	20–30 mg/d	2–3 d

Steroid doses are total mg/d IV. Hydrocortisone is generally divided every 8 hours, and methylprednisolone every 4 to 6 hours.

From Salem M, Tainsh RE Jr., Bromberg J, et al. Perioperative glucocorticoid coverage. A reassessment 42 years after emergence of a problem. *Ann Surg.* 1994;219(4):416–425; Axelrod L. Perioperative management of patients treated with glucocorticoids. *Endocrinol Metab Clin North Am.* 2003;32(2):367–383.

**TABLE 98.3** Pulmonary Risk Factors

Patient-Related	Procedure-Related	Laboratory Test
Advanced age (>60 years)	Aortic aneurysm repair	Albumin level <3.5 g/dL
ASA class $\geq$ II	Thoracic surgery	
CHF	Abdominal surgery	
Functional dependence (total or partial)	Upper abdominal surgery	
COPD	Neurosurgery	
	Prolonged surgery	
	Head and neck surgery	
	Emergency surgery	
	Vascular surgery	
	General anesthesia	

ASA, Acetylsalicylic acid; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease.

From Smetana GW, Lawrence VA, Cornell JE. Preoperative pulmonary risk stratification for noncardiothoracic surgery: systematic review for the American College of Physicians. *Ann Intern Med.* 2006;144(8):581–595.

an adrenocorticotropin hormone (ACTH) stimulation test may be performed. Patients are given synthetic ACTH (cosyntropin), 0.25 mg intravenously (IV) or intramuscularly, and then a plasma cortisol level is measured at 30 minutes and 60 minutes after administration. A plasma cortisol level >18  $\mu$ g/dL at either time point suggests the patient does not have significant adrenal suppression, and so extra perioperative glucocorticoid coverage is not necessary. Plasma cortisol values <18  $\mu$ g/dL after an ACTH stimulation test mean the patient may have adrenal suppression, and so she or he should receive perioperative glucocorticoid coverage.

## Pulmonary Risk Factors and Risk Reduction

Although less studied in the literature than perioperative cardiac complications, perioperative pulmonary complications can be a significant cause of morbidity. In one series, postoperative pulmonary complications developed in 3.4% of patients undergoing noncardiac surgery at Veterans Affairs hospitals. Postoperative pulmonary complications that contribute to this morbidity include pneumonia, respiratory failure requiring mechanical ventilation, bronchospasm, and atelectasis. A clinical guideline by Smetana et al. evaluated the literature on pulmonary risk factors for noncardiothoracic

surgery and identified a number of risk factors for which there was good evidence. These risk factors fall into the three categories: patient-related risk factors, procedure-related risk factors, and laboratory tests (Table 98.3). In one risk-prediction model, the most important risk factor was the type of surgery, with those surgeries closest to the diaphragm generally conferring the highest pulmonary risk.

The strategies to reduce perioperative pulmonary complications having the most evidence behind them are those aimed at lung expansion, including incentive spirometry and deep breathing exercises. Other interventions that may be useful include use of spinal instead of general anesthesia, use of laparoscopic instead of open procedures, and avoiding long-acting neuromuscular blocking agents during surgery. Using nasogastric tubes only when clearly needed may also be useful in decreasing perioperative pulmonary complications. The data on the effect of preoperative smoking cessation are mixed. One study found that reducing smoking 6 to 8 weeks before surgery decreased postoperative morbidity, although an effect on pulmonary complications could not be demonstrated. However, other studies have found that quitting or reducing smoking right before surgery might not be beneficial and may even be detrimental. Although this issue remains unsettled, it is preferred that preoperative smoking cessation should occur at least 2 months before surgery.

## Chapter Review

### Questions

- You are asked by the surgery service to perform preoperative evaluations. Which one of the following patients has the strongest indication for a preoperative cardiac stress test, based on the 2014 ACC/AHA preoperative evaluation guidelines?
  - A 74-year-old female who has a history of a prior stroke, atrial fibrillation, and diabetes mellitus for which the patient takes metformin. Independent at baseline, she is being admitted for a partial colectomy to treat localized colon cancer. Her

electrocardiogram (EKG) shows atrial fibrillation at a rate of 88 beats per minute with no ischemic changes.

- A 67-year-old female with a history of baseline serum creatinine of 1.7 mg/dL, diabetes mellitus for which the patient takes insulin glargine and prandial regular insulin, and osteoarthritis. She can do her own shopping. She is admitted for a right knee arthroplasty. Her EKG shows normal sinus rhythm at a rate of 78 bpm, with an isolated Q wave in lead III.

- C. An 85-year-old male with a history of polymyalgia rheumatica for which he is on prednisone 15 mg daily, osteoarthritis, diabetes mellitus type 2 on insulin, and hypertension on hydrochlorothiazide, who quit smoking 6 months ago and is admitted for knee arthroplasty. The patient is wheelchair-bound.
- D. A 72-year-old female with a history of hypertension on amlodipine, diabetes mellitus on metformin, and a distant history of atrial fibrillation for which she is not on anticoagulation, who presents for aortofemoral-popliteal bypass surgery. She needs some assistance with her daily activities.
- E. An 82-year-old male with a history of chronic obstructive pulmonary disease (COPD) on home oxygen and hypertension on amlodipine, who quit smoking 5 years ago and has fallen and requires surgical repair of his hip fracture. The patient requires some assistance to get around but can walk to the bathroom with his walker.
2. You are seeing patients for preoperative evaluation at the request of the surgery service. Which one of the following patients should be on a beta-blocker perioperatively?
- A. An 89-year-old male with a history of MI, diabetes mellitus type II, hypertension, and atrial fibrillation on warfarin, whose other medications include glyburide, amlodipine, and hydrochlorothiazide. He is scheduled for knee arthroplasty.
- B. A 65-year-old male with a history of diabetes mellitus type I on both basal glargine insulin and prandial aspart, hypertension, and peripheral vascular disease, who is scheduled for aortofemoral-popliteal bypass surgery. In addition to the insulin, the patient is on atorvastatin, candesartan, and hydrochlorothiazide.
- C. An 89-year-old female with a history of atrial fibrillation, stroke, diabetes mellitus type II, and hypertension, whose medications include metformin, aspirin, and diltiazem. She is scheduled for a hip arthroplasty.
- D. A 64-year-old male with a history of MI, diabetes mellitus type II, and atrial fibrillation, whose medications include apixaban, metoprolol, and metformin, who is scheduled for aortofemoral-popliteal bypass surgery.
- E. A 77-year-old female with hypertension, MI, diabetes mellitus type II, with chronic kidney disease and a baseline serum creatinine of 1.9 mg/dL, who is scheduled for resection of a localized rectal cancer. Her medications include aspirin, metformin, and losartan.
3. A 68-year-old male with a history of hypertension, diabetes mellitus on insulin glargine, and stroke, 5 months ago presented with chest pain after minimal exertion. At that time, he underwent a cardiac catheterization with placement of a DES in the left circumflex coronary artery. Since then, he has been free from chest pain. He is now admitted with a left femur fracture after a mechanical fall, for which he is scheduled to undergo a left hip arthroplasty. His medications include aspirin, clopidogrel, atenolol, and lisinopril. You are consulted for preoperative evaluation. You advise that the patient's beta-blocker should be continued. What is the most appropriate additional recommendation to offer at this time?
- A. The patient's aspirin should be continued, but it is appropriate to stop the clopidogrel to decrease the perioperative bleeding risk.
- B. The patient should undergo a preoperative pharmacologic myocardial perfusion imaging test.
- C. It is appropriate to stop both the aspirin and the clopidogrel to decrease the perioperative bleeding risk.
- D. The patient should not undergo the surgery without first getting a preoperative resting echocardiogram.
- E. The patient should be continued on both the aspirin and clopidogrel perioperatively if at all possible.
4. A 64-year-old female with a history of COPD, hypertension, MI 3 years ago, and osteoarthritis is seeing you for a preoperative evaluation 5 days before a scheduled left hip arthroplasty because of severe osteoarthritis and pain in her left hip that limits her mobility. She is an active smoker, consuming one pack per day of cigarettes. Current medications include tiotropium inhaled daily, albuterol/ipratropium inhaler as needed for wheezing, atenolol, and simvastatin. She has never had pulmonary function testing. The patient reports that she does not have dyspnea with her limited mobility, and she has not had any exacerbations of her COPD requiring medical attention in the last year. What perioperative recommendation is most appropriate regarding her pulmonary status?
- A. She should not undergo elective surgery until she has pulmonary function tests to establish the severity of her COPD.
- B. She should stop smoking immediately.
- C. She should stop her atenolol to prevent beta-blocker-induced bronchospasm.
- D. She should start prednisone to help control her COPD perioperatively.
- E. She should continue on the tiotropium and be given nebulized albuterol/ipratropium for any evidence of wheezing.
5. A 47-year-old female with a history of systemic lupus erythematosus, for which she has been on prednisone 10 mg orally daily for the last year, also with history of a lower gastrointestinal bleed and hypertension, has had chronic left hip pain and has been diagnosed with osteonecrosis of the femoral head. Conservative therapy has been ineffective, and she is now scheduled for a left

total hip arthroplasty. Which of the following perioperative recommendations regarding glucocorticoids in this patient is most appropriate?

- A. She does not need any glucocorticoids perioperatively.
- B. She should continue her home dose of glucocorticoids perioperatively.
- C. She should receive 50 mg of hydrocortisone IV every 8 hours the day before, the day of, and then the day after surgery, after which she should continue her home dose of glucocorticoids.
- D. She should only receive glucocorticoids if hypotension or other evidence of acute adrenal insufficiency develops.

- E. She should undergo an ACTH stimulation test, and only if it indicates adrenal suppression should the patient receive perioperative glucocorticoid coverage beyond her usual glucocorticoid dose.

### Answers

- 1. C
- 2. D
- 3. E
- 4. E
- 5. E

## Basic Principles of Epidemiology and Biostatistics

JULIE E. BURING AND I-MIN LEE

In reviewing past questions from the Boards, the important epidemiologic and biostatistics principles that are most frequently addressed include screening for disease control (including sensitivity, specificity, and predictive value of a screening test and bias in the interpretation of the results); measurement of data (including measures of disease frequency [incidence, prevalence] and measures of association [relative risk {RR}, attributable risk {AR}, number needed to treat]); and the interpretation of data (including types of epidemiologic studies and the roles of chance, bias, and confounding in the interpretation of the findings). In this chapter, we review these topics in the context of specific clinical questions. The principles summarized are drawn extensively from the textbook *Epidemiology in Medicine*, and this book should be consulted for further examples. There are many other introductory-level epidemiology and statistic sources that can also be used, and these are listed at the end of this chapter.

### Screening for Disease Control

#### Question 1:

One hundred women age >50 years received mammograms at a mobile breast cancer screening unit. Twenty-seven women had findings suspicious for malignancy on the mammogram; 19 of these women were confirmed as having breast cancer by biopsy. One woman had a negative mammogram but in the subsequent year developed breast cancer and is assumed to have had the disease at the time of screening. What is the sensitivity of the mammogram? The specificity? And the predictive value of a positive screening test?

#### Validity and Yield of a Screening Test

Screening refers to the application of a simple, inexpensive test to asymptomatic individuals to classify them as likely or unlikely to have a particular disease. A disease is appropriate for screening if (1) it is serious; (2) its preclinical prevalence is high among the population screened; and (3) treatment given while the disease is asymptomatic is more

beneficial than treatment given after symptoms develop. In addition, a valid screening test must be available. The validity of a screening test is defined by its ability to correctly classify those who have preclinical disease as screening-test positive (measured by the sensitivity of a screening test) and those who do not have preclinical disease as screening-test negative (measured by the specificity of the screening test). Finally, the yield, or the number of cases detected by the screening program, is considered using the positive predictive value or the probability that a person actually has the disease if he or she tests positive on the screening test.

Fig. 99.1 presents the data from Question 1 in the form of a  $2 \times 2$  table, summarizing the relationship between the results of the screening test (mammography) and the “true” presence of the disease as assessed by the results of the appropriate subsequent diagnostic test (breast biopsy). Sensitivity can then be calculated as the probability of screening positive

		Breast Cancer		
		Yes	No	
Mammogram	Positive	19	8	27
	Negative	1	72	73
		20	80	100

$$\text{Sensitivity} = \frac{\text{Test positive}}{\text{Disease positive}} = \frac{19}{20} = 95\%$$

$$\text{Specificity} = \frac{\text{Test negative}}{\text{Disease negative}} = \frac{72}{80} = 90\%$$

$$\text{Predictive value of a positive test} = \frac{\text{Disease positive}}{\text{Test positive}} = \frac{19}{27} = 70\%$$

• **Fig. 99.1** Characteristics of a screening test: sensitivity, specificity, and predictive value.

if the disease is truly present and specificity as the probability of screening negative if the disease is truly absent. In this example, the sensitivity of the mammography is 19/20 or 95%, meaning that of those who were found to have breast cancer at biopsy, 95% of them tested positive on the mammogram, and the specificity, 72/80 or 90%, meaning that of those who were negative for breast cancer on biopsy, 90% tested negative on the screening mammogram. Finally, of those who tested positive on the mammogram, their predictive value of a positive test, or their probability of being diagnosed with breast cancer on biopsy, was 19/27 or 70%.

### What Influences the Sensitivity, Specificity, and Predictive Value?

The sensitivity and specificity of a given screening test are in part dependent on where we are in our biological capabilities of identifying preclinical stages for a given disease and our technologic abilities to develop a good screening test, but they can also be affected by what is called the criterion of positivity—that is, the cutoff value that is used to define an “abnormal” screening test. Lowering this criterion or making it less stringent (i.e., setting the criterion of positivity for a screening for hypertension, for example, as a single systolic blood pressure of 120 mm Hg) will increase the sensitivity of the screening test and decrease the false negatives because everyone with hypertension will be picked up by the screen. But it will also lower the specificity of the test and increase the false positives in that many normotensive people will screen positive using this criterion. Similarly, raising the criterion or making it more stringent (i.e., setting the criterion for positivity to 160 mm Hg) will mean that a higher proportion of those with hypertension will test negative on the screening test (decreased sensitivity and increased false negatives), but more individuals who are truly normotensive will screen negative (increased specificity and decreased false positives). The predictive value of a positive test is only slightly affected by changes in the sensitivity and specificity of the test, but it can be increased primarily by effecting an increase in the underlying prevalence of the preclinical disease in the screened population by, for example, targeting the screening program to a group at higher risk of developing the disease by nature of their risk factor profile (such as in the earlier case, screening older women or those with a positive family history of breast cancer or a personal history of benign breast disease).

### Bias in the Interpretation of Screening Results

In evaluating the effectiveness of a screening program (i.e., whether or not the screening program is effective in reducing morbidity or mortality from the disease) the screened and unscreened populations need to be comparable with respect to all other factors affecting the course of the disease besides the screening program itself. One source of bias of particular importance in the interpretation of the results of a screening program is “lead-time bias” related

to the amount of time by which the diagnosis of the disease has been advanced as a direct result of the screening program. Because screening is applied to asymptomatic individuals, every case picked up by screen is diagnosed earlier than if the diagnosis had been based on waiting for clinical symptoms to develop. If that estimate of lead time is not considered when comparing mortality outcomes between screened and unscreened groups, survival from diagnosis may appear to be longer for the screened group only because the diagnosis was made earlier in the course of disease. Lead-time bias can be addressed by comparing the age-specific death rates in the screened and nonscreened groups rather than by comparing the length of survival from diagnosis to death.

## Measurement of Data: Measures of Disease Frequency and Measures of Association

### Question 2:

For each subsequent statement, choose the measure of disease frequency that best describes each disease frequency:

- Prevalence
- Incidence
- Standardized morbidity ratio
- Age-specific measure
- Age-adjusted measure

1. At the initial study examination, 17 persons per 1000 had evidence of coronary heart disease.
2. At the initial study examination, 31 persons age 45 to 62 years had evidence of coronary heart disease per 1000 persons examined in this age group.
3. At the initial study examination, men and women had the same prevalence of coronary heart disease, after controlling for differences in age between the groups.
4. During the first 8 years of the study, 45 persons developed coronary heart disease per 1000 persons who entered the study free of disease.
5. During the first 8 years of the study, the observed frequency of angina pectoris in heavy smokers was 1.6 times as great as the expected frequency based on nonsmokers.

### Measures of Disease Frequency

It is necessary for any epidemiologic investigation to be able to quantify the occurrence of disease by measuring the number of affected individuals given the size of the source population and the period during which the data were collected, allowing the direct comparison of disease frequencies in two or more groups of individuals. The measures of disease frequency most frequently used are incidence and prevalence. As shown in [Box 99.1](#), prevalence represents a snapshot of the status of the population at a point in time and is calculated as the number of existing cases of a disease divided by the size of the total population at that specified time. Incidence, on the other hand, represents the development of disease and is calculated as the number of new cases of a disease that developed during a specified period of

### • BOX 99.1 Measures of Disease Frequency in Epidemiologic Studies

$$\text{Prevalence} = \frac{\text{Number of existing cases at a point in time}}{\text{Total population}}$$

$$\text{Incidence} = \frac{\text{Number of new cases during a period of time}}{\text{Population at risk}}$$

$$\text{Standardized morbidity ratio} = \frac{\text{Observed number of cases}}{\text{Expected number of cases}}$$

Measures of disease frequency can be category-specific (i.e., age-specific) or category-adjusted (i.e., age-adjusted).

time divided by the population at risk of being a new case of the disease. The measures of disease frequency can be calculated for the population as a whole or can be specific to a particular category or subgroup of the population such as an age-specific or gender-specific frequency. When two or more populations are being compared, these measures can also be adjusted for baseline differences between the populations, such as an age-adjusted or gender-adjusted frequency, or the observed cases in a population can be compared with the number of cases that would be expected based on previous experience or another population (standardized morbidity ratio).

Thus the correct answers for Question 2 would be:

1. At the initial study examination, 17 persons per 1000 had evidence of coronary heart disease: Prevalence.
2. At the initial study examination, 31 persons age 45 to 62 years had coronary heart disease per 1000 persons examined in this age group: Age-specific prevalence.
3. At the initial study examination, men and women in the study had the same prevalence of coronary heart disease, controlling for differences between the groups with respect to age: Age-adjusted prevalence.
4. During the first 8 years of the study, 45 persons developed coronary heart disease per 1000 persons who entered the study free of disease: Incidence.
5. During the first 8 years of the study, the observed frequency of angina pectoris in heavy smokers was 1.6 times as great as the expected frequency based on nonsmokers: Standardized morbidity ratio.

### Calculation of Measures of Disease Frequency

#### Question 3:

At the beginning of 2012, 800 people diagnosed with diabetes lived in a city that had a midyear population estimated at 10,000. During that year, 200 new cases of diabetes were diagnosed in the city, and 40 people died of complications of diabetes.

1. What was the incidence per 1000 of diabetes during 2012?
2. What was the prevalence per 1000 of diabetes on January 1, 2012?

3. What was the prevalence per 1000 of diabetes on December 31, 2012?
4. What was the mortality per 1000 from diabetes during 2012?
5. If the prevalence of diabetes in 2012 was less than the prevalence of diabetes in 2010, could this be because of a change in the incidence rate, a change in the duration of the disease, or both?

The definitions given in Box 99.1 provide the information needed to calculate each of the individual measures of incidence and prevalence. Often the population is provided as a midyear estimate, and in that case the “population at risk” is the same as the total population. With regard to their interrelationship, prevalence (the proportion of the population that has a disease at a point in time) depends on both the rate of development of new disease during the period of time (incidence) as well as the duration of the disease from onset to termination (such as cure or death). Thus a change in prevalence from one population to another or one time period to another can reflect a change in incidence, a change in the duration of the disease, or both.

Thus the answers to Question 3 would be:

1. Incidence of diabetes during 2012 =  $200/10,000 = 20/1000$
2. Prevalence of diabetes on January 1, 2012 =  $800/10,000 = 80/1000$
3. Prevalence of diabetes on December 31, 2012 =  $(800 + 200 - 40)/10,000 = 96/1000$
4. Mortality from diabetes in the population during 2012 =  $40/10,000 = 4/1000$
5. If the prevalence of diabetes in 2012 were less than the prevalence of diabetes in 2010, this could be because of a change in the incidence rate, a change in the duration of the disease, or changes in both

### Measures of Association

Whereas the calculation of appropriate measures of disease frequency is the basis for the description and the comparison of populations, it is also efficient and informative to combine the two frequencies being compared into a single summary parameter that estimates the association between the exposure and the risk of developing the outcome. This can be accomplished by calculating either the ratio of the measures of disease frequency for the two populations, which indicates how much more likely on a relative scale one group is to develop a disease than another, or the difference between the two measures of disease frequency, which indicates on an absolute scale how much greater the frequency of disease is in one group compared with the other. These two measures of association are referred to broadly as RR and AR.

The RR estimates the magnitude of the association between the exposure and disease and represents the likelihood of developing the outcome in the exposed group relative to those who are not exposed. In a cohort study or randomized trial, this is defined as the ratio of the incidence in the exposed group ( $I_e$ ) divided by the corresponding incidence of disease in the nonexposed ( $I_o$ ) group; the RR

is a measure of the strength of the association between the exposure and the disease. If there is no association between the exposure and disease, that is, under the null hypothesis, the RR will equal 1. Values  $>1$  indicate that those who are exposed have an increased risk of developing the outcome and values  $<1$ , a decreased risk.

The AR among the exposed provides information about the absolute effect of the exposure or the excess risk of disease in those exposed compared with those nonexposed. Again, in a cohort study or randomized trial, this measure is defined as the difference between the incidence rates in the exposed and nonexposed groups, calculated as  $I_e - I_o$ . If there is no association between the exposure and the disease, that is, under the null hypothesis, the AR will equal 0. Assuming there is a causal relationship between the exposure and the disease and that the AR is  $>0$ , its value indicates the number of cases of the disease among the exposed that can be attributed to the exposure itself or, alternatively, the number of cases of the disease among the exposed that could be eliminated if the exposure were eliminated. As such, the AR among the exposed is useful as a measure of the public health impact of a particular exposure.

The AR among the exposed can also be expressed as a percentage, calculated as  $AR\% = AR/I_e \times 100$ , to estimate the proportion of the disease among the exposed that is attributable to the exposure or the proportion of the disease in that group that could be prevented by eliminating the exposure. In addition, for clinical purposes, the number needed to treat (NNT) to prevent one case of the outcome can be calculated, as the inverse of the absolute value of the AR among the exposed, or  $NNT = 1/AR$ .

The RR and AR provide very different but complementary types of information. The RR is a measure of the strength of the association between an exposure and disease and provides information that can be used to judge whether a valid observed association is likely to be causal. In contrast, the AR provides a measure of the public health impact of an exposure, assuming that the association is one of cause and effect.

### Calculation of Measures of Association

#### Question 4:

A randomized trial was conducted of a new statin drug to assess its potential benefit on death from coronary heart disease. A total of 4000 patients were entered into the study, 2000 allocated to the active statin and 2000 to placebo. Of the 2000 assigned to the statin, 200 of these died from coronary heart disease in the 5-year median duration of follow-up; of the 2000 assigned to placebo, 300 died from coronary heart disease. What is the magnitude of the association between the statin and death from coronary heart disease? What is the potential public health impact of this drug? What is the number needed to treat to prevent one coronary heart disease death?

Fig. 99.2 presents the  $2 \times 2$  table summarizing the randomized trial data from Question 4. The RR, calculated as the incidence of the outcome (dying from coronary heart disease) in the exposed (those assigned to statin) divided by the incidence in the nonexposed (those assigned to placebo),

		Death From Coronary Heart Disease		
		Yes	No	
Statin	200	1800	2000	
Placebo	300	1700	2000	
	500	3500	4000	

$$\text{Relative risk (RR)} = \frac{\text{Incidence (exposed)}}{\text{Incidence (nonexposed)}} = \frac{200/2000}{300/2000} = 0.67$$

$$\text{Attributable risk (AR)} = \text{Incidence (exposed)} - \text{Incidence (nonexposed)}$$

$$= \frac{200}{2000} - \frac{300}{2000} = -0.05$$

$$\text{Number needed to treat} = \frac{1}{AR} = \frac{1}{0.05} = 20$$

• **Fig. 99.2** Measures of association in a cohort study or randomized trial: relative risk, attributable risk, and number needed to treat.

is  $200/2000$  divided by  $300/2000$  or 0.67. This means that those assigned to the statin had 67% of the risk, or 33% less risk ( $1 - 0.67$ ), of dying from coronary heart disease during this period than those assigned to placebo. The AR, calculated as the incidence in the exposed minus the incidence in the nonexposed, is  $200/2000 - 300/2000$  or  $-0.05$ . This means that if statins are causally related to the prevention of coronary heart disease mortality, 5 per 100 of the coronary heart disease deaths in the placebo group could have been prevented by use of this statin. Taking the inverse of this AR,  $1/0.05$ , provides the number needed to treat, or 20, indicating that we would need to treat 20 patients with this statin over 5 years (the median duration of follow-up) to prevent 1 death from coronary heart disease.

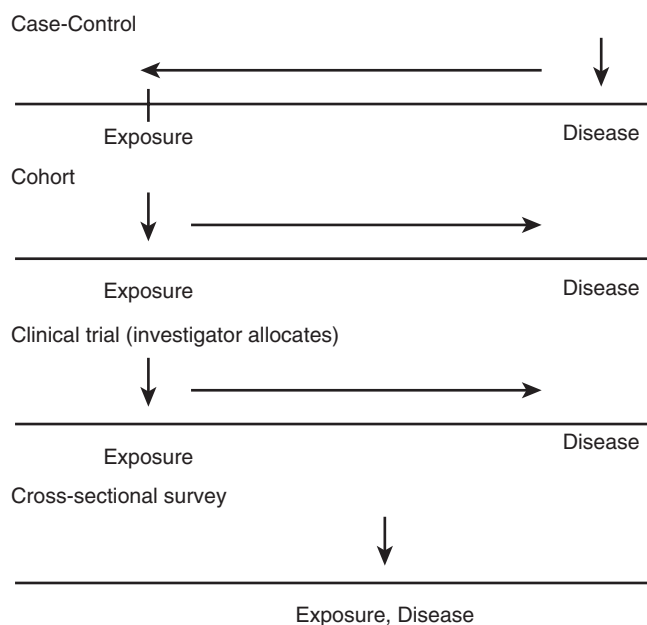

## Overview of Epidemiological Study Designs and the Interpretation of Study Results

### Question 5:

A study was undertaken to evaluate the relationship between maternal smoking during pregnancy and low birth weight. A total of 350 mothers of low-birth-weight babies and 400 mothers of normal-birth-weight babies were interviewed. Of the mothers of low-birth-weight babies, 200 reported smoking during the pregnancy, and 200 of the mothers of normal-birth-weight babies also reported such a history. What kind of study design was this? What is the observed magnitude of the association between smoking and birth weight? Is the observed association a valid one?

### What Kind of Study Design Was This?

There are a number of specific analytic study designs that can be used to evaluate an association between an exposure and disease, the choice depending on the particular

• **Fig. 99.3** Overview of epidemiologic study designs.

research question as well as logistics and feasibility. The first broad classification is whether the investigation is an observational or an intervention study, and this depends on the role of the investigator in the study. In observational studies (either case-control or cohort), as the name suggests, the investigator observes the natural course of events in terms of who is exposed or not and who develops the study outcome, without intervening in any way. In an intervention study the investigators themselves allocate the exposure; there is no self-selection of the exposure on the part of the participants.

There are two basic types of observational studies: case-control and cohort. As shown in Fig. 99.3, in a case-control study, participants are selected into the study based on their outcome status: a group of those with the disease (cases) are compared with those without the disease (controls) with respect to the proportions in each group with the exposure of interest. In contrast, in a cohort study, participants are selected into the study based on the presence or absence of the exposure of interest and followed for the development of the outcome in each exposure group. An intervention study, also called a clinical trial, is a type of cohort study in that participants are identified by their exposure status and followed for the development of the outcome, but the distinguishing feature of the trial is that the exposure of each participant is allocated by the investigator. In a cross-sectional survey, the presence or absence of both exposure and disease is assessed at the same point in time, making it often difficult to distinguish whether the exposure preceded the development of the disease or whether the presence of the preclinical or early stages of the disease affected the individual's exposure level. In an observational or intervention study, the time sequence is more clearly identifiable.

Based on these definitions, Question 5 is describing a case-control study: mothers of babies who are low weight

		Birth Weight	
		Low	Normal
Smoking	Yes	200 a	200 b
	No	150 c	200 d
		350	400

$$\text{Odds ratio (OR)} = \frac{ad}{bc} = \frac{200(200)}{200(150)} = 1.3$$

$$\text{Attributable risk \% (AR\%)} = \frac{\text{OR}-1}{\text{OR}} = \frac{1.3-1}{1.3} = 23.1\%$$

• **Fig. 99.4** Measures of association in a case-control study: odds ratio and attributable risk percentage.

at birth (cases) are being compared with mothers of babies who are normal weight at birth (controls) with respect to the exposure of interest (maternal smoking during pregnancy). If the association between low birth weight and maternal smoking during pregnancy had been studied by classifying women as smokers or nonsmokers at the time of their first prenatal visit and correlating the smoking histories with subsequent birth weight, this would have been a cohort study design. An interventional study assigning individuals to a harmful exposure such as smoking cannot be ethically conducted, but a trial could have been designed assigning participants to two different approaches to the cessation of smoking during the pregnancy, for example, and then comparing subsequent birth weights. In a cross-sectional study, the investigators would have assessed the birth weights of newborns and assessed the smoking patterns of the mothers at the same point in time—that is, at the time of the birth. There would be no way, however, to assess whether the smoking pattern at the time of the birth was reflective of the pattern of smoking at earlier times in the pregnancy, which could be of more etiologic interest.

### What Is the Magnitude of the Association Between the Exposure and the Outcome?

Fig. 99.4 presents the  $2 \times 2$  table summarizing the data from Question 5. In a case-control study, participants are selected based on the outcome under study. Thus it is not possible to calculate directly the rate of development of the outcome given the presence or absence of the exposure, and the formulae presented earlier in Fig. 99.2 for the calculation of the RR and AR in a cohort study or randomized trial cannot be used in a case-control study. An estimate of the RR, however, can be made by calculation of the odds ratio (OR), which is the ratio of the odds of exposure among the cases to that of the controls ( $\text{OR} = ad/bc$ ). In this case, the OR would be 1.3, which is interpreted as an RR and indicates that mothers who smoked during pregnancy had a 30%

increased risk of low-birth-weight babies compared with mothers who did not smoke during pregnancy. In addition, because the incidence rates cannot be directly calculated, the AR among the exposed can also not be calculated in a case-control study. However, an estimate can be made of the AR% among the exposed, calculated as:  $AR\% = (OR - 1)/OR$ . In the example, this would be  $AR\% = (1.3 - 1)/1.3$  or 23.1%, indicating that if smoking causes low birth weight, 23% of low-birth-weight babies among smoking mothers (the exposed) would be caused by the fact that mothers smoked, or 23% of low-birth-weight babies born to smoking mothers could be avoided if the mothers' smoking were eliminated.

### Is this Observed Association Valid?

To determine if an association observed in a study is valid, we need to rule out three alternative explanations for the findings: the role of chance, the role of bias, and the role of confounding (Box 99.2). Chance refers to that fact that any observed association can be caused by sampling variability or the luck of the draw because inferences about the entire population are being drawn from the results of a sample. This is measured by a test of statistical significance and its resultant *P* value. A result can also be judged to be arising from bias or a systematic error in the measurement of the association between the exposure and the disease. And finally, the results can be caused by confounding, baseline differences between the groups that are associated with the exposure and are independently associated with the disease and in themselves could be responsible totally or in part for the association seen. These three explanations must always be examined before one can conclude that the association seen in a study represents a valid or true relationship between the exposure and the disease.

#### Question 5a:

In comparing the difference in percentage of maternal smoking between mothers with and without a low-birth-weight baby, the *P* value is found to be 0.2. The correct interpretation of the result is:

1. The null hypothesis is rejected.
2. The difference is statistically significant.
3. The difference occurred by chance.
4. The difference is compatible with the null hypothesis.
5. Sampling variability is an unlikely explanation of the difference.

The *P* value is the probability that the observed data, or data more extreme, would occur because of the effects of chance alone, given that there is truly no difference or association between the two groups (the null hypothesis). By convention in the medical literature, the cutoff for statistical significance is at the  $P = .05$  level. Thus if  $P < .05$  (i.e., we would see the results we observed in our study by chance alone, given the null hypothesis that there is truly no association between the exposure and the disease, <1 out of 20 times) we reject the null hypothesis and conclude that the observed difference is statistically significant at the 0.05 level. Conversely, if  $P \geq .05$  (i.e., we would see the observed results at least 1 time out of

#### • BOX 99.2 Assessing the Validity of an Epidemiologic Study

- Is the association arising from the play of chance? Assess through tests of statistical significance and the resultant *P* value.
- Is the association caused by the role of bias? Evaluate the potential for systematic error in the way the data were obtained or reported.
- Is the association caused by the effects of confounding? Assess and control for effects of baseline differences between the groups that are also independently associated with the outcome under study and that could be responsible totally or in part for the observed association.

20 given that there is no association between the exposure and the disease) we cannot reject the null hypothesis, and we conclude the difference is not statistically significant at the 0.05 level. The level of the *P* value does not mean that the observed association is caused by chance or that chance is ruled out; it is only a measure of the likelihood that chance is an explanation of the findings.

Therefore in Question 5a, because the *P* value is  $\geq 0.05$ , the null hypothesis cannot be rejected, the difference is not statistically significant at the 0.05 level, and sampling variation is not an unlikely explanation of the data. It does not mean that the observed difference was caused by chance, but it does mean that the difference is compatible with the null hypothesis of no association (Answer 4).

#### Question 5b:

It was suggested that mothers of low-birth-weight babies who smoked would tend to deny such an activity because of feelings of guilt. Moreover, it was also observed that mothers of low-birth-weight babies tended to be younger than the mothers of the normal-birth-weight children, and smoking rates are known to be higher in younger women in this population. These scenarios would be examples of the effects of:

1. Chance
2. Selection bias
3. Recall bias
4. Confounding

What effect would each of these scenarios have on the observed RR: result in an underestimate of the true RR, an overestimate, or be the same as the true RR?

The concern that a mother of a low-birth-weight baby might deny her smoking history is an example of recall bias, where those who are affected tend to remember their experiences differently from those who are not similarly affected. In this case, the denying by mothers of low-birth-weight children of their smoking exposures during pregnancy would result in an underestimate of the true harmful association of smoking and birth weight. The fact that younger mothers are more likely to smoke and that, independently of smoking, younger mothers are more likely to have low-birth-weight babies is an example of a confounding variable. If the confounding effect of age of the mother is not controlled, it could appear that smoking is more harmful to the birth weight of the baby than it may actually be (an overestimate of the true effect) because of the mixture of the effects of smoking with the young age of the mother, which in itself will result in a higher rate of low-birth-weight babies.

In epidemiologic research, the interpretation of studies must always remain a matter of judgment based on all available evidence. However, this framework of alternative explanations that must be considered (evaluating the roles

of chance, bias, and confounding) allows us an approach to judging the validity of a study and thus allows us to begin to consider the next step, which is whether the association observed is in fact one of cause and effect.

## Contraception

KARI P. BRAATEN

The general internist needs to be up to date in contraception management. Each year nearly half of all pregnancies in the United States are unintended. Appropriate and consistent use of effective contraception can decrease the risk of unintended pregnancy. This chapter focuses on reversible contraceptive methods with an emphasis on efficacy and includes information on long-acting reversible contraceptive (LARC) methods (intrauterine devices [IUD] and implants), short-acting hormonal methods, barrier methods, and emergency contraception.

### Efficacy of Contraceptive Methods

The best method of contraception is one that the patient can use effectively, is medically appropriate, and is suited to the patient's preferences. Effectiveness is measured by failure rates (pregnancies) in the first year of use in two ways: (1) failure rate with perfect use (the percentage of women who become pregnant when they use the method perfectly) and (2) failure rate with typical use (the percentage of all women using the method who become pregnant, including those who use the method perfectly and those who do not). The typical use failure rate is the relevant rate to use when educating new-start patients because it represents real-life probabilities of pregnancy (Table 100.1). Long-acting methods offer significant advantages in terms of contraceptive efficacy because they are methods that do not require any regular action on the part of the patient and therefore have essentially no difference between perfect use and typical use.

### Long-Acting Reversible Contraception

LARC includes IUDs and implants. Currently available LARC methods in the United States include five IUDs, four of which contain the progesterone levonorgestrel (Mirena, Liletta, Kyleena, and Skyla), one copper IUD (Paragard), and the progestin-releasing etonogestrel implant (Nexplanon). LARC methods are considered first-line contraceptives for reproductive age women who wish to avoid pregnancy because they are safe, highly effective, have relatively few contraindications, require little effort on the part of the patient, can be used for years, and are easily and

rapidly reversible should the woman wish to discontinue the method for any reason. All LARC methods have perfect and typical use failure rates of <1%, high satisfaction rates, and continuation rates of approximately 80%, which is higher than for any other category of contraceptive methods. LARC methods have been shown both in a large cohort trial of almost 10,000 women (the Contraceptive CHOICE project) and real-world implementation programs to reduce rates of unintended pregnancy, abortion, and teen birth. The American College of Obstetricians and Gynecologists (ACOG) and American Association of Pediatrics (AAP) both recommend LARC methods as first-line contraceptives for women, including nulliparous women and adolescents. Use of LARC methods has increased steadily in the United States over the last decade, increasing from 2.2% of women aged 18 to 44 years using contraception in 2002 to 11.6% in 2012.

IUDs are T-shaped contraceptives that are inserted in the uterine cavity by a trained provider. Progestin-releasing IUDs prevent pregnancy by thickening the cervical mucus and decreasing sperm penetrability and by causing endometrial changes that prevent implantation. There are currently two available progestin-releasing IUDs that contain 52 mg of levonorgestrel. Mirena is currently approved for 5 years of use, although available data suggest good efficacy up to seven years, and is also US Food and Drug Administration (FDA) approved for the treatment of menorrhagia. Liletta is another 52-mg levonorgestrel IUD, similar in size and shape to Mirena, which was FDA approved in February 2015, and is a lower cost IUD. It is currently approved for 4 years of use because of available follow-up data; however, it is anticipated to eventually be approved for 5 and possibly 7 years. All available data indicate identical efficacy, side effects, bleeding profiles, and patient acceptability as Mirena. Liletta is not yet as broadly available but is becoming more so, especially at practice sites that qualify for federal drug discounts, where the cost of the IUD is dramatically lower. Skyla and Kyleena are smaller, lower dose IUDs. Skyla contains 13.5 mg of levonorgestrel and was FDA approved in 2013 for 3 years of use. Kyleena contains 19.5 mg of levonorgestrel and was FDA approved in September of 2016 for 5 years of use. The smaller design of the 13.5- and 19.5-mg IUDs may make them better suited for some nulliparous women, and they may be associated with less

insertional pain and lower rates of expulsion. All levonorgestrel IUDs reduce menstrual bleeding and dysmenorrhea, although 52-mg IUDs result in greater reduction of blood flow (~90%) and higher rates of amenorrhea (~20% Mirena/Liletta vs. 12% Kyleena and 6% Skyla). Most women who are not amenorrheic will have only light infrequent bleeding or spotting; only about 15% to 20% of women report continuation of cyclic monthly bleeding. The decreased menstrual bleeding is a significant noncontraceptive benefit for many women, and use of levonorgestrel IUDs has been shown to reduce anemia and need for hysterectomy in women with heavy menses. Hormonal side effects are less common with hormonal IUDs than with most other hormonal contraception because serum levels of progesterone are lower than with other hormonal contraception. The copper IUD (Paragard) releases copper ions, which creates a sterile inflammatory response in the uterus, decreasing sperm mobility and fertilization capability, and endometrial changes that also prevent implantation. The copper IUD is approved for 10 years although data indicate good effect up to 12 years of use, and it has no hormonal side effects. It may, however, increase menstrual blood flow and dysmenorrhea.

IUDs have relatively few contraindications, including significant distortion of the uterine cavity, active pelvic inflammatory disease, current or recent breast cancer, and active liver disease (levonorgestrel IUD only) and copper

allergy (copper IUD only). Despite some myths and associations with previously available IUDs, currently available IUDs are not associated with pelvic inflammatory disease (PID) or infertility. There is a small increase in infection in the 20 days after insertion, which is related to the insertional process itself, but beyond that, women with an IUD are no more likely to develop PID than women without IUDs. Although there is a higher proportion of ectopic pregnancies among the rare women who become pregnant with an IUD in place, the overall rate of ectopic pregnancy is reduced with IUD use, because of the higher overall contraceptive efficacy.

The etonogestrel contraceptive implant Nexplanon is approved for 3 years of use. It is a single-rod 4-cm implant, roughly the size of a matchstick. It releases 60 µg of etonogestrel daily. It is placed under the skin of the upper arm in the groove between the biceps and the triceps muscle. Clinicians must complete a drug company–sponsored training program to be able to insert or remove the device. The current Nexplanon replaced the former Implanon in 2012 and differs only in that it is radioopaque and has a simplified inserter. The implant prevents pregnancy by suppressing ovulation and also likely has contraceptive effects on cervical mucus and the endometrium. The etonogestrel implant is likely the most effective contraceptive available, with no

pregnancies seen in clinical trials and estimated rates of failure of 0.05% with a device in place. Other advantages of the implant include decreased dysmenorrhea, high continuation rates, lack of need for pelvic examination for insertion, and low rates of side effects. The etonogestrel implant does not appear to be associated with weight gain, does not show decreased efficacy among obese women, and does not cause changes in bone mineral density. The most significant disadvantage of the implant is disruption of menstrual bleeding. Rates of amenorrhea are approximately 20%, but bleeding may also become unpredictable and irregular and either heavier or more prolonged in about 25% of women. Bleeding is the most common cause of discontinuation. The etonogestrel implant is also safe for the vast majority of women, with even fewer contraindications than IUDs.

### Short-Acting Hormonal Contraception

Short-acting hormonal contraceptive methods are available as combination hormonal methods (CHCs) with both estrogen and progesterone and progestin-only methods. Combined methods are available as pills, a transdermal patch, and a vaginal ring. Short-acting progestin-only methods include pills and the injectable Depo-Provera.

### Combined Hormonal Contraception

Combined oral contraceptive (COC) pills are available in many available formulations. Most formulations contain the estrogen ethinyl estradiol, in doses of 35, 30, or 20  $\mu\text{g}$ . There is also currently one formulation available with 10  $\mu\text{g}$  of ethinyl estradiol and one with estradiol valerate. There are several available progestins, which are often categorized by generation. Oral contraceptive pills may be monophasic (same dose of estrogen and progesterone throughout the cycle) or multiphasic (varying doses throughout the cycle). The transdermal patch and vaginal ring also contain ethinyl estradiol; the patch contains the progestin norelgestromin, and the ring contains etonogestrel. Standard use of oral contraceptive pills is one hormonal pill for 21 days followed by 7 days of placebo pills. The patient applies one patch per week for 3 weeks at rotating sites, followed by 1 hormone-free week. The contraceptive vaginal ring (Nuvaring) is a flexible plastic ring that the patient inserts into the vagina herself. Standard use of the vaginal ring is one ring for 3 weeks, followed by 1 hormone-free week.

Early oral contraceptive pills (OCPs) contained higher doses of estrogen than what are currently used, and doses of 50  $\mu\text{g}$  or higher are no longer recommended. Beyond that, there is currently no strong evidence to recommend any dose formulation over another. All combined contraceptive methods increase the risk of venous thromboembolic disease (VTE). The risk of VTE is greater in pills with 50  $\mu\text{g}$  of ethinyl estradiol than in pills with 20 to 35  $\mu\text{g}$ . It is possible but not currently known if there is a difference in VTE risk between 20-, 30-, or 35- $\mu\text{g}$  formulations. Benefits of lower estrogen preparations may include few estrogenic

side effects (breast tenderness, nausea, headache); however, women taking 20- $\mu\text{g}$  pills also experience more amenorrhea and breakthrough bleeding than women taking 30- or 35- $\mu\text{g}$  pills. In clinical studies, there is no difference in contraceptive efficacy between 20- and 30- or 35- $\mu\text{g}$  pills; however, it is not known whether with typical use (forgotten or missed pills) there may be more breakthrough ovulation and thus greater pregnancy risk with lower dose formulations. The progestins that are used in combined hormonal methods are often described in terms of their "generation" and differ in androgenicity in laboratory studies; however, the extent to which different progestins produce clinical differences in side effects is less well known. The choice of progestin does not affect contraceptive efficacy in any way.

Choice of pill patch or ring depends on patient preference and ability to comply with the method because there are no major differences in risk profiles or side effects between these forms. Some women are easily able to take a pill every day, and for some, use of a weekly patch or monthly ring might improve compliance. Studies have not shown clinically significant differences in adherence with the patch or the ring, and all three methods have similar discontinuation rates and failure rates. Side effects are also relatively similar, with patch users having slightly higher rates of breast tenderness, nausea, and skin rash and ring users having some increased vaginal irritation. Overall, continuation rates for pill, patch, and ring are ~67% at 1 year.

Benefits of combined hormonal contraceptive methods include decreased menstrual flow, dysmenorrhea, and acne. CHCs may be used for the treatment of heavy periods, endometriosis, and polycystic ovarian syndrome. Some combined methods have the benefit of allowing adjustments or manipulations of the menstrual cycle. Risks of OCPs are primarily related to the estrogen component and include increased risk of VTE, hypertension, and cardiovascular disease. These risks are statistically significant compared with nonusers, but absolute rates remain very low in young healthy women. Specific concerns have arisen regarding risk of VTE with certain progestins, as well as the transdermal patch. Some studies have shown a roughly 2-fold greater risk of deep vein thrombosis (DVT) with combined contraceptive pills containing third-generation progestins (drospirenone and desogestrel) as compared with second-generation progestins, which translates into an increase in absolute risk of 1 to 2 cases of DVT per 10,000 woman-years of use. Other studies do not show this increase in risk. The transdermal patch has been shown to result in serum estrogen levels that are approximately 60% higher than oral contraceptive pills, and epidemiologic data have been mixed with some studies suggesting an approximate 2-fold increase in VTE compared with oral contraceptive users. However, other trials have not found this. Even if the increased thrombotic risk is valid with these methods, the absolute increased risk is very small, and these products remain a safe option for the vast majority of women. There is no indication for switching women who are happy using these products. Remember that the risk of VTE with combined hormonal

**TABLE 100.2 Risks of Deep Vein Thrombosis**

No OCP	4–5/100,000 women-years
OCP	12–20/100,000 women-years
Pregnancy	50–200/100,000 women-years

OCP, Oral contraceptive.  
Modified from Hatcher RA, Trussell J, Nelson A, et al. *Contraceptive Technology*. 19th ed. New York: Ardent Media; 2009.

contraception is less than the risk of DVT during pregnancy and that successful pregnancy prevention even with combined hormonal contraception leads to an overall decrease in VTE rates (Table 100.2).

Some concerns have also been raised about the efficacy of CHCs in obese women. Available data suggest that OCPs are generally effective in obese women, although epidemiologic studies are mixed, with some finding higher rates of pregnancy in obese COC users, whereas others have not. There are some data to suggest that the transdermal patch may be less effective in women weighing 198 pounds or more. There are limited data on efficacy of the contraceptive ring in obese women, but no data to suggest decreased efficacy. In general, obese patients, like all patients, should be counseled that long-acting methods provide the best protection against pregnancy and that with these methods there is no concern about decreased efficacy in obese women.

### Short-Acting Progestin-Only Contraception

Progestin-only methods are often chosen by women who have medical contraindications to estrogen but who are generally tolerant of or desire hormonal contraception. Progesterone-only methods have no increased risk of VTE, stroke, or myocardial infarction and are safe for women who are breastfeeding. Short-acting progestin-only contraception includes oral progestin-only pills (POPs) and the injectable depot medroxyprogesterone acetate (DMPA). Oral progestin-only pills are equally effective as COCs with perfect use; however, because their mechanism of action is dependent on cervical mucus and endometrial effects as opposed to ovulation inhibition, taking POPs at the same time every day is even more important for contraceptive efficacy than with COCs, and typical use efficacy may be lower. Progestin-only pills are generally well tolerated, with the most common complaint being disturbances in the menstrual cycle or irregular bleeding.

The injectable DMPA provides contraception for up to 13 weeks and is highly effective, with perfect use failure rates 0.2%. The dose is 150 mg given intramuscularly every 12 to 14 weeks. Advantages of DMPA include its high efficacy without need for daily, weekly, or monthly upkeep on the part of the patient. Studies show that adolescents on DMPA are less likely to become pregnant than adolescents

on OCPs or the patch. DMPA leads to decreased blood loss, with amenorrhea in 50% of users after 1 year, and it can decrease dysmenorrhea. DMPA is also a highly private method of contraception, which may be beneficial for adolescents or any women who need or want to conceal their contraceptive use from partners or family. Disadvantages of DMPA include irregular bleeding, weight gain in some users, and delayed return of fertility. Fertility returns on average after 10 months, but it can be delayed for up to 2 years in some patients. The need for an office visit four times per year is also a disadvantage or barrier to use for some women, which is reflected in the fact that 1-year continuation rates for DMPA are only 56%.

There have been concerns regarding the association between DMPA and decreased bone mineral density, which occurs because of a DMPA-induced hypoestrogenic state that is similar to breastfeeding. This association led to a black box warning from the FDA in 2004 stating that women who use DMPA may lose significant bone density that may not be completely reversible and that DMPA should be used for >2 years only if other birth control methods are inadequate. Subsequent studies of the relationship of DMPA and bone density have been reassuring. Most epidemiologic evidence currently suggests that DMPA-induced bone loss is substantially recovered after discontinuation in premenopausal adult and adolescent women. Best available data also suggest no increased risk of osteoporotic fracture later in life, among women at average risk for osteoporosis. Groups such as ACOG, the World Health Organization, and the Society for Adolescent Medicine recommend that use of DMPA not be restricted on the basis of skeletal concerns or limiting duration of use. In addition, use of DMPA should not be an indication for bone mineral density testing.

A subcutaneous (SC) formulation of DMPA is also available. Because of slower absorption, a lower dose of 104 mg is given with equal efficacy. The SC injection is less painful and can allow for self-administration. Side effects, benefits, and risks are otherwise similar. The disadvantages of the SC form are that it is more expensive and is not as widely available.

### Barrier Methods

Barrier methods prevent pregnancy by blocking sperm from entering the female reproductive tract. The most commonly used barrier methods include the male and female condom, the diaphragm, and sponge. Cervical caps are rarely used anymore. All barrier methods are generally less effective for preventing pregnancy because of their need to be used with each act of intercourse and potential for incorrect use, slippage, or breakage. All barrier methods have typical use failure rates of >10% and higher rates of user discontinuation than hormonal or long-acting methods. One-year continuation rates are 43% for condoms, 57% for the diaphragm, and only 36% for the sponge.

Condoms act as mechanical barriers that block both sperm and pathogens that can cause sexually transmitted

**TABLE 100.3** Emergency Contraception Efficacy

 Modified from Hatcher RA, Trussell J, Nelson A, et al. *Contraceptive Technology*. 20th ed. Atlanta: Bridging the Gap Communications; 2011.

infections (STIs) and are highly effective in protecting against HIV, gonorrhea, chlamydia, herpes simplex virus, and human papillomavirus. Condoms are available in both male and female forms and may be made from latex, polyurethane, or nitrile. Patients with any concerns about STIs should always use condoms. Dual use of condoms plus another method of contraception can reduce the risk of both pregnancy and STIs, especially if a less-effective female method is also being used. Physicians should no longer recommend spermicide-coated condoms. The spermicidal condom can be irritating to the vagina, provides no additional protection against pregnancy or STIs, is more expensive, and has a shorter shelf life. Patients and physicians should also be aware that natural membrane condoms, which are made from lamb intestine, have larger pores that may allow the passage of viruses and should not be used for the prevention of STIs. It is important to educate patients who use condoms about emergency contraception and to provide them with access information and/or a prescription.

Other barrier methods that are worn by women include the diaphragm, sponge, and cervical cap. The diaphragm is a circular latex device that is filled with spermicide and placed over the cervix. The cervical cap is a smaller device that fits over the cervix and is filled with spermicide. The contraceptive sponge is a 2-inch foam disk containing spermicide, which is moistened and then placed in the vagina before intercourse. Diaphragms and cervical caps are reusable; the sponge is disposable.

Female-controlled barrier methods are often chosen by women who wish or need to avoid all hormones and who want on-demand, woman-controlled contraception. These methods are generally less popular than other contraceptives, because of several disadvantages. Firstly, they have notable higher failure rates than most other contraceptives and must be accessible and used correctly for each act of intercourse, thus they require users who are highly motivated and have some skill. Diaphragms and cervical caps require fitting by a clinician and can be difficult for women to insert, and all of these methods must be kept in place for at least 6 hours after intercourse. The diaphragm is also associated with an increased risk of urinary tract infections. The contraceptive sponge has the benefit of not requiring fitting or prescription but has the highest failure rates.

## Emergency Contraception

Emergency contraception is the use of any method to prevent pregnancy after intercourse. There are three methods in current use: the oral progestin levonorgestrel (Plan B), the progestin antagonist ulipristal (Ella), and insertion of the copper IUD. In the past, combined oral contraceptives (Yuzpe method) were used off-label for emergency contraception; however, this has fallen out of favor because of the availability of other more effective options that have fewer side effects. The copper IUD is the most effective, followed by ulipristal and levonorgestrel. These methods prevent pregnancy by delaying ovulation, preventing fertilization, or, less commonly (in the case of intrauterine contraception only), preventing implantation. None of the current methods can cause an abortion, and none can disrupt an implanted pregnancy (Table 100.3).

The most effective method of emergency contraception is insertion of a copper IUD within 5 days of unprotected intercourse. It is ideal for women who desire long-acting highly effective contraception and who also have had recent unprotected intercourse. The levonorgestrel IUD is currently not approved for use as emergency contraception. Disadvantages include the need for a visit with a provider trained in IUD insertion. Women must also not have any other contraindications to copper IUD placement, such as active cervicitis, uterine abnormalities, or copper allergy.

Oral emergency contraceptive options include ulipristal (Ella) and levonorgestrel (Plan B). Ulipristal is a progesterone antagonist, which acts to delay ovulation. A single 30-mg dose can be taken up to 120 hours after unprotected intercourse. Levonorgestrel is usually administered as a single 1.5-mg dose (other regimens include  $2 \times 0.75$ -mg doses taken 12 hours apart) and can be taken up to 72 hours after unprotected intercourse. Neither medication has significant side effects or medical contraindications. Advantages of ulipristal are that it appears to be more effective at preventing pregnancy than levonorgestrel, especially in the time window of 72 to 120 hours after intercourse and in overweight and obese women. For women with body mass index  $>30$  or weight  $>75$  kg, the effectiveness of both medications is reduced compared with in normal-weight women, but the reduced effect is more

dramatic with levonorgestrel, where very few pregnancies are prevented among obese women. Obese women should be offered the copper IUD as first-line emergency contraception, followed by ulipristal. Disadvantages of ulipristal are that it requires a prescription and may not be available at all pharmacies. Levonorgestrel is currently available over the counter. The single 1.5-mg dose (Plan B One-Step) is now available to all women without age restriction, although availability of the generic formulation varies state by state for adolescents age <17 years. The cost is generally \$35 to \$50.

## Eligibility for Contraceptive Methods

It is important for physicians to understand which contraceptive options are safe for which patients. There are many common medical conditions and physical states such as hypertension, cardiovascular and thromboembolic disease, migraines, autoimmune disease, lactation, history of bariatric surgery, and more, for which some contraceptive methods may be contraindicated or relatively contraindicated. An excellent resource for medical eligibility is the Centers for Disease Control United States Medical Eligibility Criteria for Contraceptive Use (CDC US MEC), which is available at [http://www.cdc.gov/reproductivehealth/unintended\\_pregnancy/usmec.htm](http://www.cdc.gov/reproductivehealth/unintended_pregnancy/usmec.htm).

Summary charts and mobile apps are also available.

## Special Populations

### Adolescents

There are no restrictions on types of contraceptive methods that can be used by adolescents. Adolescents tend to rely on the least effective methods of contraception, primarily condoms, oral contraceptives, and withdrawal, use them less consistently, discontinue their methods at higher rates, and also have the highest rates of unplanned pregnancy among any age group. Professional organizations including the AAP and ACOG therefore recommend that LARC methods be considered first-line contraceptives for adolescents. Use of LARC devices among adolescents has been shown to reduce the rate of unintended pregnancy and teen birth rates. There is no additional screening or testing required for use of any contraceptive methods in adolescent patients; they should have appropriate age-based STI testing regardless of contraceptive method chosen.

### Obese Women

There are no concerns or special considerations for use of the following methods of contraception in obese women: IUDs (copper or hormonal), etonogestrel implant, DMPA, or barrier methods. Both DMPA and the etonogestrel implant have sufficiently high serum levels of progesterone that they successfully suppress ovulation in all weight groups, and clinical studies have demonstrated no difference in pregnancy rates between obese and nonobese

women. IUDs act locally and thus are not affected by any metabolic factors that may differ in obese versus nonobese women.

With regard to combined hormonal contraception and contraceptive efficacy, the data are somewhat mixed and inconclusive. Concerns about the efficacy of combined hormonal methods are based on possible decreased serum levels resulting in less effective suppression of ovulation. Most pharmacokinetic studies of COCs show similar ovarian suppression in obese women; however, there is some concern that these methods may be less forgiving of imperfect use in real world settings. Some epidemiologic studies suggest higher risk of pregnancy in obese women on OCPs (HR 1.5), whereas others do not. There are no data to suggest greater efficacy with a pill containing 30/35 µg of estrogen; however, theoretically this may improve ovarian suppression in obese women. No sizable studies of the combined hormonal ring have been done in obese women; however, small pharmacokinetic studies have shown no difference in follicular development or serum levels in obese as compared with nonobese women. There is some evidence that the contraceptive patch may be less effective in women >90 kg (198 lb). Early efficacy trials showed a higher rate of pregnancy in this subset of women, although the total numbers of obese women included in this trial were small.

Obesity must also be weighed as a risk factor for thromboembolic disease when considering use of estrogen-containing contraception. Obesity on its own, however, is not a contraindication to combined hormonal method use if there are no other medical contraindications.

Obesity does notably affect efficacy of emergency contraception, as described earlier (see section on [Emergency Contraception](#)). Obese women requesting emergency contraception should preferentially be counseled toward a copper IUD, followed by ulipristal.

As a subset of obese or previously obese women, there are also considerations for women who have undergone restrictive bariatric surgery. Although there are limited clinical data, given concerns for potential malabsorption of oral hormones, combined hormonal and progesterone-only pills are relatively contraindicated in these women. Other hormonal contraceptives that do not rely on oral absorption such as the ring and patch, DMPA, the etonogestrel implant, or hormonal IUD are without any specific concern and should be equally effective in women who have undergone bariatric surgery.

In general, obese women, similar to all women, should be counseled toward the most effective methods of contraception, which are the LARC methods, whose efficacy rates we know are not affected by obesity. However, for women who choose non-LARC methods, it is important to remember that issues of compliance and consistent use will impact contraceptive efficacy to a much greater extent than any small pharmacokinetic difference. Thus any method that a woman can use consistently will likely provide the best contraceptive efficacy.

## History of Cancer

### Women With a History of Breast Cancer

Hormonal methods of contraception are generally contraindicated in women with breast cancer. For women who have been without evidence of disease for >5 years, hormonal methods are still relatively contraindicated, and any use must be weighed carefully against the risk of recurrence and only when nonhormonal methods are felt to have significant drawbacks. Occasionally, for women on tamoxifen at high risk of the development of endometrial cancer, a progesterone-containing method such as a progestin-IUD may be considered; however, this needs to be considered in very select patients in close discussion with the patient's oncologist. In general, the first-line method of contraception for women with breast cancer will be a copper IUD.

### Other Malignancies

Hepatocellular malignancy is a contraindication to hormonal methods of contraception and is the only other malignancy with a specific restriction on contraceptive methods. For women with all other types of cancer, there are no specific restrictions on contraceptive methods based purely on the type of cancer. Many women with cancer have associated medical comorbidities that can influence their contraceptive eligibility such as increased risk of VTE, increased risk of bleeding including menstrual bleeding, immunosuppression, or treatment-related cardiopulmonary disease.

## Other Medical Problems

Other conditions commonly encountered by primary care physicians can affect contraceptive choice. LARC methods and nonhormonal methods tend to have fewer medical contraindications than estrogen-containing contraceptives and are safe for women with diabetes, hypertension, lupus, most cardiovascular and thromboembolic disease, epilepsy, and migraines. Estrogen-containing contraceptives are contraindicated or relatively contraindicated in patients with current, personal history, or high risk of thromboembolic disease, stroke, or other vascular disease. They are also contraindicated in smokers age >35 years and relatively contraindicated for any patients with hypertension, even when well controlled. Combined hormonal contraception is safe for women with diabetes without vascular disease or other end-organ damage, but other contraception should be considered for women with diabetes and vascular disease, nephropathy, retinopathy, neuropathy, or diabetes of >20 years duration. Migraine with aura is a contraindication to estrogen-containing contraception at any age, and any migraine is relative contraindication after the age of 35 years. Women with systemic lupus can use estrogen-containing contraception as long as they do not have antiphospholipid antibodies. From a safety perspective, women with seizure disorders can use any method of contraception; however, there are some significant drug-drug interactions between COCs and enzyme-inducing antiepileptic drugs (AEDs) that lower the efficacy of either the contraceptive or the AED, thus caution must be used in choosing an effective method for women with seizure disorders.

For more detailed medical eligibility for contraception, please see the CDC US MEC.

## Chapter Review

### Questions

1. A 20-year-old woman is evaluated for dysmenorrhea that has worsened over the past 2 years. Her periods are regular, last for 5 to 6 days, and are moderately heavy in flow. She sometimes misses work because of her dysmenorrhea. Ibuprofen and naproxen have not helped her pain. She is not currently sexually active. Her pelvic examination is normal.

Which of the following would be appropriate treatment for this patient?

- A. Cyclic combined OCPs
  - B. Continuous combined OCPs
  - C. DMPA
  - D. Levonorgestrel IUD
  - E. All of the above
2. A 40-year-old woman wants to discuss contraceptive options. She and her husband have been using condoms but are having problems with condom breakage. She does not want additional children. She has heavy periods. She had a DVT after a long car ride 2 years ago.

Which of the following is the safest and most effective way to prevent pregnancy in this patient?

- A. Combined hormonal contraception (pill, patch, or ring)
  - B. Progesterone-only pill
  - C. Diaphragm
  - D. Levonorgestrel IUD
3. A 26-year-old woman had intercourse last night. Her partner was using a condom, and the condom broke. She does not use any other contraception, but she has been thinking about using something more reliable than condoms. Her last menstrual period was 10 days ago. She is calling you for advice. What is the best option for emergency contraception for this patient?
    - A. Over-the-counter levonorgestrel (Plan B) followed by a prescription for OCPs
    - B. Prescription ulipristal (Ella)
    - C. Copper IUD insertion within the next 4 days
    - D. Levonorgestrel IUD insertion within the next 4 days

### Answers

1. E
2. D
3. C

# Board Simulation: Women's Health

CAREN G. SOLOMON

## Questions

- A 32-year-old woman, gravida 1 para 1 (G1P1), comes in for a visit 6-months postpartum. She is fatigued and has lost few of the 30 lb she gained during pregnancy. She takes a multivitamin and no other medications. On physical examination, weight is 150 lb, and height is 5'2". The thyroid feels slightly enlarged, without nodules, and is nontender. Her complete blood count (CBC) is normal. The thyroid-stimulating hormone (TSH) level is 24 mIU/L. Which of the following is true?

  - Subacute thyroiditis is the most likely diagnosis.
  - This condition is likely to recur following subsequent pregnancies.
  - Thyroid peroxidase (TPO) antibodies are likely to be negative.
  - You should wait for spontaneous resolution rather than treating with thyroxine ( $T_4$ ).
  - She should have a thyroid ultrasound.
- A 28-year-old woman comes to establish care. She has a long history of oligomenorrhea and hirsutism and was diagnosed by her gynecologist with polycystic ovary syndrome (PCOS). Records indicate normal prolactin and TSH levels, normal level of fasting 17-OH progesterone, and slightly elevated total testosterone level. Last menstrual period was 4 months ago, which is not unusual for her. She takes no medications. On examination, weight is 160 lb, and height is 5'3". Blood pressure is normal. There is slight terminal hair growth in the moustache and sideburn distribution, above her umbilicus, and around her nipples. Pelvic examination is limited by body habitus but appears to be within normal limits. Which of the following is false?

  - This condition is associated with increased risk for glucose intolerance or diabetes.
  - Risk for endometrial hyperplasia or cancer is increased.
  - The finding of polycystic ovaries on pelvic ultrasound is highly sensitive and specific for the diagnosis.
  - Luteinizing hormone (LH) levels are not required to make the diagnosis.
  - Spironolactone may be useful in treatment of associated hirsutism.
- A 48-year-old woman reports irregular menstrual cycles for the past year. Her last menstrual period was 9 weeks ago. She has been having hot flashes for the past 2 years, and they are interfering with sleep. She is healthy, without significant past medical history. There is no family history of blood clots or breast cancer. She takes no medications. Physical examination is unremarkable; blood pressure is normal, and she has a normal pelvic examination and breast examination. Which of the following statements is false?

  - A follicle-stimulating hormone (FSH) level should be checked to confirm menopause.
  - Low-dose hormone therapy could be considered.
  - A history of deep venous thrombosis would be a contraindication to the use of postmenopausal hormone therapy.
  - Combined therapy with low-dose estrogen and progestin would be preferable to an estrogen-only regimen.
- This patient decides at first to take nothing for her symptoms but returns a year later with persistent hot flashes and no menses for the past 6 months. She is interested in hormone therapy. Physical examination is normal. Mammogram is negative. Which of the following statements is false?

  - Hormone therapy is associated with increased risk for gallstones.
  - Hormone therapy increases the risk for deep venous thrombosis (DVT)/pulmonary embolism (PE).
  - Progestins may have negative effects on mood.
  - Vaginal bleeding is rare after the first 3 months on combined hormone replacement.
  - Hormone therapy increases the risk for stroke.
- A 24-year-old woman complains of irregular menstrual cycles. She reports a 30-lb weight gain over the past 3 years, which she has attributed to a sedentary job. She takes no medications. On examination, she is 180 lb, and height is 5'6". She has mild hirsutism and acne on the face and back. Abdomen is obese, with pale striae. Which diagnosis would not be consistent with this presentation?

  - Late-onset congenital adrenal hyperplasia
  - Polycystic ovary syndrome

- C. Cushing syndrome  
 D. Turner syndrome  
 E. Androgen-secreting tumor
6. A 62-year-old woman comes to establish primary care. Menses stopped at age 52 years, and she has never been on postmenopausal hormone therapy. History is notable for right tibia fracture while skiing 10 years ago and hypertension. She takes hydrochlorothiazide 25 mg daily. She smokes cigarettes, a half pack per day. She does not drink alcohol. She swims regularly for exercise. There is no family history of hip fracture. On physical examination, her weight is 114 lb, and height is 5'4". Blood pressure is 128/80 mm Hg. The rest of the examination is unremarkable. Which risk factor for osteoporosis in this woman would not apply?  
 A. Postmenopausal status  
 B. Cigarette smoking  
 C. Her weight  
 D. Her prior fracture  
 E. Use of hydrochlorothiazide
7. Which of the following statements is false for the management of this patient?  
 A. She should consume 1200 mg calcium daily.  
 B. Drinking two cups of milk daily will give her adequate vitamin D.  
 C. Weightbearing exercise is recommended.  
 D. Calcium carbonate supplements should be taken with meals.  
 E. Swimming would not be expected to increase her bone density.
8. You order a bone density of the spine: *T*-score is  $-2.6$ ; *Z*-score is  $-1.1$ . Which of the following is false?  
 A. She has osteoporosis.  
 B. Osteoarthritis of spine could falsely increase her bone density.  
 C. Her *Z*-score compares her with young normal women.  
 D. Bone mineral density is the single best predictor of fracture.  
 E. This *Z*-score would not suggest the need for a workup for secondary causes of osteoporosis.
9. You discuss with her recommendations regarding calcium, vitamin D, and weightbearing exercise and encourage her to stop smoking. You also recommend antiresorptive therapy. Which of the following statements is true?  
 A. Raloxifene therapy would be expected both to improve bone density and to reduce hot flashes.  
 B. Calcitonin reduces the risk for hip fracture.  
 C. Neither alendronate nor risedronate may be taken with food.  
 D. Routine dental work should be deferred in patients taking bisphosphonates.
10. A 48-year-old woman who has been your patient for several years comes in complaining of constipation and abdominal pain. She has seen two outside gastroenterologists for these complaints in the past year and has had colonoscopy, barium enema, endoscopy, and abdominal CT scan, which were all negative. She has been well except for a fracture of the radius from a fall down the stairs the preceding year. She is married, without children. Examination is remarkable only for ecchymoses on the back and right arm. You should:  
 A. Repeat a colonoscopy at your institution.  
 B. Ask her whether she has ever been hurt or threatened in her relationship.  
 C. Ask her generally about how she is doing, but avoid asking directly about domestic violence.  
 D. Call her husband, and discuss the situation with him.
11. A 37-year-old woman comes for evaluation of a lump she discovered in the left breast 1 month earlier. She is G1P1, and she had menarche at age 14. She has regular monthly menses, and her last menstrual period (LMP) occurred 1 week ago. She drinks four cups of coffee daily. Family history is negative for breast cancer. Her mother has fibrocystic breast disease. On physical examination, she is well appearing. There is a 1.5-cm mass palpable in the upper outer quadrant of the left breast, which is slightly tender to palpation. There is no axillary adenopathy. You order a mammogram, which is negative. Which of the following would be the most appropriate next step?  
 A. Reassure her. No intervention is indicated.  
 B. Schedule repeat mammogram in 4 to 6 months.  
 C. Tell her to stop coffee and other caffeine intake and return in 4 to 6 months for reexamination.  
 D. Order an ultrasound; if this is negative, no further workup is required.  
 E. Order an ultrasound; referral should be made for biopsy unless the lump is consistent with a simple cyst.
12. A 30-year-old woman, G0P0, with a 20-year history of type 1 diabetes mellitus (DM) is interested in becoming pregnant. She has a history of nonproliferative retinopathy. Her last eye examination was 2 years ago. She checks blood sugars once daily. Medications include NPH 20 U/Regular 8 U each morning and NPH 10 U at night. She also takes a prenatal vitamin. Her blood pressure is 124/80 mm Hg; the rest of the examination is unremarkable. Laboratory results: hemoglobin (Hb)A<sub>1c</sub> 9.0, creatinine 1.3 mg/dL. There is trace protein on urine dipstick. Which of the following would not be recommended before conception?  
 A. An angiotensin-converting enzyme (ACE) inhibitor should be started to minimize progression of renal disease in pregnancy.  
 B. She should increase her frequency of blood sugar monitoring.  
 C. She should be referred to ophthalmology.

- D. Blood sugar control should be tightened to achieve a normal HbA<sub>1c</sub>.
- E. She should have a prescription for glucagon.
13. A routine Pap smear in a 42-year-old woman shows ASCUS (atypical squamous cells of undetermined significance). She is in a monogamous relationship and has had normal Pap smears in previous years. Which of the following would be most appropriate?
- A. Treat empirically with doxycycline and repeat Pap in 3 months.
- B. This is a normal finding in a perimenopausal woman and does not require follow-up.
- C. Endometrial sampling should be done to exclude endometrial cancer.
- D. Perform human papilloma virus (HPV) testing for high-risk subtypes.
14. A 32-year-old woman, G1P0, 16 weeks pregnant, presents with palpitations and weight loss. Her heart rate is 110 beats per minute. She has lid lag but no appreciable exophthalmos. The thyroid gland is symmetrically enlarged to about 1.5 times normal size. TSH is <0.05 mIU/L, and T<sub>4</sub> is 22 mIU/L. Which of the following is false?
- A. Propylthiouracil (PTU) can be used in the first trimester of pregnancy.
- B. A thyroid uptake should be performed to confirm the diagnosis.
- C. A beta-blocker could be used for symptoms.
- D. Thyroid-stimulating immunoglobulins (TSIs) would likely be elevated.
- E. This condition is likely to improve with treatment over the course of pregnancy.
15. A 22-year-old woman, G0P0, comes for contraceptive counseling. Which of the following is false?
- A. The risks associated with use of oral contraceptive pills (OCPs) outweigh the benefits for women with a history of coronary heart disease or stroke.
- B. OCP use is associated with a reduced risk for ovarian cancer.
- C. Women who are at average risk of sexually transmitted diseases (without current infection) are considered appropriate candidates for intrauterine devices (IUDs).
- D. Currently used OCPs are associated with a 2-fold increase in breast cancer risk.
16. You are paged by a 32-year-old woman who is worried about pregnancy after having had unprotected intercourse 36 hours prior. Her LMP was 16 days ago. Which of the following is true?
- A. Taking two OCPs containing 20 µg ethinyl estradiol now, followed by two more 12 hours later, is appropriate for emergency contraception.
- B. Levonorgestrel, 1.5 mg as a single dose, is appropriate for use as emergency contraception.
- C. It is too late to use emergency contraception.
- D. Emergency contraception is not warranted at this time in the cycle.
17. Which of the following strategies for cervical cancer screening is consistent with current guidelines?
- A. Pap testing alone every 3 years (if testing normal) for a woman in her 40s
- B. Combined Pap and HPV testing every 5 years (if testing normal) starting at age 21
- C. Pap testing annually starting at age 18 in a sexually active woman
- D. No screening in women who have had HPV vaccination
18. A 35-year-old woman presents for her initial primary care visit. Upon reviewing her medical history, you learn that she was diagnosed with gestational diabetes during her pregnancy 3 years ago. At her 6-week postpartum visit, she completed an oral glucose tolerance test (OGTT) and was told that her diabetes in pregnancy had completely resolved. Other than this diagnosis, she has had no other significant medical problems and has not seen another physician since her delivery 3 years ago. Which of the following is true?
- A. Gestational diabetes is unlikely to recur in a subsequent pregnancy.
- B. Because she had a normal postpartum OGTT, her risk for developing diabetes in the future is no higher than that of a woman whose pregnancy was not complicated by gestational diabetes mellitus (GDM).
- C. She is at increased risk for developing type 2 diabetes, compared with the general population.
- D. Sulfonylureas are recommended to reduce future risk of diabetes.

### Answers

1. B. This patient has postpartum thyroiditis, which is considered to be a variant of autoimmune thyroiditis. Postpartum thyroiditis, a condition reported to follow 1% to 17% of pregnancies, is characterized by an initial hyperthyroid phase (within 6 months postpartum, lasting up to 2 months) caused by leakage of thyroid hormone from an inflamed thyroid gland, followed by a hypothyroid phase (typically occurring up to 10 months postpartum and lasting 3 to 6 months), and then, in most cases, return to euthyroidism. Often the hyperthyroid phase is not appreciated clinically, and the patient presents with hypothyroidism. TPO antibodies are characteristically positive, and recurrence is common following subsequent pregnancies. Symptomatic hypothyroidism should be treated with T<sub>4</sub>, which should not be required for more than 6 months unless the patient has developed permanent hypothyroidism (rare immediately, although well described over long-term follow-up). Thyroid ultrasound may be useful in the evaluation of a thyroid nodule but is not indicated in the evaluation of thyroiditis. Subacute thyroiditis is a painful inflammation of the thyroid that is often described following upper respiratory infection. (Pearce EN. Thyroid disorders during pregnancy

and postpartum. *Best Pract Res Clin Obstet Gynaecol.* 2015;29(5):700–706.)

2. C. PCOS affects approximately 5% of women of reproductive age and is clinically diagnosed by the combination of chronic anovulation and androgen excess (clinical manifestations and/or biochemical excess) not explained by another endocrine disorder (such as late-onset congenital adrenal hyperplasia, hyperprolactinemia, androgen-secreting tumor). Although a polycystic appearance of the ovaries is generally present, this has also been noted in up to one-quarter of women without other features of PCOS, and this finding is considered neither sufficient nor necessary for the diagnosis. LH levels are also typically elevated (with increased LH/FSH ratio), but this is also not considered a necessary finding for the diagnosis and need not be routinely measured.

A clear association has been observed between PCOS and insulin resistance, and studies have documented an increased prevalence of glucose intolerance and DM in affected women, even independent of associated obesity, which is common but not always present in women with PCOS. Dyslipidemia is also more common in PCOS than in normally cycling women. In the setting of oligomenorrhea and chronic anovulation, women with PCOS also have increased risk for endometrial hyperplasia and cancer. There are reports of increased risks for hypertension, coronary heart disease, gestational diabetes, and gestational hypertension in these women also, although these have been less well substantiated. Treatment approaches include the oral contraceptive pill (to protect the uterus from unopposed estrogen stimulation, regulate cycles, and treat hirsutism), intermittent medroxyprogesterone (to protect the uterus), and spironolactone (to treat hirsutism). Insulin sensitizers (metformin, thiazolidinediones) have been reported to improve insulin sensitivity, reduce androgen levels, improve cycle regularity, and to induce ovulation in this condition. (El Hayek S, Bitar L, Hamdar LH, et al. Poly cystic ovarian syndrome: an updated overview. *Front Physiol.* 2016;7:124.)

3. A. Menopause is strictly defined as cessation of menses for  $\geq 12$  months, but menopausal symptoms and changes in cycle pattern often begin well before menses cease. A high FSH is characteristic of menopause, but checking FSH levels is not indicated routinely. FSH level is an unreliable indicator of impending menopause in a perimenopausal woman. Hot flashes are common as women near or reach menopause; about 50% of women will experience them in the 2 years around cessation of menses and some for many years following. Postmenopausal hormone therapy is very useful for managing hot flashes. In a woman with an intact uterus, estrogen therapy should be accompanied by progestin therapy to prevent development of endometrial hyperplasia. Whereas estrogen should

be administered continuously to minimize the occurrence of hot flashes, progestin may be administered either continuously or in a cyclic regimen (14 days per month), to prevent endometrial hyperplasia. Progestin administration for  $< 10$  to 12 days per month has not been confirmed to prevent endometrial hyperplasia and is not recommended in the setting of estrogen therapy. Hormone therapy remains a useful approach to symptoms in a woman without contraindications, although the plan should be for short-term rather than indefinite use. However, a history of venous thromboembolism is a contraindication to its use. (Among other contraindications to use are a history of breast cancer, coronary heart disease, unexplained vaginal bleeding, and active liver disease). (Manson JE, Kaunitz AM. Menopause management—getting clinical care back on track. *N Engl J Med.* 2016;374(9):803–806.)

4. D. As stated previously, estrogen is very useful for treatment of hot flashes; even low doses (e.g., conjugated equine estrogen 0.3 mg) may be sufficient to control symptoms. Adverse effects of postmenopausal hormone therapy must be considered. Side effects of estrogen include nausea, headache, and heavy bleeding, whereas progestins may have adverse effects on mood and may cause breast tenderness. Bleeding is common on combined estrogen/progestin therapy. Bleeding is usually predictable on cyclical regimens, although unpredictable intermittent bleeding is common during the first several months on daily combined regimens. After a year of combined daily hormone therapy, the majority of women will be amenorrheic, but the duration of bleeding tends to be longer in women who are closer to menopause. In the Women's Health Initiative trial, conjugated equine estrogen/medroxyprogesterone (Prempro), as compared with placebo, increased risks for coronary events, DVT/PE, breast cancer, stroke, and dementia (the latter in women age  $\geq 65$  years). There is also an increased risk of gallstones associated with the use of postmenopausal hormone therapy.
5. D. This patient is demonstrating symptoms and signs consistent with androgen excess (irregular menstrual cycles, acne, hirsutism). Possible causes of androgen excess include polycystic ovary syndrome, late-onset congenital hyperplasia, Cushing syndrome, and androgen-secreting tumor. Turner syndrome (XO karyotype) is a cause of primary amenorrhea and is associated with other characteristic features, including short stature, failure to develop secondary sexual characteristics, and somatic abnormalities (e.g., webbed neck, shield-like chest); androgen excess is not a feature of Turner syndrome. (Mihailidis J, Dermesropian R, Taxel P, et al. Endocrine evaluation of hirsutism. *Int J Womens Dermatol.* 2017;3(1 Suppl):S6–S10.)
6. E. Risk factors for osteoporosis include age, estrogen deficiency, cigarette smoking, lean body habitus, personal history of fracture, family history of osteoporosis in a first-degree relative, excessive alcohol intake,

- physical inactivity, Caucasian race, and inadequate intake of calcium. A history of dementia, falls, or frailty also increases fracture risk. Although some medications (e.g., glucocorticoids) increase risk for osteoporosis, hydrochlorothiazide reduces urinary calcium excretion and has been associated with reduced fracture risk. (Khosla S, Hofbauer LC. Osteoporosis treatment: recent developments and ongoing challenges. *Lancet Diabetes Endocrinol.* 2017 Jul 6. [Epub ahead of print])
7. B. Approaches that are recommended to optimize bone health include adequate intake of calcium (1200 mg recommended daily in a postmenopausal woman) and vitamin D (400 to 800+ IU daily). The following each contain about 300 mg calcium: 8 oz milk, 8 oz yogurt, 1.5 oz cheese. Because most women do not take in four servings of such calcium sources daily, supplements are often recommended. Calcium carbonate (e.g., in Tums, Os-Cal, Caltrate) is reportedly better absorbed with meals, whereas calcium citrate (e.g., Citracal) can be taken at any time; the latter is recommended in patients taking proton-pump inhibitors and is better tolerated by some women but is also more expensive. Vitamin D is added to milk, but only 100 IU per 8-oz serving. A standard multivitamin will provide 400 IU vitamin D daily; there are several combined calcium/vitamin D supplements (e.g., Caltrate D, Citracal D) as well as over-the-counter vitamin D supplements that can be taken alternatively or additionally. Weightbearing exercise is recommended. Swimming is not associated with an increase in bone density.
  8. C. In interpreting bone density results, the *T*-score represents a comparison with “peak” bone density of young normal women, and the *Z*-score represents a comparison with age-matched women. The *T*-score is used to make the diagnoses of osteopenia (*T*-score between  $-1$  and  $-2.5$  standard deviations below peak) or osteoporosis (*T*-score  $\leq -2.5$  standard deviations below peak). A *Z*-score below  $-2$  suggests bone loss out of proportion for age and may be used to identify women more likely to have secondary causes of osteoporosis. Osteophytes or a compression fracture may falsely elevate bone density readings, and such affected areas should be deleted from bone density analysis. (Gourlay ML, Overman RA, Ensrud KE. Bone density screening and re-screening in postmenopausal women and older men. *Curr Osteoporos Rep.* 2015;13(6):390–398. Korownyk C, McCormack J, Allan GM. Who should receive bone mineral density testing? *Can Fam Physician.* 2015;61(7):612.)
  9. C. Several medications have been approved for the treatment of osteoporosis; these include estrogen, raloxifene (a selective estrogen receptor modulator), oral bisphosphonates (alendronate, risedronate, ibandronate), parenteral bisphosphonate (zoledronic acid), teriparatide (recombinant human parathyroid hormone, via subcutaneous injections), and denosumab (an inhibitor of RANK [receptor activator of nuclear factor kappa-B] ligand, a regulator of osteoclasts, administered via injection). Although estrogen therapy improves hot flashes, raloxifene may worsen hot flashes. Both estrogen and raloxifene increase risk for blood clots. Data indicate a significant reduction in breast cancer risk in women treated with raloxifene. A reduction in hip fracture has not been demonstrated in women treated with calcitonin or raloxifene. In contrast, bisphosphonates have been shown to significantly reduce hip fracture risk. Bisphosphonates must be taken on an empty stomach first thing in the morning (30 minutes before eating) to facilitate absorption; once-a-week formulations of alendronate and risedronate (and a once-monthly formulation of ibandronate) make compliance easier for many patients. Osteonecrosis of the jaw has been reported infrequently among patients taking bisphosphonates; the majority of reports of this complication have been in patients using high doses intravenously for metastatic bone disease, although there are scattered reports among patients taking these agents for osteoporosis. Routine dental care should not be withheld in patients taking bisphosphonates. There are also rare reports of osteonecrosis of the jaw in women taking denosumab. Also of concern are reports of atypical femur fractures associated with bisphosphonate or denosumab use, although this complication also appears to be rare.
  10. B. The possibility of domestic violence should be considered in all women, regardless of background. Gastrointestinal complaints are common in women subjected to domestic violence. Unexplained fractures or bruising are more obvious clues, but there are often no outward signs, and abuse may be psychological rather than physical. It is recommended that all women be screened with a straightforward question regarding any history of being hurt or threatened; certainly screening is warranted in the case described. (AWHONN Position Statement. Intimate partner violence. *J Obstet Gynecol Neonatal Nurs.* 2015;44(3):405–408.)
  11. E. A palpable breast mass requires further evaluation regardless of patient age or mammogram results. Although coffee has been associated with fibrocystic breast disease, a palpable discrete mass should not be attributed to this or other benign etiologies without appropriate workup. Ultrasound would be the next step; biopsy would be indicated for findings other than a simple cyst in this woman. (Klein S. Evaluation of palpable breast masses. *Am Fam Physician.* 2005;71(9):1731–1738.)
  12. A. Tight glycemic control is recommended before conception in women with DM because the risk of congenital anomalies increases with increasing first-trimester HbA<sub>1c</sub> levels. Women should be advised to check blood sugars frequently, and insulin should be adjusted to maintain glucose levels at or as close

as possible to normal levels. Eyes should be checked before pregnancy as proliferative retinopathy may progress during pregnancy. Hypoglycemia is common in the first trimester, and women should be aware of symptoms and treatment of hypoglycemia and have glucagon available. Although an ACE inhibitor or angiotensin receptor blocker is indicated generally in diabetic patients, these agents are contraindicated in pregnancy. Second-trimester and third-trimester use of these agents is associated with complications including oligohydramnios, intrauterine growth retardation, anuria, renal failure, and death. More recent data also indicate associations between first-trimester use and major congenital anomalies, including cardiac and central nervous system defects.

13. D. ASCUS is the most common abnormal finding on a Pap smear. Bacterial infection is sometimes an underlying cause and should be treated if there is good reason to suspect this but not in asymptomatic low-risk women. HPV screening for high-risk subtypes is indicated when atypical cells are found; when positive, colposcopy is indicated. (Basu P, Mittal S, Bhadra Vale D, et al. Secondary prevention of cervical cancer. *Best Pract Res Clin Obstet Gynaecol*. 2017 Sep 6. [Epub ahead of print])
14. B. The presentation is most consistent with Graves disease, which commonly presents early in pregnancy. TSIs are typically detectable but need not be checked clinically. PTU is currently considered the preferred drug when antithyroid drug therapy is needed in the first trimester, owing to concerns of teratogenicity in association with the use of the alternative antithyroid drug, methimazole (including a rare scalp defect, aplasia cutis). Outside of the first trimester of pregnancy, methimazole is now considered the preferred drug, given reports of liver toxicity and liver failure associated with PTU. The minimal dose necessary to keep  $T_4$  levels upper normal or slightly above the normal range is recommended to minimize drug exposure of the fetus (because this crosses the placenta). Beta-blockers can be used for symptom control in pregnancy. Thyroiditis could cause a similar presentation; in a woman who is not pregnant or lactating, a thyroid uptake could be checked to distinguish between these conditions. However, thyroid uptake testing or treatment with radioactive iodine is strictly contraindicated in pregnancy. Graves disease tends to remit with treatment over pregnancy, and thyroid function should be followed closely to avoid overtreatment. (De Leo S, Lee SY, Braverman LE. Hyperthyroidism. *Lancet*. 2016;388(10047):906–918.)
15. D. When used properly, OCPs are highly effective in preventing pregnancy. Risks of OCPs include DVT/PE, even with low-dose preparations (risk reported to be higher with OCPs containing desogestrel vs. progestins such as levonorgestrel). (Plu-Bureau G, Maitrot-Mantelet L, Hugon-Rodin J, et al. Hormonal contraceptives and venous thromboembolism: an epidemiological update. *Best Pract Res Clin Endocrinol Metab*. 2013;27(1):25–34.) Myocardial infarction is a rare risk; the risk is higher in women who smoke (especially older women) or who have uncontrolled hypertension. A history of cardiovascular disease is a contraindication to the use of OCPs. OCP use is associated with a reduced risk of ovarian cancer; current preparations have been associated with a modest increase in breast cancer risk (relative risk increase approximately 20%). IUDs are extremely effective (more effective than OCPs) and are safe and appropriate for most women, including adolescents and women with a history of sexually transmitted diseases (although insertion should be deferred until after effective treatment in women with current purulent cervicitis or known chlamydial infection or gonococcal infection).
16. B. Emergency contraception has proven effective in reducing pregnancy risk when given within 72 hours to up to 120 hours of unprotected intercourse. Effective therapies include (1) the Yuzpe regimen, which involves use of combination OCP to provide 100  $\mu$ g of ethinyl estradiol (e.g., two pills, each containing 50  $\mu$ g ethinyl estradiol) initially and then again at 12 hours; (2) levonorgestrel 1.5-mg single dose (Plan B One Step); (3) ulipristal acetate 30 mg; and (4) insertion of a copper IUD within 5 days of unprotected sex. The Yuzpe regimen is rarely used now because it is more often associated with nausea and vomiting and is less effective than the other regimens. Levonorgestrel 1.5 mg is available without a prescription. Ulipristal acetate is also well tolerated, and there is some evidence that it is slightly more effective than levonorgestrel, in particular when used between 72 hours and 120 hours after unprotected intercourse; however, a prescription is required for its use. A reported LMP suggesting that intercourse was in the luteal phase does not effectively rule out possible pregnancy, and emergency contraception is still appropriate in this setting.
17. A. Cervical cancer screening is recommended in women starting at age 21 years. For average risk women age <30 years, cytologic testing (conventional or liquid-based) is recommended every 3 years (if testing negative). Screening with combined cytology and HPV (i.e., HPV cotesting) is not generally recommended in women age <30 years, although reflex testing with HPV is recommended in women in this age group for ASCUS Pap smears. For average-risk women age 30 to 65 years, acceptable strategies include cytologic testing every 3 years or combined cytologic/HPV testing every 5 years (if testing negative); the latter is considered the preferred strategy by some experts. (Sawaya GF, Huchko MJ. Cervical cancer screening. *Med Clin North Am*. 2017;101(4):743–753.)

18. C. GDM, or diabetes diagnosed in pregnancy, complicates about 7% of pregnancies. Screening for GDM is routinely recommended between 24 and 28 weeks of gestation in women age  $\geq 25$  years and in those with recognized risk factors (e.g., obesity, family history of diabetes). The recommended screening test is a 50-g oral glucose load; a 1-hour glucose level of  $\geq 130$  to 140 mg/dL is considered abnormal and warrants a 3-hour 100-g oral glucose tolerance test (with glucose levels checked fasting and at 1, 2, and 3 hours after glucose load); two or more abnormal values on this test are considered diagnostic of gestational diabetes. Nutritional counseling is important in this setting; the majority of women with GDM are successfully managed with diet alone. Close attention to glucose levels is important. Treatment of gestational diabetes (with diet and insulin if needed) has been shown to significantly reduce the risk of serious perinatal complications. If fasting or postprandial sugars are inadequately

controlled with diet, medication is needed. Insulin has been the standard therapy, although glyburide and metformin have also been reported to be effective and safe in women with GDM. Glucose levels return to normal in the vast majority of women with GDM immediately after the pregnancy, but women who have had this condition are at significantly increased risk for later development of DM. Randomized trial data have shown that lifestyle changes (diet and exercise) or metformin therapy reduce the risk for development of type 2 DM among women with impaired glucose tolerance, including those with a history of GDM; sulfonylureas are not used for diabetes prevention. (Immanuel J, Simmons D. Screening and treatment for early-onset gestational diabetes mellitus: a systematic review and meta-analysis. *Curr Diab Rep.* 2017;17(11):115. Mack LR, Tomich PG. Gestational diabetes: diagnosis, classification, and clinical care. *Obstet Gynecol Clin North Am.* 2017;44(2):207–217.)

Skin findings can be separated into two types: primary and secondary lesions. A primary lesion is one in which the inciting process or pathology is still discernible, such as the vesicle associated with dermatitis herpetiformis, the plaque of psoriasis, or the macule of vitiligo. Secondary lesions are those that have evolved or have been manipulated by the patient, such as excoriation, crusts, or ulcerations. See [Tables 102.1 and 102.2](#) for a complete summary of lesion descriptions.

The most common therapeutic approach in dermatology involves the use of topical medicaments applied directly to affected skin. The main base used for most medicaments is white petrolatum. Ointments, creams, and lotions, whether compounded as a prescription or as an over-the-counter product, are petrolatum based. An ointment has no water added and thus does not need a preservative. A cream is petrolatum with added water to make it more cosmetically elegant and

easier to rub into the skin. A lotion is a cream with even more water content. All products with water added require a preservative to prevent bacterial and/or fungal overgrowth plus a masking fragrance. Many of these added chemicals can provoke allergic contact dermatitis (discussed further later). Ointments are the most protective and moisturizing for the skin, although the least accepted by patients because of their greasy nature. Creams are most commonly prescribed for their preferable absorption profile. Other bases include solutions, foams, and gels, which are easier to apply on hair-bearing areas.

### Premalignant and Malignant Skin Neoplasms

Skin cancer is a common problem related to ultraviolet (UV) radiation exposure. At the rates currently seen in the

**TABLE 102.1** Primary Lesions

Lesion Type	Description	Examples/Causes
Macule/patch	Flat, nonpalpable color change in the skin, patches are >10 mm	Lentigo or "freckle"
Papule	Palpable elevation in the epidermis, ≤5 mm	Verruca vulgaris, nevi
Plaque	Palpable flat topped raised lesion, >5 mm	Psoriasis, eczema
Pustule	Pus-filled, discrete lesions	Acne, folliculitis
Vesicle	A fluid-filled lesion, ≤5 mm	Allergic contact dermatitis, dyshidrotic eczema, dermatitis herpetiformis
Bulla	A larger fluid-filled lesion, >5 mm	Bullous pemphigoid, bullous impetigo
Nodule	A lesion with a deep component, into the dermis; also may be exophytic	Squamous cell carcinoma, epidermal inclusion cyst
Wheal	Elevated, erythematous papules or plaques secondary to localized dermal edema	Urticaria ("hives")
Telangiectasia	Superficial small permanently dilated blood vessel	Rosacea
Petechia	Nonblanchable discrete pinpoint focus of hemorrhage	Infections (meningococcemia/Rocky Mountain spotted fever), vasculitis, platelet dysfunction
Purpura	Larger area of hemorrhage, may be palpable or macular	Vasculitis
Ecchymosis	Large macular hemorrhagic area	Trauma

**TABLE 102.2** Secondary Lesions

Lesion	Description	Example
Erosion	Open area with partial thickness loss of epidermis	Impetigo, pemphigus foliaceus
Ulceration	Full-thickness loss of epidermis; heals with scar	Bullous pemphigoid, pyoderma gangrenosum
Excoriation	Linear, caused by scratching, usually partial epidermal thickness only	Any condition that is pruritic, causing scratching
Crust	Dried serum and blood on wound surface	“Scab” following an acute injury
Scar	Pink to white patch to plaque caused by injury	Surgical wound
Lichenification	Thickened epidermis with characteristic cross-hatched pattern	Lichen simplex chronicus
Atrophy	Dermal thinning	Long-term steroid use, lupus, scleroderma

United States, 1 in 5 people will develop a skin cancer in their lifetime (1 in 3 for Caucasians). Skin cancer rates are directly correlated with the amount of annual UV radiation a person receives. Exposure to UV radiation causes mutations most commonly in the *p53* tumor suppressor gene. In mice, UV carcinogenesis is highest at 293 nm, with lesser peaks at 354 and 380 nm. Melanoma risk is increased with exposures to ultraviolet B (UVB) in the 290- to 320-nm range. Ultraviolet A (UVA) waves are of higher energy and penetrate deeper into the dermis, whereas UVB tends to penetrate only in the epidermis. UVA damage to collagen in the dermis is responsible for photoaging, such as facial lines/creases (rhytids), lentigines, and other pigmentary changes on sun-exposed skin.

Actinic keratoses (AKs) are premalignant lesions noted as rough/gritty or keratotic papules or patches on sun-exposed surfaces, such as the scalp (Fig. 102.1), face, ears, neck, upper chest/back, and extensor arms/legs. They are sometimes easier to identify by palpation than by visual inspection. AKs often remain stable or even regress over time. Whereas a small percentage of AKs will transform to squamous cell carcinoma (SCC) (Fig. 102.2), it is estimated that 60% of all SCCs are derived from an AK. Any keratotic papule that begins to grow, thicken, and become tender, especially with pressure, should be biopsied as a potential SCC.

The mainstay of therapy for AK is liquid nitrogen (LN<sub>2</sub>) destruction. Most thin papules and patches, especially on the face, require only one cycle of 4- to 5-second freezing. Thicker papules on noncosmetically sensitive areas can be treated for longer and with a second cycle of LN<sub>2</sub>. Other treatment modalities include electrocautery/curettage, chemical peels, dermabrasion, and topical medical therapy. Currently, topical treatments of AK include 5-fluorouracil, diclofenac, topical retinoids, ingenol mebutate, and imiquimod. 5-Fluorouracil is a topical chemotherapeutic agent that causes destruction of cells growing at an increased rate. Imiquimod is a topical immunomodulator that increases keratinocyte production of interferon- $\gamma$  and interleukin (IL)-2 through activation of toll-like receptor 7. Ingenol mebutate (derived from the *Euphorbia peplus* plant) induces

• **Fig. 102.1** Multiple hyperkeratotic papules on the bald scalp of a patient with actinic keratoses. Rapid growth or tenderness should prompt biopsy for transformation to squamous cell carcinoma.

cell necrosis. Diclofenac, a topical inhibitor of cyclooxygenase, is useful for some patients. Treatment regimens vary by the agent and preference of the clinician.

### Nonmelanoma Skin Cancers

The most common cancer of the skin is basal cell carcinoma (BCC; Fig. 102.3), which classically presents as pearly telangiectatic papules, sometimes centrally ulcerated, on sun-exposed sites. Although prognosis is excellent for BCC, with exceedingly rare instances of metastasis, it is important not to neglect them because BCCs can be locally destructive to skin and underlying muscle and bone. A rare genodermatosis called basal cell nevus syndrome (Gorlin syndrome) is an autosomal dominant condition in which BCCs develop early in life (age <20 years). These patients may develop

• **Fig. 102.2** Biopsy-proven squamous cell carcinoma presenting as a tender hyperkeratotic nodule.

• **Fig. 102.3** Pearly nodule on the lip. This is a typical nodular basal cell carcinoma.

medulloblastoma and ovarian or cardiac fibromas at an early age and can present with frontal bossing/macrocephaly, odontogenic keratocysts, palmar/plantar pits, calcification of the falx cerebri, and bifid ribs.

SCC is less common than BCC, other than in chronically immunosuppressed patients or patients who received psoralen/UVA therapy for psoriasis. This cancer also develops because of chronic sun exposure. SCC metastasis rate for SCC arising in normal sun-exposed skin is 0.5% to 3%, whereas SCC arising in mucocutaneous locations, burn scars, x-ray scars, or foci of chronic osteomyelitis has a rate of metastasis of 10% to 30%. Rate of SCC is increased significantly for chronically immunosuppressed patients. In kidney and heart transplant patients, the risk of SCC was increased 65-fold. The risk of SCC in this population increases from 7% at 1 year to 45% after 11 years and 70%

• **Fig. 102.4** Typical erythematous plaque of Bowen disease, squamous cell carcinoma in situ.

after 20 years of immunosuppression. High-risk SCCs (for metastasis and death) include tumors >2 cm diameter, tumors thicker than 4 mm, moderately/poorly differentiated SCC, location on ears/lips/hands/feet/genitals, and perineural or lymphovascular invasion.

Bowen disease (SCC in situ; Fig. 102.4) appears as a scaly, erythematous plaque, rather than the discrete keratotic papule of AK. Invasive SCC can present as an erythematous, hyperkeratotic papule or nodule that occasionally ulcerates. Keratoacanthomas (KAs) are rapidly growing dome-shaped nodules with a characteristic central core of keratin; some practitioners believe that KAs represent SCC variant, whereas others consider them benign. Many KAs spontaneously regress without therapy, although there also have been multiple cases of metastatic SCC related to them. For this reason, it is general practice to reexcise KAs.

There are multiple methods for treatment of nonmelanoma skin cancers (NMSCs). Treatment ranges from the same topical therapies used for treating AKs (imiquimod or 5-fluorouracil) for early and thin lesions, to electrodesiccation and curettage, cryotherapy with LN<sub>2</sub>, simple excision, or Mohs surgery. The most definitive method for ensuring complete removal of an NMSC is the technique attributed to Dr. Frederic Mohs. This procedure involves histopathologically examining the entire lateral and inferior margins of the fresh frozen surgical specimen to ensure complete removal of a tumor before closure of the surgical defect. For extensive tumors in older individuals, consultation with a radiation oncologist may also be helpful for consideration of local radiation therapy.

## Melanoma

There are four common types of melanoma: (1) superficial spreading (Fig. 102.5) (~70% of melanomas); (2) nodular (~15%); (3) lentigo maligna melanoma (~10%); and (4) acral lentiginous melanoma (~5%). Amelanotic melanoma and desmoplastic neurotrophic variants of melanoma are much rarer. Superficial spreading melanomas are the most common in individuals with lighter skin types. Nodular

• **Fig. 102.5** Superficial spreading melanoma on the preauricular cheek. The depth was 1.6 mm, and it was metastatic to the lymph nodes at the time of biopsy.

**TABLE 102.3 ABCDE Criteria for Pigmented Lesions Suspicious for Cutaneous Melanoma**

	Description
A	Asymmetry of the lesion
B	Borders are irregular or hazy
C	Color within the lesion is irregular, or there are multiple colors present
D	Diameter >6 mm (a pencil eraser)
E	Evolution of the lesion (growing/changing rapidly)

melanoma tends to develop in those age >60 years and arises from normal-appearing skin (not from a preexisting nevus), especially in men. Nodular melanoma is faster growing and more aggressive compared with other types of cutaneous melanoma. Lentigo maligna melanoma develops most often on the sun-exposed surfaces of the face of older individuals. Initially, it can be mistaken for a benign age spot (lentigo). Pigmented patches that are changing color or growing should be considered for biopsy. Sometimes multiple samples are necessary to increase sampling yield for clinical suspicious lentigo maligna melanoma. Acral lentiginous melanomas account for 5% of melanomas overall, but in Asian races and people of darker skin types, it accounts for about 50% of melanoma cases. Clinical features of melanoma can be summarized by the ABCDE criterion (Table 102.3).

Melanoma grading is determined histopathologically. The most important feature for staging is the Breslow thickness. Melanomas that are limited to the epidermis (no dermal invasion) are considered in situ. Invasive melanomas are classified by their depth of invasion, presence of ulceration,

• **Fig. 102.6** Multiple brown macules on the back. Note the larger, darker thin papule on the right upper back that warranted biopsy (pathology: dysplastic nevus with severe cytologic atypia; reexcision was recommended).

and rate of mitoses. The depth of a melanoma invasion is conveyed both in millimeters (Breslow thickness) and by level of invasion of the anatomic layers of the skin (Clark level). Staging includes pathologic information about the primary melanoma as well as information obtained from sentinel lymph node biopsy, if warranted. Stages are determined by the American Joint Committee on Cancer guidelines. Recent published data demonstrated that for high-risk stage III melanoma, ipilimumab as adjuvant therapy at a dose of 10 mg/kg IV every 3 weeks for four doses, then 10 mg/kg every 12 weeks for up to 3 years resulted in significantly higher rates of recurrence-free survival, overall survival, and distant metastasis-free survival than placebo.

## Benign Skin Growths

### Nevi

Nevi are benign hamartomas of melanocytes within the epidermis and/or dermis. Histopathologically, common types are junctional nevi (flat, with melanocytes only in the epidermis), intradermal nevus (nests of melanocytes only in the dermis; appears as a papule, with varying pigmentation, but usually pink or skin-colored), and compound nevus (combines both types of epidermal and dermal nevus). Atypical or dysplastic nevi have clinically atypical features that often prompt biopsy. Histologic atypia of dysplastic nevi are graded as mild, moderate, or severe based on architectural and cytologic features of melanocytes. Mildly atypical nevi are often not treated further. Moderately atypical nevi have traditionally been reexcised, although recent data suggest that reexcision does not lead to upgrading of the diagnosis. For this reason, there is an increasing trend toward close clinical monitoring of moderately atypical nevi. Severely dysplastic nevi are universally reexcised to prevent potential progression to melanoma (Fig. 102.6).

• **Fig. 102.7** Stuck-on verrucous plaque. This is a typical seborrheic keratosis.

### Seborrheic Keratosis

Seborrheic keratosis (SK), inherited in an autosomal dominant fashion, is a very common papule or plaque found on almost every skin surface of older adults (Fig. 102.7). There are multiple subtypes, and they can vary greatly in morphology, but the clearest identifying feature is their somewhat warty, greasy, and stuck-on appearance. *Dermatosis papulosa nigra* is a variant of SK, identified as dark brown to black smooth stuck-on papules in the head/neck area of darker-skinned individuals; these occur at a younger age than classic SKs. Inflammatory or malignancy-related SKs can occur. The sign of Leser-Trélat refers to explosive, new appearance of hundreds of SK lesions in the distribution of skin lines (“Christmas tree” distribution also seen in pityriasis rosea, see later) associated with gastrointestinal malignancy. SKs do not need to be treated but can be removed with LN<sub>2</sub> or curettage if irritated or inflamed.

The acrochordon is a benign skin-colored pedunculated papule seen most commonly in areas of friction, such as the neck, axillae, groin, and inframammary areas of middle-aged and older adults. There is no malignant potential. Tags frequently occur in obese or prep-diabetic individuals, often in association with *acanthosis nigricans* (velvety hyperpigmented plaque on the neck, axillae, and groin). In some patients, multiple tags can be a marker of impaired carbohydrate metabolism. Skin tags can occur more frequently in pregnancy and Birt-Hogg-Dubé syndrome (a genodermatosis characterized by renal cell carcinoma and characteristic skin lesions, including increased numbers of skin tags).

### Keratin-Filled Cysts

Hair follicle–derived cysts are common in the skin and on the scalp. Epidermal inclusion cysts (EIC; also referred to as *sebaceous cysts*, although not sebaceous in origin) are subcutaneous, mobile nodules with central (or offset) punctum commonly seen on the trunk and upper extremities (Fig. 102.8). EICs are the most common type of cutaneous cysts, and patients are often able to manipulate the nodules to express off-white, smelly keratinaceous “cheesy” debris. Pilar cysts (also known as wens or trichilemmal cysts) are almost exclusively seen on

• **Fig. 102.8** Subcutaneous mobile nodule with central punctum (black dot) on the left medial breast.

• **Fig. 102.9** Comedones and inflammatory papules of acne vulgaris. (From Bangal R. File: acne vulgaris on a very oily skin.jpg. <https://commons.wikimedia.org/w/index.php?curid=47832556>. Accessed September 12, 2017.)

the scalp and appear as slightly deeper in the skin without epidermal connection. The EIC is derived from the infundibular portion of the hair follicle, and the pilar cyst is likely derived from the epithelium of the hair follicle distal to or at the insertion of the sebaceous duct. In patients with multiple EICs on atypical locations (lower extremities/scalp/face), occurring at an early age (around puberty), the diagnosis of familial adenomatous polyposis (Gardner syndrome) should be considered. Treatment of both types of cysts is elective surgical excision. Noninflamed nodules do not require treatment.

## Acne and Rosacea

### Acne Pathogenesis and Therapy

Acne vulgaris is nearly ubiquitous among teens and young adults and manifests with comedones ± inflammatory papules and pustules in areas of higher sebaceous gland density (face, upper chest, and back; Fig. 102.9). Development of acne tends to coincide with onset of adrenarche. Comedones are the

primary lesions of acne, and their pathogenesis is promoted by (1) hyperproliferation of the follicular epithelium with subsequent plugging; (2) excess sebum production; and (3) presence of *Propionibacterium acnes*, all within an inflammatory milieu mediated by the innate immune system. Androgens are hypothesized to play a role in the follicular plugging and excess sebum production; of note, individuals with nonfunctioning androgen receptors do not develop acne. *P. acnes* in the follicle produce proinflammatory mediators that stimulate toll-like receptor 2 on neutrophils and monocytes, with subsequent production of IL-1, IL-6, IL-8, and tumor necrosis factor-alpha (TNF- $\alpha$ ), which promote further inflammation.

New research is revealing acne to be an inflammatory skin disease, even in patients with only comedonal presentation. Acne is graded mild, moderate, or severe based on clinical appearance of comedones versus inflammatory papules and pustules versus cysts. Nodulocystic acne has severe inflammatory deep-seated papules, pustules, nodules, and comedones with residual scarring. Acne conglobata is a rare severe type of nodulocystic acne with multiple nodules interconnected by burrowing between and severe scarring/disfigurement. Pyogenic arthritis, pyoderma gangrenosum and acne syndrome is the combination of pyoderma gangrenosum, acne conglobata, and aseptic arthritis that was reported in one kindred. Other causes of acne include polycystic ovarian syndrome, congenital adrenal hyperplasia, and oral medications (e.g., lithium, antiepileptics, steroids, epidermal growth factor receptor inhibitors, and iodides).

Treatment of acne attempts to address one or more of the underlying causes and begins with topical regimens, with escalation to oral medications based on acne severity. Most patients have tried over-the-counter salicylic acid (comedolytic) and benzoyl peroxide (antimicrobial/antiinflammatory) preparations before seeking medical attention. For mild acne, first-line approach involves topical preparations, such as retinoids (i.e., adapalene, tretinoin, and tazarotene), clindamycin and clindamycin/benzoyl peroxide combinations, sodium sulfacetamide, or azelaic acid. For moderate to severe acne, an oral antibiotic from the tetracycline (TCN) family (TCN, doxycycline, or minocycline) or second-line agents, such as a penicillin derivative or sulfa, is added. Topical retinoids are comedolytic and antiinflammatory. Topical antibiotics are used for their anti-*P. acnes* properties, and salicylic acid/benzoyl peroxide are active against *P. acnes* but without reports of resistance. Oral antibiotic therapy is used against *P. acnes* as well as for its antiinflammatory properties. Isotretinoin (oral retinoid) is US Food and Drug Administration (FDA)-approved for the treatment of nodulocystic acne. Isotretinoin is severely teratogenic and should be used with caution in females of childbearing potential. Patients on isotretinoin are enrolled in a federally mandated pregnancy prevention program (iPledge) and require monthly clinical follow-up while on the medication.

### Rosacea/Periorificial Dermatitis

Rosacea is a disease of facial flushing, papules, pustules, and telangiectasias most commonly observed on the central face

**TABLE 102.4** Rosacea Subtypes

Type	Description
Erythematotelangiectatic	Red cheeks, small telangiectasias
Papulopustular	Papules and pustules in addition to erythema and telangiectasias, often involving the central one-third of the face
Phymatous	Overgrowth of soft tissue, most usually nose (rhinophyma)
Ocular	Confined to eyelids/ocular surface. For example, blepharitis, conjunctivitis, corneal keratitis. May coexist with cutaneous rosacea.

of middle-aged women. There are four subtypes that are summarized in [Table 102.4](#). Therapy for erythematotelangiectatic and papulopustular types of rosacea includes avoidance of food and environmental triggers (e.g., spicy foods, alcohol, chocolate), a broad-spectrum sunscreen (UVA and UVB) daily, topicals (e.g., metronidazole cream, azelaic acid, tretinoin, or sodium sulfacetamide), oral antibiotics (doxycycline or minocycline), and lasers for the telangiectatic component. Severe cases of rosacea respond well to low-dose isotretinoin, although this is not an FDA-approved indication. Treatment of phymatous rosacea includes surgical or laser removal of excessive connective tissue. Ocular rosacea is treated with oral antibiotics and ocular topical preparations.

Periorificial dermatitis is a variant of rosacea, characterized by inflammatory papules and pustules around the orifices (eyes, nose, mouth, and, rarely, ears). Treatment with oral TCN derivatives or topical metronidazole is usually successful. Recurrences do occur, requiring continued therapy.

## Dermatitis

### Atopic Dermatitis

Atopic dermatitis (AD) is a common pruritic skin condition that starts in early infancy and may persist for a lifetime. It is commonly seen as part of the atopic triad, which also includes asthma and seasonal allergies, and is thought to be driven by superantigen stimulation. In some developed countries, the rate is as high as approximately 18%. Pathogenesis is unknown, but a link to filaggrin mutations has been shown; those with filaggrin defects have a relative risk of 3 to develop AD. Heterozygotes for a known mutation have a 60% chance, and homozygotes have a 90% chance, of having AD. Filaggrin mutations predispose to asthma, but only in people who have AD as well as high IgE levels. Chronic colonization of the skin with *Staphylococcus aureus* can exacerbate AD and make it more resistant to treatment. A spectrum of findings is present in many patients with AD

and their families, including asthma, allergic rhinitis/seasonal allergies, urticaria, increased production of IgE, and acute allergic reactions to foods.

Skin findings evolve over the course of the disease, although xerosis and pruritus are present in all stages. Infants develop erythematous scaly and vesicular plaques initially in the antecubital/popliteal fossae and/or cheeks, but AD can progress to involve the entire body, with the diaper area generally spared. Children and adults develop similar morphologic lesions, but their greater ability to scratch can lead to lichenification and prurigo nodules of the skin. AD often resolves by adolescence, although predisposition for hand and eyelid dermatitis may remain.

Therapy for AD depends on the severity of disease. Topical emollients (containing ceramides) should be a mainstay of skin care because xerosis marks the beginning of active dermatitis in many cases. In patients with suspected bacterial colonization, dilute bleach baths two to three times weekly followed by topical steroid application may be helpful as a method to decolonize surface bacteria. Eczema on the face should be treated with mild topical corticosteroids (e.g., desonide or hydrocortisone acetate), whereas moderate-potency agents (e.g., triamcinolone acetonide, hydrocortisone butyrate) can be applied to affected areas on the trunk and extremities. For moderate to severe cases (especially on the face) that have failed initial topical therapy, a steroid-sparing topical, such as tacrolimus (Protopic) or pimecrolimus (Elidel) should be considered. A high-potency topical steroid (e.g., clobetasol or betamethasone) can be used for thicker plaques on the trunk/extremities (do not apply to face or intertriginous areas). For severe flares, a prednisone taper based on weight with dose reductions at 4- to 5-day intervals may halt a flare (e.g., 40 mg daily  $\times$  4 days, 30 mg daily  $\times$  4 days, 20 mg daily  $\times$  4 days, 10 mg daily  $\times$  4 days, then stop). Short tapers, such as a 5- or 7-day course, are less helpful because many cases will flare after the medication is stopped. Narrow-band UVB therapy two to three times weekly also can be very helpful for decreasing dermatitis and pruritus in severely affected atopic patients. In severe cases that do not clear with oral steroids (or if phototherapy is not an option), other immunosuppressive agents may be necessary (e.g., cyclosporine, mycophenolate mofetil, or methotrexate).

Two nonsteroidal medications have recently been FDA approved for atopic dermatitis. Crisaborole ointment 2% applied twice daily is a phosphodiesterase-4 inhibitor approved for treatment of mild-to-moderate atopic dermatitis in patients  $>2$  years old (FDA approval December 2016). Dupilumab (600 mg subcutaneously once, then 300 mg subcutaneously every other week) is a monoclonal antibody that inhibits IL-4 and IL-13 signaling and has been approved for adults with moderate-to-severe atopic dermatitis (FDA approval March 2017).

### Contact Dermatitis

There are many chemical and natural botanic agents that cause contact dermatitis, which is divided into two groups:

allergic contact dermatitis (ACD) (~20% of cases) and irritant contact dermatitis (ICD) (~80%). ICD is caused either acutely by strong irritants, such as alkalis and acids that damage the epidermis directly, or by chronic, longer-term contact with weaker irritants such as water or detergents. Patients with an atopic background are more likely to develop ICD, especially in the form of hand eczema. ACD is a type I immediate or type IV delayed-type reaction. Contact urticaria (type I reaction) can occur from a variety of chemicals (cinnamic aldehyde, benzyl alcohol) and plants (such as nettles). Delayed-type hypersensitivity (type IV) usually occurs because of small chemical compounds (haptens) that are  $<500$  Da in size. Haptens bind cutaneous proteins that are recognized and phagocytized by epidermal Langerhans cells or dermal dendrocytes, which then migrate to a regional lymph node and are presented to T cells, thus sensitizing the individual to the hapten. If the individual contacts the hapten again, it is recognized, and a T-cell-mediated type IV reaction develops with characteristic erythema, pruritus, and vesiculation within 24 to 72 hours after exposure.

In some cases, sunlight (often UVB 290–320 nm) acts on drugs or topically applied chemicals, altering the molecules and creating haptens. Drugs, such as 6-methylcoumarin, salicylanilide, hydrochlorothiazide, chlorpromazine, nonsteroidal antiinflammatory agents, sulfonamides, and 5-methoxypsoralen, can all induce photoallergic contact dermatitis. Common topically applied chemicals causing photoallergic contact dermatitis are sunscreens, such as those derived from paraaminobenzoic acid or benzophenones, although this is exceedingly rare. Fragrances (musk ambrette or oil of Bergamot) or other topical agents (e.g., benzocaine or neomycin) may also cause photoallergic contact dermatitis.

Phototoxic reactions to UV light (most commonly UVA 320–400) can occur to anyone who comes into contact with or ingests these substances. No sensitizing period is required. Presentation usually looks like intense sunburn. Common culprits include amiodarone, chlorpromazine, fluoroquinolones (nalidixic acid, ciprofloxacin), nonsteroidal antiinflammatory drugs (NSAIDs) (piroxicam, benoxaprofen), tetracyclines (demeclocycline  $>$  doxycycline/tetracycline), and plants containing furocoumarins, including the families Rutaceae (lime, lemon, bergamot, bitter orange, gas plant, burning bush), Apiaceae (*Umbelliferae*) (carrots, cow parsley, celery, wild chervil, parsnip, fennel, dill, hogweed), and *Moracea* (figs).

### Drug Rashes

A multitude of oral medications can cause morbilliform or exanthematous dermatitis. Although almost any type of morphology can be seen (bullous, urticarial, etc.), morbilliform reactions are most common. A drug reaction should be suspected in cases where a symmetric dermatitis develops soon after starting a new medication (typically 7–14 days). Common causes include antibiotics and sulfa-based diuretics, NSAIDs, allopurinol, chemotherapeutic agents, anticonvulsants (phenytoin, carbamazepine, phenobarbital), and psychotropic agents, although almost any medication can cause dermatitis.

Most drug reactions are self-limited and not life threatening, but important findings to watch for include blistering and mucous membrane involvement. The Stevens-Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN) spectrum causes significant morbidity and potential mortality. SJS initially presents as three-zone target lesions (dusky, purple center, surrounding white, lighter skin, and an outer ring of erythema), morbilliform dermatitis, and mucosal erosions/bullae; these can progress to full-thickness skin sloughing. TEN does not have the typical target lesions but will begin with painful erythematous skin (similar to a sunburn), followed by full-thickness epidermal sloughing. Both conditions should be managed as inpatients, preferentially in a burn unit. It is imperative to quickly and accurately identify the culprit medication and discontinue it. Treatment is supportive; some believe that intravenous immunoglobulin is useful, although this is controversial. Use of systemic corticosteroids is also controversial, as there is concern for increased risk of infection in patients with SJS.

Anticonvulsant hypersensitivity syndrome is a potentially life-threatening complex of symptoms caused by aromatic anticonvulsants (phenytoin, phenobarbital, and carbamazepine). Symptoms include fever, pharyngitis, SJS-like dermatitis, and lymphadenopathy and laboratory abnormalities, including hepatitis, nephritis, and leukocytosis with eosinophilia. Presentation is often within 3 weeks after starting the medication or dose increase, although it can occur 3 months or more into therapy. It may occur as frequently as 1:1000 to 1:10,000 exposures. It is a dose-independent, idiosyncratic reaction requiring complete avoidance of all aromatic anticonvulsants. Alternatives to the aromatic anticonvulsants include levetiracetam and valproic acid.

## Autoimmune Connective Tissue Diseases

There are multiple diseases that are within the spectrum of “connective tissue diseases.” Most of these syndromes have specific criteria for diagnosis, but the presentation initially may show overlaps between the syndromes. The most common autoimmune connective tissue diseases are lupus erythematosus, morphea, systemic sclerosis, and dermatomyositis.

### Lupus Erythematosus

The most common autoimmune disease is the lupus erythematosus spectrum, which includes cutaneous lupus (acute, subacute, and chronic) and systemic lupus erythematosus (SLE). Skin findings can be present in SLE that are consistent with all three types of cutaneous lupus in any patient. SLE presents with malar rash (55%–90%) and polyarthralgias; other presenting systemic symptoms include weight loss, anorexia, fever, fatigue, and malaise. It is more commonly seen in females (90%) and in blacks (1:250) versus Caucasians (1:1000). The survival rate is 75% to 85% (10-year) and 70% (20-year). Four of 11 criteria are necessary for diagnosis of SLE, according to the American Rheumatologic Association, and are summarized in [Table 102.5](#) (mnemonic “MD SOAP BRAIN”).

Acute cutaneous lupus erythematosus presents with erythema of the malar cheeks and nose, often with edema and fine scale ([Fig. 102.10](#)). This is the classic cutaneous finding in patients with SLE (see earlier). Sun exposure can cause flares of systemic disease, and strict photoprotection is imperative. Subacute cutaneous lupus erythematosus (SCLE) lesions are pink, scaly plaques resembling psoriasis or, sometimes, annular lesions more similar to erythema multiforme.

**TABLE 102.5** Criteria for Diagnosis of Systemic Lupus Erythematosus: 4 of 11 Required

Finding	Description
Malar rash	55%–90% of patients with SLE. On cheeks/nose, sparing eyelids/nasolabial folds.
Discoid rash (chronic cutaneous lupus)	Discoid skin lesions as below. ~20% of patients with SLE will have these lesions.
Serositis	Pleuritic pain or rub, pleural or pericardial effusion, pericarditis in 20%–30% of patients; myocarditis less common.
Oral ulcers	Aphthous and genital ulcerations. Painless or painful.
Arthritis	Most common finding in SLE. Polyarticular. Most common proximal interphalangeal and metacarpophalangeal joints of hands.
Photosensitivity	Sun exposure causes skin rash and potentially systemic flare.
Blood disorder	Anemia (of chronic disease or hemolytic), thrombocytopenia, leukopenia, lymphopenia.
Renal disorder	May not have symptoms until renal failure or nephrotic syndrome present. Follow BUN/Cr.
Antinuclear antibody	Presence of antibodies against nuclear DNA-histone complexes. 95% sensitive but not specific. Double-stranded DNA more specific for lupus.
Immunologic test positive	Anti-dsDNA or anti-Smith antibody, positive antiphospholipid antibody, false-positive serologic syphilis test (confirmed by FTA-ABS).
Neurologic disorder	Seizures and neuropathies > psychosis.

BUN/Cr, Blood urea nitrogen/creatinine; dsDNA, double-stranded DNA; FTA-ABS, fluorescent treponemal antibody absorption; SLE, systemic lupus erythematosus.

• **Fig. 102.10** Erythematous patches on forehead, cheeks, and chin. Note the malar prominence (and nasolabial sparing) and ulcerations on lower lip. Systemic lupus erythematosus.

• **Fig. 102.11** Pink annular thin scaly plaques on dorsal arms of patient with subacute cutaneous lupus erythematosus.

Papulosquamous-type lesions are more often seen on the trunk and extensor surfaces of the upper extremities and dorsal hands (Fig. 102.11), with sparing of face, flexor surface of arms, and below the waist. The annular-type of SCLE involves the same distribution but typically starts as discrete erythematous papules that become confluent arcuate or polycyclic plaques. Chronic cutaneous lupus erythematosus (CCLE) is also referred to as discoid lupus. It classically presents as erythematous scaling papules or plaques with follicular plugging (“carpet-tacking”) on the scalp, face, and ears. Long-standing plaques have central atrophy, scarring, and hypopigmentation and hyperpigmentation. Whereas only 5% to 10% of patients with CCLE will develop SLE, CCLE is one of the diagnostic criteria for SLE (see Table 102.5).

The primary laboratory test for diagnosis of lupus is the antinuclear antibody (ANA). This test is 95% sensitive but not specific to lupus. The extracted nuclear antibodies, such as double-stranded DNA, anti-Smith, anti-RNP, and anti-Ro/La, are more specific for lupus. ANA reaction patterns are summarized in Table 102.6.

### Autoimmune Disorders of Skin Thickening

Autoimmune diseases of skin thickening include morphea and systemic sclerosis. Morphea is an inflammatory disease of the dermis and subcutis that presents with scar-like thickening of the skin in linear or asymmetric patchy distribution. Although it is frequently referred to as *localized scleroderma* (and can be histologically indistinguishable from scleroderma), morphea is a unique clinical entity that is not associated with the systemic findings of scleroderma (systemic sclerosis). Morphea affects quality of life through symptoms of joint mobility restriction, pain, and skin tightness.

Systemic sclerosis (SSc) (scleroderma) is a rare autoimmune connective tissue that affects women more than men; there is no racial predilection. It is caused by extra collagen deposition in the skin and internal organs, leading to skin thickening (sclerosis) and multiple internal manifestations. Skin findings begin as edematous plaques that progressively

**TABLE 102.6 Antinuclear Antibody Reaction Patterns**

Pattern	Target Site	AB Association	Disease Association
Homogeneous	Native DNA/dsDNA RNP Histone	Anti-DNA Antihistone	SLE Drug-induced LE
Peripheral/rim	Nuclear membrane	Anti-DNA, antilaminin	SLE (most specific)
Particulate (clumpy dots)	Smith antigen		SLE
Fine speckled	RNP		Mixed connective tissue disease
Large speckle		Anti-Ro	
Discrete speckled (tiny dots)	Kinetochore	Anticentromere	CREST
Nucleolar (round pebbles)			Scleroderma

CREST, Calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia; dsDNA, double-stranded DNA; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus.

become indurated and then atrophic/bound-down. Major criteria for SSc include skin sclerosis affecting face, neck, and/or arms. Minor criteria are sclerodactyly, erosions, atrophy of the fingertips, and bilateral lung fibrosis. The major subtypes of SSc are diffuse and limited (CREST is limited SSc: calcinosis cutis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and mat telangiectasias). Deaths related to SSc are most commonly from pulmonary hypertension, lung fibrosis, and renal/cardiac disease.

The pathogenesis of SSc is incompletely understood, although immune system activation is believed to play a role in sclerosis. Antigen-activated T cells infiltrate the skin, producing profibrotic IL-4, and B cells may also contribute to fibrosis. Some exogenous agents are thought to precipitate SSc (Schwartz and Dzikowska-Bartkowiak, 2011). Laboratory diagnosis of SSc is most specific with the anti-topoisomerase I DNA (SCL-70) antibody, with two-thirds of patients with SSc and lung fibrosis having this antibody positivity. Anticentromere antibodies are diagnostic for CREST syndrome and are associated with less frequent involvement of the heart, kidneys, and nonfibrotic pulmonary changes. Other antibodies include antifibrillar, Th-RNP, and PM-Scl. Anti-PM-Scl antibodies are seen in patients with a polymyositis/SSc overlap syndrome and 3% to 10% of patients with SSc alone.

Evidence for the treatment of cutaneous SSc is largely based on observational studies because of the rarity of the disease. The results of the European Scleroderma Observational Study published recently using methotrexate, mycophenolate mofetil, or cyclophosphamide

immunosuppressants for early dcSSc suggest that overall benefit is modest over 12 months.

## Dermatomyositis

Dermatomyositis is a rare disease, presenting in both children and adults. Presentation of proximal muscle weakness with characteristic rashes is classic. Cutaneous findings include facial erythema with violaceous patches on the eyelids (heliotrope rash), scaling plaques on metacarpophalangeal and interphalangeal joints with sparing of space between joints (Gottron papules), and an erythematous papulosquamous. Other common although not specific skin findings include poikiloderma, sun-exposed distribution, periungual telangiectasias, and ragged cuticles.

Diagnostic testing for dermatomyositis incorporates multiple hematologic tests. A positive ANA is frequently found in addition to one of the more specific antibodies for dermatomyositis. Anti-Mi-2 (antihistidyl transfer RNA synthetase) is specific for dermatomyositis, but it is not sensitive because only 25% of dermatomyositis patients have this finding. Anti-Jo-1 is more specific for polymyositis than dermatomyositis and is associated with interstitial lung disease, Raynaud phenomenon, arthritis, and rough, scaling dermatitis of the hands (mechanic's hands).

Pathogenesis of dermatomyositis is unknown, but association with internal malignancy has been recognized in adults. Age-appropriate malignancy screening is warranted in adults with new diagnosis of dermatomyositis. Other paraneoplastic skin syndromes are summarized in [Table 102.7](#).

**TABLE 102.7 Paraneoplastic Syndromes**

Condition	Description/Notes
Acanthosis nigricans	Gastric CA
Bazex syndrome	SCC of aerodigestive tract; psoriasiform and eczematous papules over fingers, toes, nose, ears; keratoderma, nail dystrophy
Dermatomyositis	Often solid tumors, GI or GU
Eruptive keratoacanthoma	Associated with immunosuppression, lupus, leukemia, leprosy, kidney transplant, photochemotherapy, thermal burns, x-ray therapy, Muir-Torre syndrome
Erythema gyratum repens	Lung cancer; rarely associated with pulmonary TB
Flord cutaneous papillomatosis	Gastric CA, presents as verrucous papillomas
Hypertrichosis lanuginosa	Lung CA, colon CA; most common location = face
Migratory thrombophlebitis	Pancreatic CA (also prostate, lung, liver, bowel, gallbladder, ovary, lymphoma/leukemia)
Necrolytic migratory erythema (glucagonoma syndrome)	Pancreatic tumor of APUD cells that secrete glucagon; low serum Zn levels, hypoaminoacidemia
Paraneoplastic pemphigus	Non-Hodgkin lymphoma, CLL, Castleman disease, sarcoma, thymoma, Waldenstrom macroglobulinemia
Pityriasis rotunda	Hepatic cancer, leukemia
Tripe palm (acanthosis nigricans)	Lung and gastric CA; honeycombed and thickened palms

APUD, Amine precursor uptake decarboxylase; CA, cancer; CLL, chronic lymphocytic leukemia; GI, gastrointestinal; GU, genitourinary; SCC, squamous cell carcinoma; TB, tuberculosis; Zn, zinc.

## Papulosquamous Diseases

*Papulosquamous* refers to the surface morphology of skin conditions comprising this differential. These lesions tend to be well-demarcated, erythematous scaly plaques. Psoriasis is the most common papulosquamous disease; others include lichen planus, pityriasis rosea, dermatophytosis, and pityriasis rubra pilaris. Some drug reactions may also have papulosquamous appearance.

Psoriasis (Fig. 102.12) affects about 2% to 3% of the population and is characterized by well-demarcated erythematous plaques with thick white (micaceous) scale, commonly on the scalp, umbilicus, gluteal cleft, elbows, and knees, although generalized involvement may also occur. Nail involvement with irregular nail pitting, thickening, onycholysis, and oil spots are also common features. Variants of psoriasis include inverse (intertriginous), guttate, generalized pustular, and palmoplantar pustulosis. Psoriasis is caused by T-cell stimulation of the epidermis, causing keratinocyte hyperproliferation without proper maturation. It is a familial condition, linked to a mutation on chromosome 6, in *PSORS1* and has a strong linkage to human leukocyte antigen (HLA)-B17.

Psoriatic arthritis occurs in 10% to 30% of those with cutaneous psoriasis. There are five subtypes of psoriatic arthritis. Symmetric arthritis is similar to rheumatoid arthritis but milder with less joint deformity, and it usually affects multiple symmetric pairs of joints. Asymmetric arthritis can affect any joint, and the hands and feet may have enlarged “sausage” digits. The classic type of psoriatic arthritis is distal interphalangeal predominant of fingers and toes, but it is only found in approximately 5% of people with psoriatic arthritis. This form can be confused with osteoarthritis, but the latter does not feature the nail changes of psoriasis. Spondylitis occurs in 5% of individuals with psoriatic arthritis and is characterized by stiffness of the neck, lower back, and sacroiliac or spinal vertebrae. Peripheral disease may present in the hands, arms, hips, legs, and feet. Arthritis mutilans is a rare destructive arthritis of the small joints of the hands and feet that results in severe joint deformity; it is associated with neck and lower back pain.

• Fig. 102.12 Pink scaly periumbilical plaque consistent with psoriasis.

Therapies vary depending on the severity of psoriasis. Mild psoriasis can often be treated with topical steroids and/or topical calcipotriene alone. UV light therapy with narrow band UVB (311–312 nm) or ingested psoralens plus UVA are helpful for more advanced cases. Methotrexate and acitretin are commonly prescribed oral medications for more severe psoriasis. Patients with the most severe disease may require combination therapy or even a biologic agent (TNF- $\alpha$  inhibitor, such as infliximab, adalimumab, etanercept, certolizumab, and golimumab). TNF- $\alpha$  inhibitors should not be used in patients with active systemic fungal or mycobacterial infections or multiple sclerosis. Other side effects with immunosuppressive agents include a potential increase in lymphomas and a lupus-like drug reaction (to TNF- $\alpha$  inhibitors). Newer biologics block other cytokines that are involved in psoriasis pathogenesis (ustekinumab inhibits IL-12 and IL-23; secukinumab and ixekizumab inhibit IL-17a).

Lichen planus (LP) is a cell-mediated immune response at the dermoepidermal junction, classically presenting as purple, polygonal papules on the flexor surfaces of the arms, white linear patches on the oral mucosa (Wickham striae) and on the genitalia. Familial LP has been linked to HLA-B7 and idiopathic LP to HLA-DR1 and DR10. LP may be limited to mucosal surfaces, causing severe ulcerations and pain, as well as an erosive vaginitis. LP has been associated with hepatitis C, chronic active hepatitis, and primary biliary cirrhosis. Medications (e.g., gold, anti-malarials, and angiotensin-converting enzyme inhibitors) have been associated with lichenoid drug eruptions that can be indistinguishable from lichen planus. Variants of LP include lichen planopilaris (a scarring alopecia) and isolated nail LP (Fig. 102.13). Treatments include topical steroids, UV therapy similar to psoriasis, systemic corticosteroids, and oral retinoids (acitretin).

Pityriasis rosea is a self-limited condition occurring frequently after a viral infection (possible association with human herpes virus 6/7). Classic presentation is that of a “herald patch,”

• Fig. 102.13 Nail-plate thinning and longitudinal ridging of nail lichen planus (toenails similarly affected). Note the thin lichenoid plaques on the dorsal fingers as only other manifestations of this patient's lichen planus (pathology was consistent with lichen planus).

a large erythematous scaling plaque on the trunk. Within a week of this lesion's appearance, multiple small, scaly dull red plaques develop on the extremities and trunk in a "Christmas tree" distribution along skin lines. A fine "collarete" of scale is noted at the edge of the plaques. This condition resolves in 3 to 6 weeks and only requires therapy for the mild-to-moderate pruritus that may occur. Moderate-potency topical steroid and/or oral antihistamine is frequently sufficient, although phototherapy may be necessary for more extensive disease.

Pityriasis rubra pilaris (PRP) is an idiopathic papulosquamous disease characterized by red to orange scaling plaques, palmoplantar keratoderma, and keratotic follicular papules. A classic feature is the uninvolved areas of skin surrounded by PRP lesions, known as "islands of sparing." Familial PRP is an autosomal dominant trait that begins in early childhood. Idiopathic PRP has peaks in the first and fifth decade, but it can start at any age. Therapy is similar to that for psoriasis but may be less responsive.

The various forms of dermatophyte infection (tinea; see [Chapter 7](#)) are considered on the differential diagnosis of papulosquamous diseases, and there should be a low threshold for performing potassium hydroxide examination or sending fungal cultures. Secondary syphilis may have papulosquamous presentation. Infectious diseases on the papulosquamous differential are discussed in [Chapter 7](#).

## Pigmentary Disorders

There are a number of disorders involving too much or too little pigmentation. Many medications have the potential for differential deposition in the skin, causing skin coloration changes. The more common pigmentary disorders such as postinflammatory hypopigmentation and hyperpigmentation, melasma, vitiligo, systemic causes of skin pigmentation, drug-related pigmentary changes, and albinism are discussed later.

Postinflammatory changes can either be hypopigmentation or hyperpigmentation. These changes are often more noticeable in darker-skinned individuals compared with lighter-skinned individuals. Postinflammatory hyperpigmentation results from either epidermal or dermal melanosis, or both. When the epidermis is inflamed, stimulation of the melanocytes causes increased melanin production in the melanocytes and transfer to the epidermal keratinocytes, causing a transient superficial brown hyperpigmentation. In cases where the inflammation is deeper, involving disruption of the dermal-epidermal junction, dermal melanin deposition may occur. This pigmentation is longer lasting and more challenging to treat. Hypopigmentation occurs from decrease or loss of epidermal production of melanin by the melanocyte or loss of the melanocyte completely.

Melasma (or chloasma) is hormonally influenced hyperpigmentation on the lateral cheeks, upper lip, and forehead. Most commonly this change occurs in women taking oral contraceptives or following pregnancy, although mild thyroid and ovarian dysfunction may also play a role in the development of melasma. Ninety percent of affected patients are women, although men can present with a similar picture.

Both epidermal and dermal pigmentation may occur. Sun exposure worsens the dyspigmentation; thus strict photoprotection is a necessary aspect of management.

Vitiligo presents with depigmented patches on the skin, which result from autoimmune destruction of melanocytes. Patients develop symmetric involvement around orifice of the face, elbows, hands, knees, and feet, although any area may be involved. There may be total loss of pigmentation (depigmentation) or of lighter areas (hypopigmentation), sometimes in three zones called trichrome vitiligo ([Fig. 102.14](#)). Pathogenesis is not clearly identified. Certain HLA types have increased risk of vitiligo, including HLA-DR4 in blacks, HLA-B13 (Moroccan Jews), HLA-B35 (Yemenite Jews), and HLA-B13 (with antithyroid antibodies). Vitiligo is associated with other autoimmune conditions, such as thyroid disease (hyperthyroid or hypothyroid), diabetes mellitus, pernicious anemia, Addison disease, and alopecia areata.

Several systemic diseases can cause diffuse hyperpigmentation of the skin. Addison disease is adrenal insufficiency that does not manifest clinical symptoms until after 90% of the adrenal cortex is destroyed. Generalized "bronze" skin hyperpigmentation is noted in 95% of Addison disease patients. These findings occur secondary to increased production of melanocyte-stimulating hormone, which is produced as a cleavage product of the prohormone for corticotropin. Iron overload in hemochromatosis causes a triad of cirrhosis, diabetes mellitus, and skin hyperpigmentation. Skin findings are a late finding and occur in about 70% of patients. Patients with primary biliary cirrhosis may also have generalized skin hyperpigmentation.

Many oral medications can cause skin pigmentation. One commonly used medication that produces a slate-gray pigmentation on sun-exposed areas is amiodarone. Minocycline can produce black, blue-gray, or brown pigmentation over longer durations of therapy ([Fig. 102.15](#)). Zidovudine produces pigmentation of the nails, both longitudinal streaks and blue coloration of the lunula. Medications causing pigmentary changes are summarized in [Table 102.8](#).

There are various congenital hypopigmentation syndromes. Oculocutaneous albinism (OCA) has four subtypes, depending on the gene defect present. Other

• **Fig. 102.14** Trichrome vitiligo. Note the multiple hues of brown to white skin present.

• **Fig. 102.15** Blue-gray dyspigmentation on the bilateral lower legs from chronic minocycline use.

conditions with similar findings are Hermansky-Pudlak, Chédiak-Higashi, and Griscelli syndromes. These diseases are summarized in [Table 102.9](#).

## Bullous Disorders

Autoimmune bullous disorders are uncommon and cause both cutaneous and mucosal disease. With the advent of systemic immunosuppressive agents (i.e., prednisone, azathioprine, and mycophenolate mofetil), the mortality of these diseases has significantly decreased, but the morbidity and decrease in quality of life are still considerable. This group of disorders is caused by autoimmune attack on the various components of the epidermis or the dermal-epidermal junction.

These diseases can be divided into two groups by the location of the split in the blister. The pemphigus group and linear IgA disease have intraepidermal splits, whereas pemphigoid/epidermolysis bullosa have splits in the dermal-epidermal junction or in the dermis. Each split is specific to the antigen that is the target of autoimmune destruction. For the pemphigus group, the antigens are components of the desmosome, the complex responsible for holding keratinocyte to keratinocyte in the epidermis. For the pemphigoid group,

**TABLE 102.8** Pigmentary Changes

Drug	Clinical
Amiodarone	Slate-gray on sun-exposed face and hands
Antimalarials	Yellow-brown to gray on tibial surfaces, face, mouth, nails
Arsenic	Black generalized pigmentation or truncal pigment that spares face with depigmented scattered macules that resemble raindrops
Bismuth	Pigment line in gingiva
Bleomycin	Flagellate hyperpigmentation on back or areas of excoriation
Busulfan	Blue lunula
Chlorpromazine	Slate-gray-violaceous on sun-exposed skin and conjunctiva
Clofazimine	Red-brown color; reddish tinge of tissue due to clofazimine accumulation, brown due to ceroid lipofuscinosis
Gold	Lilac, begins on eyelid, then face, hands
Hemosiderin	Red-brown
Lead	“Gingival line”
Mercury	Slate-gray gingival pigment on mouth, eyelids, neck, nasolabial fold
Methacycline	Gray-black photo-exposed skin, yellow-brown conjunctival pigment
Minocycline	Three types: Blue-black in scars Blue-gray in normal skin, common on anterior of tibia Muddy brown, sun-exposed areas
Silver	Slate-gray, sun-exposed skin
Zidovudine (AZT)	Nail pigmentation: blue lunula or longitudinal streaks

**TABLE 102.9** Congenital Hypopigmentation Syndromes

Disease	Gene Defect	Notes
Oculocutaneous albinism, type 1	Tyrosinase	No morbidity/mortality outside ocular and ultraviolet sensitivity for all four types of oculocutaneous albinism. Complete absence of pigment: skin, hair, eyes.
Oculocutaneous albinism, type 2	<i>P</i> gene	Minimal but not complete pigment loss of skin, hair, eyes
Oculocutaneous albinism, type 3	Tyrosinase-related protein-1 ( <i>Tyrp1</i> )	Minimal pigment loss. Only confirmed in African heritages: “brown” or “rufous” albinism.
Oculocutaneous albinism, type 4	SLC45A2	Phenotype similar to type 2
Hermansky-Pudlak	Multiple mutations ( <i>HPS</i> gene)	Bleeding diathesis secondary to platelet deficiency. Ceroid storage disease—ceroid-lipofuscin material accumulates in solid organs. Pulmonary fibrosis frequently fatal, in fourth or fifth decade of life
Chédiak-Higashi	<i>LYST</i> gene	Silvery-metallic hair. Immunodeficiency. Frequent respiratory infections, bleeding diathesis.
Griscelli	<i>RAB27A/MYO5A</i>	Severe immunodeficiency, usually fatal in early childhood

• **Fig. 102.16** Flaccid bullae, crusting, and reepithelializing erosions on the back of a patient with pemphigus vulgaris.

the responsible proteins are in the hemidesmosome, basement membrane, or dermal anchoring collagen.

A flaccid bulla is the hallmark of an epidermal split (pemphigus), and a tense bulla indicates a subepidermal split (pemphigoid) (Fig. 102.16). The Asboe-Hansen sign shows progression of an existing blister with pressure on the bulla, and the Nikolsky sign is positive when a new blister is formed with friction on the skin. Both are positive in epidermal processes and negative in subepidermal processes (Fig. 102.17). The blistering disorders are summarized in Table 102.10.

### Hair and Nails

Hair and nails are keratin-derived skin appendages that are cosmetically and socially problematic when diseased or absent. Nails are derived from keratins produced in the proximal nail matrix. They grow at an average rate of 1.8 to 4.6 mm per month and will completely regrow in 6 to 9 months.

• **Fig. 102.17** Urticarial plaques on the thigh of a patient with biopsy-proven prebullous bullous pemphigoid. These are very pruritic (note the excoriations).

Fingernails are important for tactile sensation and important for grasping small objects. Nails are affected in diseases such as psoriasis/alopecia areata (pitting) and LP (rough nails and pterygium) or may be diseased in many genodermatoses (i.e., pachyonychia congenita). In addition, examination of the nails may give important clues to internal deficiencies or diseases. Nail findings are summarized in Table 102.11.

Hair is produced in an epidermal invagination into the dermis. The matrix cells produce the hair shaft that grows to become the visible hair. Pigment is produced by melanocytes in the matrix. Scalp hair grows approximately 0.35 mm/d or 2.5 mm/wk.

There are three phases to hair growth: anagen, catagen, and telogen. Active growth occurs in the anagen phase (84% of all hairs), lasting 3 to 4 years. The catagen phase (1%–2%) lasts 2 to 3 weeks, and follicular regression occurs during this time. The telogen phase (10%–15%) lasts about 3 months and is a resting phase before renewed anagen growth. Normal hair loss is approximately 100 hairs per day. An important issue for many presenting with hair complaints is hair loss (alopecia), especially on the scalp. Alopecias can be classified as either scarring (permanent) or non-scarring (potential for hair regrowth) (Fig. 102.18). The various conditions are summarized in Table 102.12.

**TABLE 102.10** Summary of Bullous Diseases

Disease	Antigen	Notes
<b>Epidermal Split</b>		
IgA pemphigus	Intraepidermal neutrophilic type: Dsg 3 Subcorneal pustular type: Desmocollin 1 and 2	Initially clear vesicles/bullae that become pustules. Common location: chest/inframammary, scalp/postauricular. Superficial epidermal split.
Pemphigus foliaceus/ fogo selvagem	Desmoglein (Dsg) 1	Mucous membranes uncommonly involved. Fogo selvagem endemic pemphigus, common in Brazil (possible sand fly vector). Superficial epidermal split with flaccid bullae and superficial erosions.
Pemphigus vulgaris (see Fig. 102.16)	100% Dsg 3 50%–75% Dsg 1	Mucous membranes commonly involved. Flaccid bulla, deep erosions. Split in basal layer of epidermis.
Pemphigus vegetans	Dsg 3	Variant of PV. Vegetative plaques (axillae).
Pemphigus erythematosus	Dsg 1	Senear-Usher syndrome. Overlap of SLE and PV. Small, flaccid bullae on scalp, face, upper chest/back. Similar to pemphigus foliaceus.
Paraneoplastic pemphigus	Plectin Desmoplakin I BPAg 1 Desmoplakin II/envoplakin Periplakin Dsg 1 Dsg 3	Associated with lymphoproliferative disorders and other malignancies (thymoma, sarcoma, and lung carcinoma). Mucosal sores in mouth, esophagus, and prominent crusting/erosions of lips. Polymorphous presentation on skin: erythema, vesiculobullous lesions, crusts.
<b>Subepidermal Split</b>		
Bullous pemphigoid	BPAg 1 BPAg 2 (less)	Tense bullae on any skin surface. Rare mucous membrane involvement. Can present with eczematous or urticarial pre-BP (see Fig. 102.17).
Cicatricial pemphigoid	Laminin 5 (epiligrin) Laminin 6 BPA 2 (lamina lucida)	Scarring of MM primarily—eyes, oral MM. Bullae on upper body common.
Herpes (pemphigoid) gestationis	BPA 2 = collagen 17	Pregnant women, recurs with subsequent pregnancies. Increased incidence of Hashimoto thyroiditis, Graves disease, pernicious anemia. Associated with HLA-DR3/DR4.
Dermatitis herpetiformis	Transglutaminase	Increased incidence of thyroid disease, small bowel lymphoma, and non-Hodgkin lymphoma. Gluten-sensitive enteropathy, responsive to dapsone.
Linear IgA dz	Collagen VII BPA 1 and 2	Presentation similar to BP. Idiopathic or medication reaction: vancomycin most common.
Bullous lupus erythematosus	Collagen VII Laminin 5 Laminin 6 BPA 1	Appearance varies from BP-like to DH-like
Bullous diabeticorum	Split is in lamina lucida	Not autoimmune. Occurs on lower legs and feet.
Epidermolysis bullosa acquisita	Collagen VII	Blisters, scars, milia in areas of trauma, rarely MM. Associated with Crohn disease.
Porphyria cutanea tarda	Familial type: uroporphyrinogen decarboxylase deficiency Acquired: flares with hepatitis (often Hep B/C), ethanol, increased estrogen, HIV infection, and in hemochromatosis	Either acquired or hereditary. Tense bullae on sun-exposed surfaces, milia. Hirsutism on lateral face.

BP, Bullous pemphigoid; DH, dermatitis herpetiformis; Ig, immunoglobulin; MM, mucous membrane; PV, pemphigus vulgaris; SLE, systemic lupus erythematosus.

**TABLE 102.11** Nails

Condition	Description
Koilonychia	Spoon-shaped concave nails related to iron deficiency
Beau line (transverse ridges)	Because of acute systemic injury. Halfway on nail plate = insult was 3 months ago.
Terry nails	Proximal 2/3 white, distal 1/3 red. Secondary to hepatic disease, hypoalbuminemia from cirrhosis or CHF.
Half and half (Lindsay)	Proximal 1/2 white, distal 1/2 pink. Occurs in renal disease.
Muehrcke lines	Paired white parallel bands that do not grow out with the nail plate because of an abnormal nail bed. Secondary to hypoalbuminemia.
Mees lines	Horizontal leukonychia, defect nail plate. From arsenic poisoning (treat acutely with dimercaprol).
Onychogryphosis	Long hypertrophied nails resembling a ram's horn because of neglect
Onycholysis	Nail plate split from nail bed (can be caused by tinea)
Onychomadesis	Periodic idiopathic shedding of nail (complete onycholysis)
Onychorrhexis	Brittle nails, longitudinal striations, treatment with B-complex vitamin biotin
Onychoschizia	Splitting of distal nail plate into layers at the free edge
Pitting	Caused by damage to proximal matrix; common in psoriasis (irregular) and alopecia areata (regular)
Pterygium	Scarring and fusion of the cuticle to the nail plate; common in lichen planus

CHF, Congestive heart failure.

• **Fig. 102.18** Round patch of nonscarring alopecia in the beard of a patient with alopecia areata.

**TABLE 102.12** Alopecia

Disease	Notes
<b>Scarring</b>	
Lichen planopilaris	Form of follicular lichen planus. Perifollicular erythema, itching, scarring.
Pseudopelade of Brocq	Nonspecific scarring hair loss. Likely end-stage result of other scarring conditions.
Chronic cutaneous lupus	Similar to cutaneous presentation. Follicular plugging, erythema, scarring.
Traction	From hairstyles with sustained traction. Results in scarring and loss of hair follicles.
Scleroderma	En coup de sabre, extends onto scalp. Linear scarring atrophic plaque.
<b>Nonscarring</b>	
Alopecia areata (see Fig. 102.18)	Round patches of hair loss. Related to thyroid disease in some cases. Can progress to entire scalp, head, or body.
Male pattern	Secondary to action of dihydrotestosterone causing miniaturization of the hair follicle. Often begins on vertex scalp, spares occipital and temporal hair.
Medication induced (Shapiro, 2007)	Anagen effluvium (~2 weeks after starting): chemotherapeutic agents such as busulfan, cyclophosphamide, vinblastine/vincristine, doxorubicin Telogen effluvium (2–3 months after starting): many including retinoids, heparin, lithium, ramipril, terbinafine, valproic acid, warfarin
Telogen effluvium (Shapiro, 2007)	Increase number of telogen hairs. Begins ~3 months following major illness or stress (e.g., surgery, childbirth, rapid weight loss, nutritional deficiency, high fever, hemorrhage) or hormonal derangement (e.g., thyroid dysfunction).
Metabolic	Thyroid, nutritional deficiency, iron deficiency, HIV

## Chapter Review

### Questions

1. A 23-year-old man presents with well-demarcated erythematous plaques with silvery scale on the elbows, knees, and buttocks (<5% body surface area). He has never treated this rash before. What would be first-line treatment approach?
  - A. Acitretin
  - B. Methotrexate
  - C. Secukinumab
  - D. Adalimumab
  - E. Triamcinolone cream
2. A 61-year-old man with a history of cerebrovascular accident and grand mal seizures is started on carbamazepine. He develops fever, pharyngitis, skin sloughing, and lymphadenopathy on physical examination. Laboratory abnormalities include hepatitis, nephritis, and leukocytosis with eosinophilia. What would be an appropriate antiepileptic to substitute?
  - A. Phenytoin
  - B. Phenobarbital
  - C. Levetiracetam
  - D. None; continue carbamazepine
  - E. Oxcarbazepine
3. Which of the following is true regarding melanoma?
  - A. Because the majority of cutaneous melanoma cases arise in association with a precursor nevus, the wholesale removal of melanocytic nevi is important for melanoma prevention.
  - B. A new or changing mole or blemish is the most common warning sign for melanoma and warrants biopsy.
  - C. Caucasian patients are at greater risk for developing acral lentiginous melanoma compared with darker-skinned individuals.
  - D. Melanoma is a more common skin cancer than squamous cell carcinoma and basal cell carcinoma.
  - E. The presence of xeroderma pigmentosum only increases the risk for nonmelanoma skin cancers not the risk for melanoma.
4. Which of the following features of cutaneous squamous cell carcinoma is more likely to increase risk for metastasis?
  - A. Location on the ears
  - B. Tumor diameter <2 cm
  - C. Well differentiated
  - D. Location on the back
  - E. Tumor thickness of 1 mm

### Answers

1. E
2. C
3. B
4. A

# 103

## Occupational Medicine

EBRAHIM BARKOUDAH AND LORI WIVIOTT TISHLER

The International Labor Organization and World Health Organization define occupational health as “the promotion and maintenance of the highest degree of physical, mental and social well-being of workers in all occupations by preventing departures from health, controlling risks and the adaptation of work to people, and people to their jobs” (International Labor Organization and World Health Organization 1950).

Occupational injuries are among the leading causes of morbidity and mortality in the United States. Hence occupational medicine and internal medicine physicians play roles in preventing, recognizing, diagnosing, and treating these work-related illnesses with the ultimate aim of establishing and maintaining a healthy and safe working environment for employees (including mental and physical aspects in relation to their work). Their roles could also be extrapolated to include identification and assessment of health hazards in the workplace along with advising and planning work space and surveillance of workers’ health in relation to work and achieving a well-functioning working community. However, many illnesses that can be occupationally related are indistinguishable from other sorts of chronic illness. This chapter provides an overview of occupational medicine with a focus on the occupational background history, disability, and worker’s compensation using a system-based review.

### The Occupational Medicine Epidemiology

Occupational illnesses are underrecognized and therefore undertreated. They are responsible for slightly more than 3 million nonfatal workplace injuries and illnesses and >60,000 deaths annually in the United States. Globally, there are over 200,000 mortality cases and over 100 million injured workers annually related directly to hazardous exposures. According to the Bureau of Labor Statistics, the incidence of nonfatal occupational illness and injury cases requiring out-of-work days exceeded 100 cases per 10,000 full-time workers in 2014 alone. These reported statistics could still underestimate the real-world incidence rate because it is largely dependent upon employer-reported workplace injuries. Although major advancements have been put in place by government and nongovernmental regulating agencies,

the economic sequelae of occupational illnesses and injuries continue to be a major burden of this health outcome and its impact on the health of the population.

### Occupational Medicine Effective History Elements

The essential role for physicians while obtaining history should be focusing on the fundamental principles of occupational health and safety in the domains of screening assessment and management. However, barriers to taking a comprehensive occupational history include inadequate information on the part of both patient and doctor about occupational exposures and the plausible association of occupational and nonoccupational manifestations, along with the lack of systematic evaluation strategies. Hence opportunities for prevention and treatment are missed. For patients, there can also be a long latency between the exposure (e.g., asbestos in a naval shipyard) and the ultimate terminal illness (mesothelioma). Many physicians are inadequately trained to recognize occupational illness, and most physicians find it difficult to negotiate the maze of recording, reporting, and notifying appropriate governing boards about occupational injuries and illness.

When one is taking an occupational history, consider whether or not a pattern of symptoms might be clarified by elucidating information about a patient’s work. It is important to remember that over 80% of American workers do not have access to physician services through their workplace or a primary care practitioner who provides occupational health along with primary care services. Therefore it is important to emphasize the integration of occupational medicine and comprehensive primary care services through one general internist. Moreover, the physician-patient relationship plays an important role in the occupational medicine activities; however, this could be challenged through the process of assessment and legal and ethical dilemma as related to compensation and disability, when it occurs. In addition, be aware (specifically if the patient was informed a priori) of a patient’s job and its potential impact on his or her health. For most patients, a quick survey is all that is necessary to help delineate whether or not a more detailed

occupational history needs to be taken. Simple questions such as “What do you do for work?” and “Do you think your health problems are related to your work?” are a good place to start. If a positive answer is elicited in the initial history, a more comprehensive occupational history should be taken. This should include a detailed chronology of jobs, exposures, and temporal correlations among exposures, occupations, and symptoms (Fig. 103.1). Many occupational medicine physicians have detailed questionnaires to help them with this complicated task. Obtain a baseline comprehensive history and physical examination along with laboratory data when available upon the beginning of the employment, and remember that patients may have exposures to toxic substances that occur outside of their work lives. If the clinician is concerned about an exposure, elicit a good history of their community, home, hobbies, diet, and drugs (herbal, legal, and illegal). It can be helpful to ask about similar symptoms in family members and coworkers as well. Remember that occupational diseases sometimes produce symptoms that mimic other common health problems and vice versa.

There are numerous databases and organizations that can help physicians in the occupational assessment along with regulations and state-specific mandates regarding safety law and policy in documenting and reporting. The National Library of Medicine has an online bibliography titled Toxline ([toxnet.nlm.nih.gov/index.html](http://toxnet.nlm.nih.gov/index.html)), which covers the toxicologic effects of drugs and chemicals. The Hazardous Substances Data Bank ([www.nlm.nih.gov/pubs/factsheets/hsdbfs.html](http://www.nlm.nih.gov/pubs/factsheets/hsdbfs.html)) focuses on the toxic responses to potentially hazardous substances and is peer-reviewed by the Scientific Review Panel. Other internet resources include the Centers for Disease Control and Prevention (can be accessed at [www.cdc.gov](http://www.cdc.gov)) through its National Institute for Occupational Safety and Health and World Health Organization Occupational Health ([www.who.int/occupational\\_health/en](http://www.who.int/occupational_health/en)). The American College of Occupational and

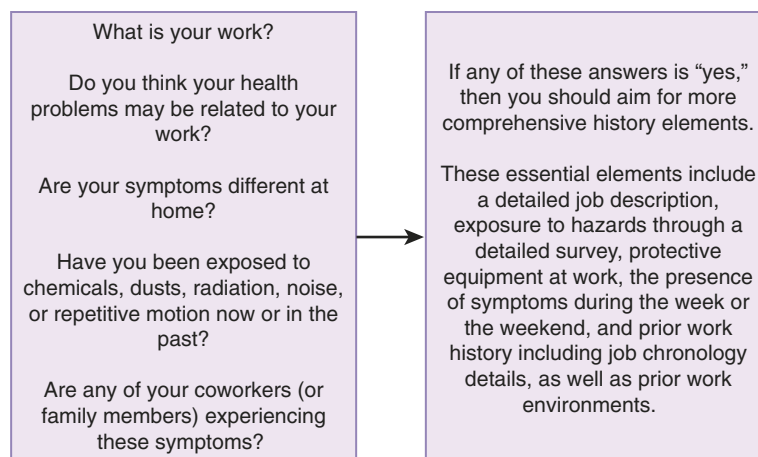

Environmental Medicine can also help to direct clinicians to resources ([www.ocoem.org](http://www.ocoem.org)).

It is key to ask enough questions to help discern whether a patient's symptoms could be attributed to workplace exposure. If so, then the next step is to focus in more detail, not forgetting that exposures can be nonoccupational as well. There are many published questionnaires and validated tools that can be helpful when one is deciding whether or not to refer to an appropriate subspecialist or occupational medicine physician. Based on the initial evaluation and assessment of the adult and pediatric dermatologic evidence of environmental and occupational exposure and determination of toxicologic evidence, further comprehensive physical examination along with operator testing, mental status examination, and rehabilitation assessment will be required.

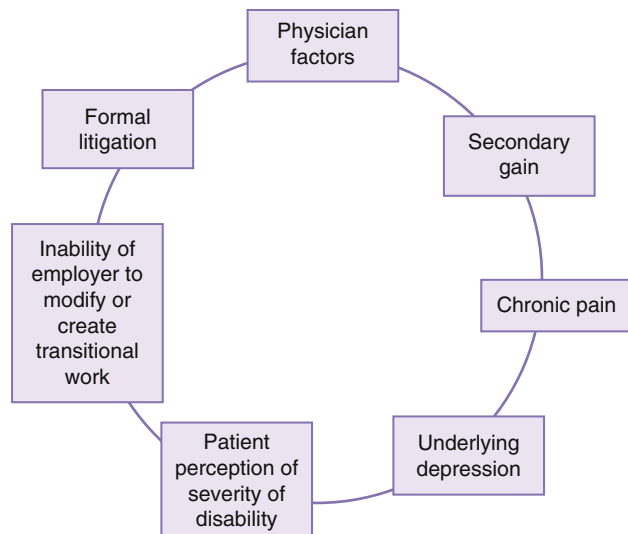

## Disability and Return to Work

The earliest worker's compensation laws in the United States occurred after 1910. Mostly focused on occupational injuries, these initial laws were far from the complex workers' compensation and disability doctrine in place today. Today, the role of the physician is complex, often confusing, and sometimes distasteful in determining the proper pathways for occupational and environmental exposure to assess compensation. It is helpful to remember that the determination of disability is an organizational or legal decision. It is the doctor's task to help provide supporting information in as accurate and truthful a manner as possible as the capstone for evaluation regardless of apportionment or ascertainment of causation.

The role of the physician in determining disability is to help determine whether or not an illness or injury is related to the patient's work. As the physician treats the patient, he or she can help determine when maximum improvement has been made and when the patient may return to work. The American Medical Association Guides to the Evaluation of

• **Fig. 103.1** Occupational history screening tool questionnaire. (From Lax MB, Grant WD, Manetta FA, et al. Recognizing occupational disease—taking an effective occupational history. *Am Fam Physician*. 1998;58(4):935–944.)

• **Fig. 103.2** Risk factors for delayed return to work after occupational injury or illness.

Permanent Impairment can help physicians determine the level and type of impairment through standardized methodology in evaluation. If the patient's case results in litigation, it is not uncommon for the patient to be assigned to an independent medical examiner, a physician not involved in the longitudinal care of the patient, who may provide a report on the patient's injury, illness, expected improvement, and level of impairment.

The majority of workers who have work-related medical problems will be treated, improve, and return to work promptly, even when a worker's compensation case is involved. Nonetheless, in a small number of cases, patients will not improve or will have a delayed recovery. *Delayed recovery* is a term that means prolonged time to improvement that is out of proportion to clinical findings. These cases are most costly for the system and often most frustrating for the physician. The longer patients are on disability, the lower their chance of ever returning to work. Delineating temporary versus permanent disability is vital and is usually done by an occupational medicine specialist or an independent examiner. Risk factors for delayed return to work are listed in Fig. 103.2.

It can be difficult to decide when a patient is truly ready to return to work. Questions to ask patients might include, "Can you work around this problem while you recover?" and "What, specifically, is preventing you from working today?" The answers to these questions can be helpful in determining readiness to return to work and identifying patients who are at risk for delayed recovery. Some specialists suggest the grocery store test. Ask yourself, "If this patient was the sole proprietor of a corner store, could he or she get to work and be safe at work?" If you think so, he or she is probably medically safe to return to work.

For many patients who are anxious or reluctant about returning to work, the physician can help to create an environment in which the worker can return successfully. For some, this may mean helping him or her to return on a lighter schedule with a plan of working up to the previous

full-time schedule. Other helpful suggestions are to be available to meet with the patient in person or by phone while he or she is making the transition back to work.

## Organs-Based Highlights of Occupational Illnesses and Diseases

The next section of this chapter considers specific issues in occupational medicine including work-related injuries, illnesses, and exposures. It is by no means a comprehensive list, but the goal is to help physicians become aware of work-related risk factors for these problems, specific at-risk occupations, and strategies for treatment and prevention. A review of these illnesses, injuries, and exposures is presented here by system. For any type of occupational exposure, try to quantify the exposure with laboratory tests when appropriate and, sometimes, evaluate the work site.

## Musculoskeletal and Peripheral Nervous System

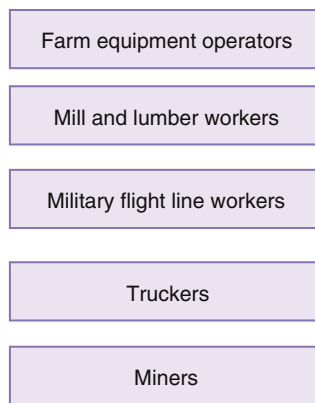

Work-related injuries affect every part of the body. Risk factors for work-related injuries include repetitive activities, prolonged awkward positions, and lack of rest along with performing extensive physical efforts and hearing special sounds. Mechanical stresses, vibration, and cold temperatures can contribute as well. Peripheral nerve injuries are also common occupational illnesses. Predisposing factors to these injuries may include exposures to chemicals or gases, but more commonly, injuries to individual nerves may come from repetitive motion, abnormal posture, and carrying heavy objects. Many of these injuries can be diagnosed by physical examination alone; others might require imaging such as MRI and ultrasound scan or electromyogram studies to confirm the findings. Most importantly, good safety practices and ergonomics can prevent many of these injuries. Workers should be encouraged to contact their occupational health program to train them to improve their positioning, posture, workstations, and mechanical stressors at their jobs. Referral to occupational therapy may help to treat and prevent these injuries.

## Special Senses

Many workers are at risk for ocular injury from trauma as well as exposures to chemicals, radiation, and even the visible light spectrum. Because many eye injuries need immediate treatment, it is essential for treatment to begin on site by the employee or his or her colleagues. Attention should be paid to proper ocular protection with face masks, goggles, or equipment most appropriate to the work setting.

Occupational hearing loss is another common injury. In general, hearing loss occurs because of repeated exposure to loud noise, head injury, or exposure to substances toxic to the ear. Workers in noisy work environments (prolonged exposure to sounds louder than 85 dBA) are at increased

• **Fig. 103.3** Selected workers at risk of hearing-related problems.

risk for hearing loss. Workers in noisy environments also may be at greater risk for hearing loss from ototoxic medications. Prevention is the best treatment, including an awareness of the noise level in the workplace, hearing testing as appropriate, worker education, and hearing protection devices (Fig. 103.3).

Chemical workers have reported alterations in their sense of smell. Occupations at risk for this include battery workers, tank cleaners, and chemical plant workers. Skin disorders can be related to allergic reactions, infection, and mechanical trauma such as heat and cold. Certain workers are also at risk for occupation-related skin cancer, including outdoor workers and those exposed to tar products, arsenic, and repeated trauma.

## Immune System

Infections are an important component of occupational medicines. Microbial exposures are common in the agricultural industry and from animal exposures. Occupations at risk for zoonoses include farmers, veterinarians, abattoir workers, and ranchers. Less obvious and more urban occupations might be zoo attendants or pet shop workers.

Hospital and other health care workers are at risk for numerous blood-borne diseases from needle sticks and other exposures. These include tuberculosis, all forms of infectious hepatitis, and HIV. Hypersensitivity pneumonitis (see respiratory system section) is also commonly related to bacteria, fungi, and animal exposures. White-collar workers, too, can be at risk for occupational infection. Business travelers, aid workers, and global health practitioners, for example, are susceptible to various travel illnesses, many of which can be prevented with appropriate vaccinations or prophylactic medications.

## Respiratory System (Upper and Lower)

In the upper respiratory tract, patients might present with occupationally related allergic rhinitis. Table 103.1 lists the exposures that are associated with allergic rhinitis and asthma. Diagnosis of occupational allergic rhinitis might be aided by radioallergosorbent testing or challenge testing

in the workplace with controlled observation when specific culprits are not laboratory available. Treatment is the same as for nonoccupation-related disease. In addition, specific recommendations regarding exposure-induced illness should be included regarding modification of workplace. Some agents and processes are associated with sinonasal and laryngeal cancer risk. The strongest findings are associated with leatherworkers and woodworkers. Laryngeal cancer can be associated most strongly with asbestos and smoke inhalation. Cigarette smoking increases patient risk for these conditions. Lower respiratory tract disorders include asthma, toxic inhalation, hypersensitivity pneumonitis, pneumoconiosis, lung cancer, and pleural disorders such as mesothelioma.

## Cardiovascular System

Because cardiovascular disease (CVD) is so common in our society, it is easy to overlook occupational exposure as a source. Increased CVD has been reported in people who work blue-collar jobs in the service industry. However, it can also be very difficult, given the long lag time between exposure and diagnosis, to attribute CVD to occupational risk. In fact, job-related factors are more likely to be additive risk factors for patients, in combination with more classic risk factors such as smoking, hypertension, and diabetes, than standalone causes of heart disease. Chronic exposures to air pollution, carbon disulfides, and carbon monoxide may accelerate the development of coronary artery disease. Heavy metals such as antimony can prolong the QT interval; arsenic can cause vasospasm and may contribute to hypertension; cobalt exposure is a probable cause of cardiomyopathy; and lead exposure may contribute to hypertension, cardiomyopathy, and a host of other conditions.

## Gastrointestinal and Renal Systems

The liver, as the body's detoxification system, is the part of the gastrointestinal tract most at risk for workplace exposures. As with cardiac disease, changes caused by toxins and exposures are not specific. Many chemical agents can cause liver injury (Table 103.2). Some agents such as anesthetic gases or trinitrotoluene cause acute hepatic injury, but we also see patients with cirrhosis, hepatic sclerosis, steatosis, and granulomatous disease that can be caused by chronic or repeated exposures. Although many chemical agents are potential causes of hepatocellular carcinoma, there are few definitive studies. Risk of hepatic damage also increases in patients who have other injuries to their livers from alcoholism or chronic hepatitis (viral infection or autoimmune). In workers who are at higher risk for liver disease, baseline transaminases might be helpful, but routine monitoring is not recommended unless exposure to a toxin exceeds specific levels. Health care workers are at risk for hepatitis viruses' infection; however, agricultural workers, farmers, and sanitary workers could be at risk for infection caused by *Coxiella burnetii*, *Burkholderia pseudomallei*, or schistosomes.

**TABLE 103.1****Some Exposures Associated With Allergic Rhinitis and Asthma Exposure Employees**

Asthma Exposure	Employees
Animal antigens	Farmers, veterinarians, animal workers
Grains/grain contaminants	Grain workers, bakers, farmers
Food and biologics (environmental and nonenvironmental)	Food industry and health care workers
Insect antigens	Many occupations, especially urban, inside, dusty places
Diisocyanates (polyurethanes)	Painters, boat builders
Acid anhydrides (plastics)	Painters, manufacturers
Antibiotics	Health care workers

**TABLE 103.2****Types of Occupational Liver Injury and Representative Causal Agent**

Causal Agent	Acute	Chronic
Steatosis	Carbon tetrachloride	Carbon tetrachloride
Cholestasis	Rapeseed oil	
Necrosis	Carbon tetrachloride, nitrate compounds, chloroform (zonal); TNT (massive)	4,4'-methylenedianiline, dimethylformamide
Cirrhosis		TNT and occupational exposure to viral hepatitis
Sclerosis		Vinyl chloride
Neoplasia		Arsenic
Granulomas		Copper
<i>TNT, Trinitrotoluene.</i>		

A comprehensive evaluation is required given that factors could be occupational- or nonoccupational-related illnesses with the same agent.

As with the other systems in the body, chronic renal disease is common. Often the causes are multifactorial, and patients have many risk factors. Some occupational exposures do, however, affect the kidneys. Acute renal failure can develop after high-dose exposures to specific metals, solvents, and pesticides, usually from acute tubular necrosis. Chronic renal failure can be caused by lead, cadmium, mercury, and uranium exposure.

## Reproductive System

Over 30 million women of childbearing age were employed in the United States in 2004. Although only a few substances have clear associations with poor reproductive outcomes, the stress and social cost of such occurrences are devastating for patients, their families, and communities. Agents that are specific reproductive toxins include ionizing radiation and polychlorinated biphenyls.

Health care workers may be exposed to infection and antineoplastic drugs. When providing preconception counseling for patients or considering an infertility evaluation,

find out about these and other occupational exposures to help patients minimize risk in every way.

Studying male reproductive risk not only helps us to prevent unfavorable outcomes but can also be helpful as a marker for occupational risk in general. For example, it may take years for a person to develop occupationally related liver or lung disease, but an abnormal sperm count from the same exposure would happen more quickly. If we remove toxins that affect the sperm count, it is certainly possible that we are preventing long-term consequences for other organ systems as well. Many chemicals can cause male reproductive toxicity. A selection of them includes anabolic steroids, benzene, ethylene dibromide, lead, and tobacco smoke. Dichlorodiphenyltrichloroethane (DDT) has been found in semen of infertile men. Excessive heat can lead to a low sperm count, as can greenhouse work.

## Central Nervous System

Peripheral nervous system disorders, common in many occupations, are discussed earlier. Central nervous system (CNS) disorders are fortunately rarer. They can be hard to detect, but a few principles should be kept in mind. In CNS problems related to job exposure, patients often have

a nonfocal or symmetric syndrome. There is a strong time correlation between exposure and symptoms. Few toxins have a clear attached syndrome. Exclude other neurologic diseases before attributing neurologic disease to an occupational cause. Heavy metal exposure, organophosphates, and solvents are the most common sources of injury.

## Psychological Stressors, Mental and Behavioral Illness, and Substance Abuse

Psychiatric stress in the workplace as well as substance abuse affecting a patient's ability to work may be the most common occupational diseases seen by internists. Common workplace stressors include relationships within the workplace, career development and promotion, role ambiguity, work environment, and shift work. The psychological hazards at work contain interpersonal relationships, career development, and verbal and physical violence, along with harassment, including sexual. Consider the role of shift work in patients who present with accidents (both on and off the job), sleep disorders, overuse or abuse of stimulants, and social problems. Older patients, in particular, may be at greater risk from psychological and physical consequences

### Summary

Occupational diseases and illnesses can affect every occupation and every organ system and could present with wide varieties of symptoms and signs. For the generalist or nonoccupational specialist, the major points are the following: (1) the occupational (including military service) history is important; (2) if potential exposures are elicited, be aware of the specific historical questions and tools that exist to help you sort out the issues; (3) consider appropriate referrals; and (4) disability assessment is complicated, but it is in the patient's best interest to return to work quickly; delayed return to work is a risk factor for never returning to work, and there are specific approaches to ameliorate this. Physician-patient

of shift work. It is important to recognize that the incidence of such stressors may be affected by underreporting.

Considering that up to 10% of the population may have a substance abuse disorder, this leads to a large number of people working with these problems. The cost of alcohol and substance abuse in the workplace is in the hundreds of billions of dollars annually. Consideration should also be given to patients who are taking legally prescribed pain medications or sedatives. Attention should be paid to patients at risk of addiction, and appropriate treatment and referral with the aim of primary and secondary prevention, sometimes even within the workplace setting, should be initiated. The risk assessment of such behavior at work should be addressed within the scope of conceptualization to promote healing. Because work-related stress is a product of individual characteristics along with social, organization, and working environment factors, developing an action plan to address all domains is important. Organizations are currently promoting work-life balance along with good practice culture, with clear collective agreements regarding the work environment both physically and psychologically, by providing individual resources along with aftercare programs including counseling and therapy.

relationship plays an important role of screening, assessing, and diagnosing a suspected or known occupational disease and illness. Preemployment examination along with focused assessment on the exposure and periodic follow-up evaluation satisfy the objectives of occupational medicine.

Occupational exposures are not limited to chemicals but can be exposures to infectious agents, sound, radiation, drugs, and stress. Many classic risk factors for chronic disease are heightened by occupational exposures. Much occupational disease is preventable with good workplace safety and Occupational Safety and Health Administration compliance, reduction of exposures, and reduction of more classic risk factors as well.

## Chapter Review

### Questions

1. A 42-year-old factory worker has been out of work for 4 weeks because of low-back pain. She has successfully completed a course of nonsteroidal antiinflammatory drugs and physical therapy. She can do her activities of daily living with no problem but complains of persistent pain. She tells you that she cannot possibly return to work at this time. Your detailed medical assessment reveals no red flags; the physical therapist thinks she is doing very well. What might help you avoid delaying her return to work?
  - A. Tell her to stop malingering and get back to work.
  - B. Screen for and treat depression.
  - C. Work with her and her company to come up with a transition back to work plan.
  - D. Inquire about pending litigation.
  - E. B, C, and D
2. A patient who has lead exposure in his work as an instructor in the police academy firing range comes in to the emergency department with a left-sided facial droop and a right-sided hemiparesis. As he is recovering from what appears to be a cerebrovascular accident, his wife tells you that she is sure that the lead exposure caused the stroke. What is the correct response to her?
  - A. She is probably right. Check a lead level immediately.
  - B. She is probably wrong. Lead exposure only causes peripheral neuropathies.

- C. She is wrong. It is uncommon for occupational exposures to cause focal neurologic problems such as strokes. It would be more common to see nonfocal or multifocal problems caused by lead exposure including encephalopathy or motor neuropathy.
- D. She is right. Lead can cause encephalopathy, so why not strokes?
3. A 60-year-old city employee with a desk job presents to your office several times over a few months. He has a bad cough. Initially, you treat symptomatically, and he gets a bit better, but the cough continues, progressing to frank shortness of breath. He has decreased O<sub>2</sub> saturation and some fine crackles on examination. A chest x-ray, which was initially normal, shows interstitial changes, and his CT scan is consistent with hypersensitivity pneumonitis. He works in an old building, and his office has some water damage from a recent roof leak. He definitely feels better when he is on vacation. He is even better on the weekend. There are a few other employees with similar symptoms. He has no other respiratory diseases, and he does not smoke or use drugs.
- The most likely cause of his hypersensitivity pneumonitis is:
- Rodent proteins (found in droppings)
  - Thermophilic actinomycetes
  - Fungal species such as *Aspergillus*, *Penicillium*, and others
  - B or C is most likely
  - It is probably not occupationally related because it is not a widespread problem at work
4. Routine serum transaminases should be followed for workers who are potentially exposed to liver toxins in the workplace.
- True; it is the best way to find and treat disease before real problems happen.
  - False; some occupations might benefit from baseline serum liver function tests (LFTs), but routine testing in the absence of specific exposure or high-level exposure is not recommended. LFTs are not very specific.
  - True, but only in employees who drink more than seven drinks a week.
5. A retired asbestos-removal contractor is in your office. He has numerous chronic illnesses including heart disease and type 2 diabetes. He smokes about a pack a day. You advise him that smoking actually multiplies the level of risk that he might have to get lung cancer from his long-ago asbestos exposures. “Come on, Doc,” he responds, “you’re just trying to scare me into quitting again.” Who is right?
- The patient: smoking does not increase your risk of asbestos-related lung cancer.
  - The doctor: smoking multiplies the risk of asbestos-related lung cancer.

Allergic and immunologic diseases, including asthma, are the fifth leading chronic diseases in the United States and affect people of all ages. It is very likely the prevalence is much higher if drug and food allergies are included. The incidence of allergic disorders is increasing. In this chapter, the overall objective is to focus on the broad spectrum of these disorders. A more detailed review of asthma is available elsewhere in this book.

### Allergic Rhinitis and Conjunctivitis

Allergic rhinoconjunctivitis is the most common of allergic diseases. It affects 20% of the population and is associated with allergic sensitivity mediated by the presence of specific immunoglobulin E (IgE) (to allergens such as pollen, dust mites, molds, cat, dog, and animal dander) bound to tissue mast cells. Cross-linking of specific IgE with allergens induces local mast cell degranulation and the release of powerful inflammatory mediators such as histamine, proteases, prostaglandins, leukotrienes, and cytokines. These mediators bind to tissue receptors and act locally (nose, eyes, oropharynx, and ears) to induce allergic symptoms such as clear bilateral nasal discharge, sneezing, and congestion. Nasal turbinates are pale and swollen. Pruritus is typically present and affects the nasal passages, the palate, the Eustachian tubes, and the eyes. Conjunctivitis with clear discharge and ear blockage are common symptoms. Symptoms can be seasonal or perennial: seasonal symptoms are associated with sensitivities to pollen from trees, grasses, and weeds, whereas perennial symptoms are associated with sensitivities to indoor allergens such as dust mites, cat and dog dander, and molds such as *Aspergillus* and *Alternaria* species. Allergic rhinoconjunctivitis is associated with asthma in a substantial proportion of patients. One study reported that 28% of patients with asthma have allergic rhinitis, and 17% of patients with allergic rhinitis have asthma.

The diagnosis is made based on clinical symptoms and by the presence of a positive response to prick and intradermal skin testing with environmental allergens.

The differential diagnosis of allergic rhinitis includes infectious rhinitis, cholinergic rhinitis, and sinusitis. The treatment includes environmental control and allergen avoidance, pharmacologic agents, and allergen-specific immunotherapy. In sensitized patients, removal of furry

animals from the house can completely eliminate the symptoms. Intranasal medications include steroids and antihistamines. Oral nonsedating H<sub>1</sub> histamine receptor antagonists include loratadine, desloratadine, zetiricene, and fexofenadine. In addition, oral decongestants, nasal mast cell stabilizers (including cromolyn sodium), ocular agents (including olopatadine), and intranasal anticholinergics (including ipratropium bromide) can help control symptoms. Allergen vaccination or immunotherapy is indicated to provide long-term relief of symptoms in qualified patients (see later). Modalities of allergen immunotherapy include classical subcutaneous injections, and, recently, sublingual tablets have become available with similar efficacy.

### Asthma

The Global Initiative for Asthma was formed in 1993 under the auspices of the National Heart, Lung, and Blood Institute and the World Health Organization and was aimed at decreasing the chronic disability and premature deaths associated with asthma. The first workshop led to the Global Strategy for Asthma Management and Prevention, which published its initial report with the classification of asthma severity and the recommendations for its treatment in 1995. Since then there have been several updates, the last one in 2009, that established a comprehensive asthma management plan and emphasized the critical importance of inhaled steroids. Asthma is a chronic disorder of the airway associated with hyperresponsiveness and recurrent episodes of reversible airflow obstruction. Depending on the severity, airflow limitation is associated with shortness of breath, wheezing, chest tightness, and cough and can resolve spontaneously or with medications. The classification includes four degrees of severity. In mild intermittent asthma, a patient has brief exacerbations, nocturnal symptoms no more than twice per month, and normal pulmonary function tests between episodes. Mild persistent asthmatics experience symptoms more than once per week but less than once per day. The nocturnal symptoms are twice per month but less than once per week, and there is normal lung function between episodes. Moderate persistent asthmatics have daily symptoms, exacerbations may be affecting activity and sleep, and the nocturnal symptoms occur at least once per week. The forced expiratory

volume in 1 second (FEV<sub>1</sub>) can vary between 60% and 80% of the predictive pulmonary peak flow meter values. Patients with severe persistent asthma have daily symptoms, frequent exacerbations, daily nocturnal symptoms, and an FEV<sub>1</sub> <60% of the predictive, or peak flow is <60% of the best.

Factors affecting asthma severity include exposure to environmental allergens, tobacco (passive and active smoking), air pollution (outdoors: sulfur dioxide, ozone, nitrogen oxides; indoors: fumes from wood stoves, kerosene, volatile organic compounds), diesel exhaust, presence of rhinitis or sinusitis, gastroesophageal reflux, medications such as beta-blockers, occupational exposure, and viral infections.

Death-prone asthmatics include those with prior intubations, those who overuse bronchodilators (more than one canister per month of rapid onset of action bronchodilator), and those with food allergies. Asthma endotypes include allergic asthma, aspirin-sensitive asthma, severe late-onset hypereosinophilic asthma, viral exacerbated asthma, premenstrual asthma, and noneosinophilic asthma.

### Immunotherapy for the Treatment of Allergic Asthma and Rhinoconjunctivitis

Immunotherapy with allergen-specific vaccinations blunts seasonal increase in IgE levels and increases allergen-specific IgG and interleukin (IL)-10. Immune protection is generated by switching from a Th2 (IL-4 and IL-5-mediated) to an IL-10-mediated, T regulatory cell-driven response. Randomized trials have provided evidence that allergen immunotherapy has been successful in preventing symptoms of asthma and rhinitis in patients monosensitized to either ragweed, *Alternaria* mold, dust mites, or cat dander allergen. This treatment modality is also used in patients sensitized to multiple allergens who are refractory to environmental avoidance and pharmacologic intervention. Recent data indicate that immunotherapy prevents the development of asthma in sensitized children and adolescents with allergic rhinitis. Immunotherapy includes weekly subcutaneous injections with increasing amounts of the allergens up to maintenance levels (varying from 1 to 13 µg of purified or recombinant allergenic proteins) and monthly injections for up to 5 years. Reduction of up to 80% of nasal, ocular, and respiratory symptoms can be achieved at that time. Sublingual immunotherapy, peptide vaccination (using T-cell peptides devoid of allergenic potential), and immunostimulatory DNA (unmethylated DNA containing CpG motifs active through TLR9 on dendritic cells) are being considered to improve safety and efficacy of conventional immunotherapy. New therapies include a humanized monoclonal antibody against IgE, which was US Food and Drug Administration (FDA)-approved in March 2003, for moderate-to-severe persistent asthma in patients with FEV<sub>1</sub> <80%, elevated IgE, and evidence of allergen-specific IgE, and more recently humanized monoclonal antibodies against IL-5 were approved in 2015 by the FDA, which target patients with asthma and peripheral or tissue eosinophilia.

### Asthma and Aspirin Sensitivity: Aspirin-Exacerbated Respiratory Disease

Up to 20% of all adult asthmatics have aspirin sensitivity and present an acute asthma flare on aspirin and cyclooxygenase (COX)-1/COX-2 nonsteroidal antiinflammatory drug (NSAID) exposure. These asthmatics present with the triad initially described by Samter including moderate persistent-to-severe asthma, nasal polyposis with loss of smell, and aspirin and NSAID intolerance. Chronic rhinosinusitis is also present in the majority of patients. On exposure to aspirin and NSAIDs, the FEV<sub>1</sub> decreases by 12% or more. Elevated numbers of eosinophils and increased expression of leukotriene C<sub>4</sub> (LTC<sub>4</sub>) synthase (which generates the leukotrienes LTC<sub>4</sub>, D<sub>4</sub>, and E<sub>4</sub>) in the polyps and increased leukotrienes in urine and bronchoalveolar lavage fluid are characteristic. The management of these patients includes 5-lipoxygenase blockade or leukotriene receptor antagonists and surgery. For patients with recurrent nasal polyposis with multiple surgeries who do not recover the sense of smell, or whose asthma is not well controlled, aspirin desensitization is recommended. Aspirin is slowly reintroduced to induce a controlled reaction, which produces unresponsiveness to full doses. Increased doses up to 1200 mg daily are used to maintain the desensitization state. Cross-desensitization to all NSAIDs is achieved by aspirin desensitization, and these patients can use COX-1 inhibitors for pain or inflammation. Markers that can identify aspirin-intolerant patients have been described recently and include aggregates of leukocytes and platelets in peripheral blood.

### Urticaria and Angioedema

Urticaria is characterized by the presence of hives that can be acute (<6 weeks) or chronic (>6 weeks) (Fig. 104.1). The lesions are variable in size (>3 mm), macular, round or with geographic shape and central clearing, very pruritic, and of short duration (<24 hours). Upper and lower extremities are mostly affected, and palms, soles, face, and neck can be spared. Angioedema can be associated with urticaria in up to 50% of the cases and presents with deep dermis swelling and pain. Degranulation of dermal mast cells is the pathologic finding of urticaria and angioedema lesions, but mononuclear cells, eosinophils, and basophils can also infiltrate. In contrast, urticarial vasculitis presents with small vessel vasculitis and lesions of urticaria lasting >24 hours and resolving with bruising.

Acute urticaria is a short-lived disease in which a cause is found in fewer than 20% of the cases. Drugs such as aspirin and NSAIDs, foods (egg, milk, peanut, nuts, seafood, and shellfish), infections, bacterial and viral (hepatitis B and C) infections, and contact (pollen from trees, grass, and weeds and animal dander and saliva) are the most common causes.

Chronic urticaria is a long-lived and recurrent disease in which the cause is found in <10% of cases. Urticaria occurs in episodes and can last days to months. Triggers are not apparent except for the physical urticarias, in which

• **Fig. 104.1** (A–B) Examples of urticaria.

symptoms are induced by physical activity, changes in temperature, or solar exposure. Physical urticarias include symptomatic dermatographism as well as delayed-pressure, cholinergic, exercise-induced, cold-induced, solar, aquagenic, and vibratory symptoms.

More recently, autoimmune forms of chronic urticaria have been described in patients with IgG antibodies against the IgE receptor or soluble IgE. The diagnosis is made by the autologous serum skin test in which autologous serum is injected under the skin to produce a wheal-and-flare reaction (Fig. 104.2), and the treatment includes steroids and hydroxychloroquine.

Hashimoto thyroiditis with elevated antiperoxidase and antimicrobial antibodies and Graves disease have been associated with chronic and recurrent urticaria. Thyroid replacement is most effective in the forms associated with hypothyroidism. Cryoglobulinemia, connective tissue diseases (lupus, leukocytoclastic vasculitis), and malignancies (multiple myeloma, plasmocytoma) have been associated with chronic urticaria through the generation of complement fragments C3a and C5a (anaphylatoxins), which can activate mast cells.

The treatment of urticaria includes antihistamine H<sub>1</sub>-receptor antagonist (nonsedating and sedating), H<sub>2</sub> antagonists such as ranitidine and cimetidine, and doxepin.

• **Fig. 104.2** Typical wheal-and-flare reaction. Reaction (upper right corner) to skin test with histamine (positive control).

Leukotriene receptor antagonists (montelukast, zafirlukast) and corticosteroids on alternate days can be added to increase efficacy. Severe cases and cases unresponsive to conventional therapies should be treated with colchicine, dapsone, hydroxychloroquine, sulfasalazine, cyclosporine, plasmapheresis, or intravenous immunoglobulin (IVIG). Levothyroxine in nonhypothyroid Hashimoto associated with chronic urticaria has been used with variable results. Recently cold-induced and autoimmune-induced urticaria has been successfully treated with anti-IgE (omalizumab), and a controlled placebo study provided evidence of efficacy in chronic idiopathic urticaria. In 2014 the FDA approved omalizumab for all cases of chronic idiopathic urticaria resistant to standard treatment.

## Angioedema

Angioedema not associated with urticaria can be hereditary or acquired. In hereditary familial angioedema, there is a mutation of the serpin gene inducing decreased or absent C1 inhibitor (C1INH; type I: 85% of patients) or presenting with normal C1INH but deficient in function (type II: 15% of patients). More than 100 mutations have been identified, and 20% to 25% of cases are new spontaneous mutations. Type III or estrogen-dependent angioedema is a hereditary form of angioedema seen in females in kindreds, with symptoms that mimic C1INH deficiency but with normal C1INH levels and function and normal C4. The syndrome is associated with activating mutations of factor XII. In the acquired form of angioedema there is an excessive consumption of a C1INH. The consumption can be caused by a malignancy or the presence of IgG and/or anti-idiotypic antibodies secreted from lymphoma B cells that inhibit the function of C1INH.

Symptoms of hereditary and acquired angioedema include episodic swelling of the head, face, neck, extremities, and gastrointestinal tract with abdominal pain, nausea, and vomiting, responsive to fluids and narcotics. Laryngeal edema is the most severe complication and can lead to asphyxia when intubation or tracheotomy is delayed.

Bradykinin levels in serum are elevated in hereditary forms and are thought to be the cause of tissue swelling.

The diagnosis is made by the measurement of complement levels. In hereditary angioedema C4 level is decreased, C1INH can be decreased but may be present in nonfunctional forms; C1q is always present and in the normal range, and C2 may be decreased. In the acquired forms C4 is low, as well as C1q and C1INH. C2 levels may be decreased.

During acute attacks of pain and tissue swelling, fresh frozen plasma, epsilon-aminocaproic acid, purified C1INH or recombinant C1INH, and kinin and bradykinin receptor inhibitors have been proven effective. These latter therapies have been recently FDA approved and are available in the United States. Long-term management includes androgenic steroids such as danazol and stanozolol and use of recombinant or purified C1INH on a weekly or daily basis. Epinephrine and steroids are not helpful during acute attacks and should be avoided. Death by asphyxiation has been reported resulting from severe laryngeal attacks.

### Allergic Bronchopulmonary Aspergillosis

The disease presents with asthma, pulmonary infiltrates, and central bronchiectasis. It is associated with elevated total serum IgE above 1000 ng/mL, peripheral eosinophilia, positive skin tests to *Aspergillus*, and the presence of IgG precipitins against *Aspergillus*. The treatment includes oral steroids and, in refractory cases, antifungals. There is an association between cystic fibrosis and allergic bronchopulmonary aspergillosis in human leukocyte antigen (HLA)-DR patients. Anti-IgE therapy has been proposed recently as of potential benefit.

### Food Allergy

Food allergy is defined as a hypersensitivity reaction to a specific food that is reproduced upon reexposure in sensitized individuals and is caused by a specific immune response to food allergens. Some allergens from fruits and vegetables elicit reactions when consumed raw but can be tolerated cooked. Nuts, seafood, shellfish, and grains retain their allergenic potential even after cooking. Symptoms of food allergy can be elicited by ingestion of cross-reactive foods, which share common allergenic epitopes. Oral allergy syndrome occurs in patients allergic to pollen (such as birch tree pollen) who react when eating raw fruits such as apples because of sensitization to the common profilin antigens. Symptoms of food allergy include urticaria, angioedema, nausea, vomiting, diarrhea, wheezing, sneezing, anaphylaxis, reactivation of atopic dermatitis/eczema, eosinophilic gastrointestinal syndromes, food protein-induced allergic proctocolitis, food protein-induced enterocolitis, and Heiner syndrome. The prevalence of food allergy in the United States is increasing, with 0.6% of the population sensitized to peanuts. The prevalence of seafood allergy is higher in females with 2.6% versus 1.5% in males. Milk, egg, soy, and wheat allergy are typically outgrown in puberty. Avoidance is the only treatment, and allergic individuals need to

wear labeling at all times and carry autoinjectable epinephrine. Asthmatic patients who have food allergy are at risk for death from anaphylaxis. Food desensitizations and oral immunotherapy have been explored recently, and tolerance has been induced in patients with milk, egg, and peanut allergy and other allergens. The 2015 results of the LEAP (Learning Early About Peanut allergy) study indicated that childhood avoidance of peanut is associated with increased rates of peanut allergy in sharp contrast to early introduction of peanut allergens, which protects children age <3 years. Oral immunotherapy is currently used to treat food allergies.

### Anaphylaxis

Anaphylaxis is an underreported and underrecognized medical emergency caused by the acute release of mediators from mast cells and basophils that involves more than one organ system or presents with laryngeal edema and can lead to cardiovascular collapse, asphyxia, and death in minutes unless treated.

The symptoms include flushing, pruritus, urticaria, angioedema, rhinoconjunctivitis, bronchospasm, abdominal pain, nausea, vomiting, diarrhea, and dizziness and can progress to respiratory failure, hypotension, cardiovascular shock, organ failure, seizures, disseminated intravascular coagulation, and death. Asphyxia caused by laryngeal edema can be the presenting symptom. The major risk factor for fatal anaphylaxis is asthma, but a previous severe reaction, the usage of beta-blockers, and the usage of angiotensin-converting enzyme (ACE) inhibitors have also been associated with fatal outcomes. The incidence of fatal anaphylaxis in the general population is 0.002% for drugs such as penicillin, 0.001% for hymenoptera, which induce 40 deaths per year, and food-induced anaphylaxis, with peanut as the leading offending food. Nonfatal anaphylaxis occurs in 1:2700 hospitalizations and can be caused either by hymenoptera stings, radiocontrast media, penicillin and other antibiotics, general anesthesia, or hemodialysis as well as latex exposure. Other causes of IgE-induced anaphylaxis include nuts, seafood, and milk; allergy extracts; hymenoptera venom and fire ants; vaccines; and hormones. Chemotherapy drugs such as platin derivatives (carboplatin, cisplatin, and oxaliplatin), taxanes (paclitaxel, docetaxel), and monoclonal antibodies have also been shown to induce anaphylaxis in recent years.

Other causes of non-IgE-mediated anaphylaxis include complement activation and direct mast cell activation by radiocontrast media, curare derivatives, vancomycin, opiate metabolites, COX-1, COX-2 inhibitors such as aspirin, and NSAIDs. Latex-associated reactions and/or food cross-reactivity include banana, chestnut, avocado, kiwi, mango, passion fruit, papaya, peach, watermelon, potato, and tomato. Health care workers, rubber industry workers, and spina bifida patients with urogenital abnormalities with multiple surgeries are at higher risk for latex allergy and anaphylaxis.

The diagnosis of anaphylaxis includes, in the acute phase, the serum elevation of total tryptase >11.5 ng/mL or mature

tryptase >1 ng/mL within 30 minutes to 2 hours of the onset of the severe symptoms or hypotension. Histamine metabolites can be elevated in 24-hour urine collection; complement activation or hemoconcentration with postcapillary leakage can also be found.

Retrospective diagnosis of anaphylaxis includes antigen-specific IgE measured in serum and skin testing. Testing for latex includes the measurement in serum of specific IgE with 38% to 82% sensitivity and skin test, which is not available in the United States.

## Hymenoptera Allergy and Anaphylaxis

Hymenoptera venom stings can induce hypersensitivity reaction, and in IgE-sensitized patients, these reactions can be severe and include anaphylaxis. Patients with hypotensive reactions after hymenoptera stings and elevated tryptase need to be evaluated by bone marrow biopsy for systemic mastocytosis, even in the absence of cutaneous mastocytosis, because a subset of these patients will have mast cell aggregates and will be candidates for lifesaving immunotherapy. The natural history of hymenoptera sting allergy in nonmastocytosis patients is that re-sting reactions occur only in 60% of the patients who reacted initially. The more severe the initial anaphylactic reaction, the more likely there will be a re-sting reaction, and the severity of the sting reaction is not related to the degree of skin test sensitivity or the titer of the serum venom-specific IgE. Tryptase elevations can predict patients with most severe reactions and patients who will react to venom immunotherapy. The risk of systemic reactions to sting for patients treated with venom immunotherapy decreases to <10% as compared with patients treated conservatively, in whom re-sting reactions can induce up to 60% systemic reactions. Patients with hymenoptera venom-induced anaphylaxis should receive lifelong immunotherapy, because deaths after hymenoptera stings have been reported in patients who had discontinued allergen immunotherapy. Patients with hymenoptera anaphylaxis who also have elevated tryptase have mastocytosis.

## Management of Anaphylaxis

Epinephrine is the gold standard treatment for anaphylaxis, and failure or delay in its administration results in prolonged hypotension, cardiovascular collapse, or death. Epinephrine should be administered intramuscularly (IM) in the quadriceps muscle at 0.3 mL of a 1/1000 solution and repeated twice at 5-minute intervals for prolonged hypotension. IV administration should be reserved for cardiovascular collapse, because Tako Tsubo and Kounis syndromes with cardiac failure have been reported during anaphylaxis after prolonged IV epinephrine. The treatment includes adequate oxygenation and nebulized bronchodilators, monitoring cardiac output and tissue perfusion, and the use of antihistamine H<sub>1</sub> and H<sub>2</sub> blockade with 25 to 50 mg of diphenhydramine IM or IV, ranitidine 150 mg, and methylprednisolone IV 0.5 to 1 mg/kg. If beta-blockade is

present, glucagon 5 to 15 µg/min IV in continuous infusion should be administered, and the patient with anaphylaxis should be observed for 6 to 12 hours because of delayed reactions. After discharge, education to avoid future reactions, referral for an allergy consultation, and an autoinjectable epinephrine prescription are mandatory. Patients taking ACE inhibitors or beta-blockers are recommended to change their antihypertensive medication. Recent evidence indicates that anti-IgE, omalizumab, can protect patients with idiopathic anaphylaxis.

## Exercise-Induced Anaphylaxis

Exercise-induced anaphylaxis (EIA) is a rare presentation of anaphylaxis during or shortly after exercise. Typically, patients will present with flushing, itching, hives, and other manifestations leading to anaphylaxis including hypotension once the heart rate is 1.5 times the baseline rate. It can occur within minutes of starting the exercise or shortly after it and may not be associated with asthma symptoms. Exercises implicated in EIA include running, biking, hiking, and dancing but rarely swimming. In more than 30% of cases there is an associated food ingestion preceding the anaphylactic event, and the most commonly implicated food is wheat, but other foods such as celery or shrimp have also been associated. Management of those patients includes the immediate discontinuation of exercise and the use of epinephrine. Until the cause of EIA is found, food should be avoided 4 to 6 hours before exercise. Medication such as COX-1 inhibitors, hot humid days, and menstrual period can be aggravating factors. Avoidance of exercise is mandatory after allergen injections for immunotherapy as well as beta-blockers and ACE inhibitors, which can lead to severe hypotensive episodes. Epinephrine reverses most of the reactions, and patients need to wear or carry a bracelet with identification of the condition and treatment plan. Investigation of the potential food associated with EIA reactions is mandatory, and its avoidance can cure the syndrome.

## Adverse Reactions to Medications

Adverse reactions to medications can be immediate hypersensitivity reactions type I related to IgE and non-IgE sensitization and presenting with pruritus, flushing, hives, and including anaphylaxis and delayed hypersensitivity reactions type IV, which typically present as macula papular rashes. Adverse reactions to penicillin and other beta-lactams can present as type I hypersensitivity reactions. Cephalosporins and penicillin share IgE antigenic epitopes, and there is 3% to 11% cross-reactivity, with aztreonam cross-reacting with ceftazidime. The diagnosis of type I hypersensitivity adverse drug reactions includes the measurement of blood tryptase levels at the time of the reaction to confirm mast cell activation and skin testing to demonstrate the presence of specific IgE. Negative skin testing should be followed by a graded challenge because the probability of a reaction is very low. More than 80% of patients labeled as penicillin allergic have negative skin testing and can tolerate penicillin. If the

skin test is positive, the specific drug is to be avoided, and a bracelet or chain with the identified medication should be used. Severe skin reactions (SSRs) include Stevens-Johnson syndrome, toxic epidermic necrolysis, drug reactions with eosinophilia and systemic symptoms, and acute generalized exanthematous pustulosis. Several specific HLA genotypes have been associated with SSRs, such as HLA-B5710 and abacavir reactions and HLA-B1501 and carbamazepine and anticonvulsants reactions. Aspirin and NSAIDs can cause aspirin-exacerbated respiratory disease characterized by nasal polyposis, anosmia, and asthma exacerbation upon aspirin challenge. These patients react to all COX-1 inhibitors, tolerate COX-2 inhibitors, and benefit from aspirin desensitization. The generation of inflammatory bradykinins has been implicated in ACE inhibitor–induced angioedema.

Hypersensitivity type I reactions including anaphylaxis have increased in cancer patients treated with chemotherapy, patients with chronic inflammatory diseases treated with monoclonal antibodies, and cystic fibrosis patients exposed to multiple courses of antibiotics. Drug desensitization is a novel treatment option that has been developed in the last few years to allow patients to be treated with their allergic medications, improving their quality of life and increasing their life expectancy. Aspirin-allergic cardiac patients are also candidates. Drug desensitization for type I reactions is done by rapid progressive escalation of 3-fold to 4-fold to 10-fold diluted solutions and 12 to 16 doubling steps to reach the target dose in few hours for patients on IV or intraperitoneal treatments. For type IV reactions, oral desensitization protocols are available in slower escalations spanning days.

## Mastocytosis

Mastocytosis is a rare disease presenting as localized (cutaneous) or systemic clonal expansion of mast cells caused by exon 17 mutations of *c-kit*, a tyrosine kinase receptor for stem cell factor. The most common mutation is D816V and presents in over 90% of patient with systemic mastocytosis, precluding the treatment with imatinib, a tyrosine kinase inhibitor used for chronic myeloid leukemia, which binds at the D816V site. Urticaria pigmentosa or maculopapular mastocytosis is the most common form of cutaneous mastocytosis and involves 1- to 3-mm brown/tanned nonconfluent lesions in upper and lower extremities that present positive Darier sign on stroking (wheal and flare reaction). Systemic mastocytosis presents with increased mast cell aggregates in the bone marrow, bones, gastrointestinal tract, lymph nodes, and other organs such as liver and spleen. The diagnostic criteria include one major criterion of multifocal infiltrates of 15 or more mast cells in bone marrow or in extracutaneous organs and four minor criteria including mast cell aggregates in which 25% of the mast cells are spindle shaped, the presence of KIT D816V mutation, and the aberrant expression of CD25 marker on mast cells by flow cytometry as well as elevated tryptase (a secreted mast cell protease) levels of 20 ng/mL in the absence of anaphylactic symptoms. Patients with cutaneous mastocytosis and

mast cell activation–related symptoms should be evaluated for systemic mastocytosis by bone marrow biopsy. Common symptoms include pruritus, flushing, abdominal pain, diarrhea, mental fogginess, bone pain, osteoporosis, vertebral fractures, and hypotensive episodes, which can be disabling. Indolent systemic mastocytosis is the most common form with a normal life span. The treatment is aimed at controlling symptoms with antihistamine H<sub>1</sub>- and H<sub>2</sub>-receptor blockers, cromolyn sodium, and leukotriene inhibitors. Aggressive forms and mast cell leukemia are treated with chemotherapy such as cladribine, interferon alpha 2b, and new serine/threonine protein kinase C inhibitors, including midostaurin, which is effective in aggressive mastocytosis and mast cell leukemia and can address mutated KIT.

A syndrome of clonal mast cell activation named monoclonal mast cell activation syndrome has been described in patients presenting with acute hypotensive episodes and labeled as idiopathic anaphylaxis, in which *c-kit* mutation D816V is found on bone marrow mast cells or peripheral blood mast cell precursors. These patients present acute or chronic symptoms of mast cell activation but do not present mast cell aggregates in the bone marrow and can have normal tryptase levels. Methyl histamine and prostaglandin metabolites, both products of mast cell activation, can be increased in 24-hour urine collection. A nonclonal mast cell activation syndrome has been recently described in patients without KIT mutation and lack of mast cell hyperplasia and symptoms compatible with mast cell activation. Elevated levels of histamine and prostaglandin D2 metabolites can be found elevated in urine.

## Immunodeficiencies

The most common of immunodeficiencies found in adult patients include common variable immunodeficiency (CVID) and IgA deficiency. IgA deficiency is found in 1 in 400 of the general population and is typically asymptomatic. Sinusitis, pneumonia, and urinary infections are increased in patients with very low or absent IgA, and these patients are at risk for anaphylaxis during blood transfusions and IV gamma globulin replacement because of preformed anti-IgA antibodies. CVID is associated with sinus and lung infections including two or more episodes a year of sinusitis, one or two episodes of pneumonia, urinary tract infections, and deep-seated infections. The presence of levels of IgG, IgA, and IgM that are two standard deviations below the normal range makes the diagnosis. These patients have poor responses to pneumonia, *Haemophilus influenzae*, or hepatitis vaccinations. The treatment includes lifelong replacement with gammaglobulin, subcutaneously or IV, at 400 to 1200 mg/kg every 3 to 4 weeks. Recently molecular defects have been identified with CVID, such as mutations of the tumor necrosis factor receptor family TACI (transmembrane activator and CAML [calcium-modulator and cyclophilin ligand] interactor) and others, in which there is increased association with autoimmune diseases and lymphoma, but molecular testing for CVID is not routinely recommended.

## Chapter Review

### Questions

1. A 20-year-old female who is actively trying to become pregnant sees you in the office for advice on what medications she should take for management of her asthma when she is pregnant. She currently reports symptoms of asthma two times per week, and she needs to use a rescue inhaler daily. She denies nighttime symptoms and has had no emergency department (ED) visits in the past year. She reports symptoms of seasonal allergic rhinitis. Examination indicates engorged nasal turbinates, and FEV<sub>1</sub> is normal.  
Which medication would you recommend?
  - A. Fluticasone salmeterol inhaler
  - B. Fexofenadine
  - C. Budesonide inhaler
  - D. Formoterol inhaler
2. A neighbor calls the emergency medical technicians (EMTs) to report that a male in his early 50s has fallen off his ladder while cleaning gutters in his house. When the EMTs arrive, they find a flushed and distressed patient with generalized hives and audible wheezing, and systolic blood pressure is noted to be 70 mm Hg. A nest of wasps is found near the patient. He is given a bolus of IV fluids and epinephrine IM and recovers. Blood tryptase level drawn 1 hour into the reaction is 30 ng/mL (upper normal range 11.5 ng/mL). The most likely diagnosis is:
  - A. Reaction to fall trauma
  - B. Anaphylaxis caused by hymenoptera venom
  - C. Cardiac arrhythmia
  - D. Pulmonary embolism
3. A 62-year-old African-American female with a history of type 2 diabetes mellitus is evaluated in the ED with abrupt swelling of her upper lip that she noticed when she woke up in the morning. The patient denies any dyspnea, hoarseness, sore throat, wheezing, or rash. She says that she has recently been started on lisinopril to manage her high blood pressure. Physical examination reveals upper lip swelling but is otherwise unremarkable. A diagnosis of lisinopril-associated angioedema is made. Which one of the following statements is correct?
  - A. There is a high level of cross-reactivity between an ACE inhibitor (lisinopril) and angiotensin receptor blockers, and consequently switching to losartan is contraindicated.
  - B. African Americans are more susceptible than white patients to ACE inhibitor-associated angioedema.
  - C. C4 level is typically decreased in patients with ACE inhibitor-associated angioedema.
  - D. C1INH level should be abnormally low.

### Answers

1. C
2. B
3. B

Mood disorders, anxiety disorders, and somatoform disorders are common psychiatric conditions confronting general physicians in the outpatient setting. In the inpatient setting, the most common problems are delirium, dementia, mood and anxiety disorders, adjustment reactions to illness, and substance abuse. Mood disorders include various depressive disorders and bipolar disorder. The *Diagnostic and Statistical Manual 5* (DSM-5) criteria for specific disorders reviewed in this chapter will be found subsequently.

## Depression

Depression is a major public health problem and a leading cause of functional disability and mortality. The lifetime incidence of major depressive disorder is estimated to be 20% in women and 12% in men, with a prevalence of approximately 10% in patients in a medical setting. Most adults with clinically significant depression do not see a mental health provider; instead, they often initially present to a primary care physician. A substantial number of depressed patients remain undiagnosed or undertreated.

Important subtypes of depression include premenstrual dysphoric disorder (PMDD) and depressive disorders associated with onset in peripartum and postpartum. PMDD is characterized by symptoms that may include depressed mood, irritability, anger, mood lability, or anxiety; these symptoms begin in the final week before the onset of menses and become minimal or absent in the week postmenses. PMDD is effectively treated by selective serotonin reuptake inhibitor (SSRI) antidepressants, often in a low-dosage range. Some clinicians limit recommending the SSRIs to 10 to 14 days before the onset of menses. Peripartum and postpartum depression may present as very significant major depressive disorders that require treatment with antidepressant medication; depression with psychosis and/or mania is the most serious manifestation of this disorder and requires treatment with antipsychotic medication. These disorders are highly recurrent in subsequent pregnancies. Milder depression presenting in the peripartum or postpartum period primarily as sad mood with no other depressive symptoms may be managed with psychotherapy alone.

Seasonal affective disorder (SAD), also described as major depressive disorder with seasonal pattern, refers to a recurrent depressive disorder that occurs at a particular time of year, usually the fall or winter; remissions also occur at a particular time, usually the spring. The diagnosis is established if the seasonal pattern is demonstrated by recurrent depressive episodes with the characteristic seasonal onset and offset and the absence, or much less common prevalence, of depressive episodes at other times during the year. An “anniversary reaction” type depression, such as sad mood or depression around remembering the death of a loved one that occurred around Christmas, is not described as SAD. The characteristics of SAD often include the “atypical” depressive symptoms of social withdrawal, overeating, oversleeping, carbohydrate craving, rejection sensitivity, and waves of fatigue. This disorder responds to light-box–based light therapy regimens, often characterized by exposure to  $\geq 10,000$  lux of light over 30 minutes to 1 hour. Treatment response occurs within 1 to 2 weeks of daily light therapy. Light treatment regimens (dosage and duration of light) vary, and no one regimen is the gold standard. Patients with SAD may also respond to antidepressant medications, most often SSRIs or serotonin norepinephrine reuptake inhibitors (SNRIs).

Depressive disorders are commonly associated with prominent comorbid anxiety symptoms. The specifier used for this presentation of depression is “depressive disorder with anxious distress.” In some cases, it may be difficult to distinguish whether the primary disorder is an anxiety disorder or a major depressive disorder. In addition to exhibiting symptoms of depression, the patient may present as feeling tense, keyed up, or restless, fearing something awful might happen, or having difficulty concentrating because of persistent worry. In these anxious depressive states, or “mixed anxiety and depression,” the SSRI or SNRI antidepressants or monoamine oxidase inhibitor (MAOI) antidepressants are preferable to bupropion or tricyclic antidepressants (TCAs), which have less anxiolytic properties. Patients with major depression and comorbid prominent anxiety are at higher risk for adverse outcomes, including treatment refractoriness and suicidal ideation and behavior. Both the depressive and the anxiety components of this disorder require therapeutic attention.

### • BOX 105.1 DSM-5 Diagnostic Criteria for a Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly caused by a general medical condition.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, or hopeless) or observation made by others (e.g., appears tearful). (Note: in children and adolescents, can be irritable mood)
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation)
3. Significant weight loss when not dieting or weight gain (e.g., a change of >5% of body weight in a month) or decrease or increase in appetite nearly every day (note: in children, consider failure to make expected weight gain)
4. Insomnia or hypersomnia nearly every day
5. Psychomotor agitation or retardation nearly every day (observable by others; not merely subjective feelings of restlessness or being slowed down)
6. Fatigue or loss of energy nearly every day
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The episode is not attributable to the physiologic effects of a substance or another medical condition.

Note: Criteria A to C constitute a major depressive episode. Major depressive episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

Note: Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.

D. The occurrence of the major depressive episode is not better explained by schizoaffective disorder, schizophrenia, schizophrenia spectrum, and other psychiatric disorders.

E. There has never been a manic episode or a hypomanic episode.

Note: This exclusion does not apply to all of the manic-like or hypomanic-like episodes that are substance induced or are attributable to the physiologic effects of another medical condition.

## Diagnosis

Please refer to [Box 105.1](#) for the DSM-5 criteria for a major depressive disorder. The symptom criteria for depressive disorders are required to have a duration of 2 weeks. Subtypes of depression include melancholic, psychotic, seasonal depressive disorder (winter time depression), and atypical depressive disorders. The severity of depression is measured by rating scales including the Hamilton Rating Scale for Depression and the Beck Depression Inventory. The severity of a depressive disorder is an important indicator of whether psychotherapy alone or psychotherapy in combination with somatic treatment will be required for resolution of the disorder. Depressive disorders characterized by feelings of sadness but no evidence of physical impairment, suicidal ideation, or psychosis may be treated initially with psychotherapy alone. But more severe depressive disorders with marked lack of energy, loss of interest, impaired sleep, and appetite disturbance require biological treatments, including antidepressant medication.

The DSM-5 includes a subcategory of depression, “depressive disorder caused by another medical condition.” This diagnosis refers to a persistent period of depressed mood that is judged to be the direct pathophysiologic

consequence of another medical condition and not the result of an adjustment disorder in which the stressor is the medical condition. Common medical conditions that may directly be a pathophysiologic cause of depression include a range of neurologic diseases, including Parkinson disease, poststroke depression, chronic subdural hematoma, and frontal lobe tumors; postconcussive syndromes and chronic traumatic encephalopathy secondary to repetitive brain injury are also associated with major depression. Endocrine disorders, including apathetic thyrotoxicosis, hypothyroidism, hypoglycemia, Cushing syndrome, and hyperparathyroidism may cause depression. Neoplasms, particularly carcinoma of the pancreas, may induce depression, even before the carcinoma is diagnosed. The elderly are particularly sensitive to depressive disorders being induced by chronic infection, including influenza and bacterial urinary tract infections. Metabolic abnormalities including hyponatremia are common in the elderly and are a cause of behavioral dysfunction, including depression. Prescription medications such as antihypertensives and sedatives, including sedative hypnotics, may also cause depression, particularly in the elderly. In patients with substance abuse disorders, cocaine and amphetamine withdrawal may cause a significant depressive disorder.

Other important medical conditions causing depressive disorders include coronary artery disease (including status postacute myocardial infarction); depression is very common postacute myocardial infarction and is a cause of significantly increased morbidity and mortality in coronary artery disease patients. In postmyocardial infarction patients, quality of life is improved and morbidity and mortality significantly reduced by antidepressant treatment.

Obstructive sleep apnea and idiopathic sleep disorders are medical conditions that also need to be ruled out as a factor in causing depressive disorders. Chronic insomnia is highly correlated with risk of onset of depression, and obstructive sleep apnea is a contributor to refractory depression if left undiagnosed and untreated.

New onset of depression after the age of 60 years is very commonly caused by cerebrovascular disease; these “vascular depressions” are associated with a history of hypertension, diabetes mellitus (DM), atrial fibrillation, history of stroke, and cigarette smoking.

All of the depressive disorders caused by a primary medical condition are managed by treating the underlying medical condition if possible and using antidepressant medications. There is clear evidence, for example, that poststroke depression and depression postacute myocardial infarction respond positively to antidepressant treatment with SSRI antidepressants.

Subcategories of depressive disorders are of particular importance in relation to appropriate treatment planning. Major depressive disorder is characterized by subcategories including whether the depression is a single episode or reflects a recurrent episode, whether the depression has melancholic features characterized by severe neurovegetative symptoms of depression such as marked weight loss, agitation or psychomotor retardation, guilt, prominent lack of energy, and loss of appetite, and whether the depression is characterized by psychotic symptoms such as delusions or hallucinations. Melancholic depression requires treatment with a somatic intervention such as a medication. Psychotic depression requires antipsychotic medication in combination with antidepressant or electroconvulsive therapy (ECT). Intense acute suicidal intent is another indication for ECT. Milder depressive disorders, without melancholia, psychosis, or suicidal ideation in which the patient is dysphoric, may be treated with psychotherapy alone. A patient with a history of mania who presents with depression is described as having bipolar depression; this clinical presentation requires a different medication approach with the use of mood stabilizing medications with antidepressant properties or the use of low-dose standard antidepressants “covered” by mood stabilizing antimanic medications. Standard antidepressant treatment alone may trigger agitation, psychosis, and/or mania in patients with bipolar depression.

**Box 105.1** lists the DSM-5 diagnostic criteria for a major depressive episode. These criteria for depressive disorders, as with other mental disorders, require that the depressive episode cause significant distress or dysfunction. Once a diagnosis of major depressive disorder is established, the clinician

needs to assess whether the depression presents with the following features: the presence of melancholic symptoms, psychotic symptoms, or bipolar (manic-depressive) symptoms by history.

Assess whether the depressive episode is a single, initial episode or a recurrent episode. Depressive disorder is a relapsing condition unless treated preventively. The incidence of recurrence of depression after the patient is in remission from an initial episode of depression and off of preventive antidepressant medication is 50%. If a patient has had two lifetime episodes of major depression and is not treated preventively, the likelihood of relapse of depression within 3 years is 70%; if the patient has a history of three or more lifetime episodes of depression and is not treated preventively, the likelihood of relapse within 3 years is 90%.

Persistent depression is characterized by 2 years of ongoing chronic depressive symptoms that may include symptoms consistent with major depressive disorder or dysthymic disorder. Dysthymic disorder is characterized by at least 2 years of depressed mood for more days than not, accompanied by an additional two of the following symptoms: poor appetite, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration, difficulty making decisions, and feelings of hopelessness. These depressive symptoms do not meet the severity criteria for major depression.

Adjustment disorder with depressed mood is a reaction that develops in response to an identifiable psychosocial stressor. The severity of depression and degree of impairment do not always parallel the intensity of the precipitating event. Treatment is usually supportive psychotherapy, psychosocial intervention, and antidepressant medication if the patient does not respond to psychotherapy or psychosocial treatments within a reasonable time frame (4–6 weeks).

Mood disorder caused by a general medical disorder is characterized by a prominent and persistent disturbance in mood that is judged to be a direct physiologic consequence of a general medical condition. Mood disorder caused by a general medical condition increases the risk of attempted and completed suicide (DSM-5). Suicide risk is heightened by chronic illness and persisting severe pain.

Substance-induced mood disorder is characterized by prominent and persistent disturbance in mood that is judged to be direct physiologic consequence of a drug of abuse, a medication, another medical treatment, or toxin exposure. Cocaine intoxication may present with manic symptoms; alcohol abuse worsens symptoms of depression. Some medications such as stimulants, steroids, and L-dopa can cause mania, and medications such as alpha-methyl-dopa and interferon can cause depression.

## Screening for Depression

There are several screening instruments available for use in primary care settings, including the Center for Epidemiologic Studies Depression Scale and the Geriatric Depression

Scale. The Patient Health Questionnaire, which is available in two versions, the PHQ-2 and PHQ-9, is a rapid assessment instrument that the patient may complete in 2 to 3 minutes. It offers an excellent screen to assess symptoms of depression. The Hamilton Rating Scale for Depression is a questionnaire completed by the clinical interviewer. This rating scale is commonly used in research and clinical settings and gives a comprehensive assessment of severity of depression, with a score of 18 or greater suggesting significant depression. This rating scale requires 20 minutes for completion. The Beck Depression Inventory is another commonly used assessment instrument.

## Suicide

Suicide is a major public health problem: it is the eighth leading cause of death in the United States. The suicide rate in the United States has averaged 12.5/100,000. Patients who are age  $\geq 65$  years have the highest rate of completed suicide per suicide attempt. The suicide rate for the elderly is 50% higher than the rate for teenagers or the US national average.

Recognizing the suicidal patient can be challenging in primary care settings. No studies have demonstrated that screening for suicidality in the primary care setting reduces completed suicides or attempts. Depression screening and severity assessment instruments such as PHQ-9 and the Quick Inventory of Depressive Symptomatology include questions about suicidal ideation that can trigger further inquiry by the physician. Because we do not have instruments that predict which patients with suicidal thoughts will attempt suicide, once such thoughts are recognized, further inquiry and physician judgment should determine any intervention.

Some 75% of patients who committed suicide had contact with their primary care providers in the year of their death compared with one-third who had contact with a mental health service. Similarly, twice as many suicide victims had contact with their primary care providers as had contact with mental health services the month before their suicide.

### Suicide Risk Assessment

The most important tool in assessment of suicide risk is the clinical interview. The clinician is encouraged to discuss with the patient his or her experience of three dimensions of suicidal assessment: suicidal press (the sense of urgency to die), suicidal perturbation (the specific stresses experienced such as medical illness, divorce, financial failure), and suicidal pain (the intensity of anguish experienced by the patient). This tripartite model of suicide risk is advocated by Edwin Schneideman. Also important is assessing previous suicide attempts in terms of risk and rescue. High risk/low rescue would be taking a shotgun to a motel under an assumed name. Low risk/high rescue would be taking six aspirin and calling the doctor. Both behaviors are concerning, the former much more so. The chart should reflect a discussion

with the patient around the specifics of his or her suicidal ideation, intent, and plan, if any. The stock phrase “patient contracts for safety” is not an adequate suicide assessment.

No specific methodology can predict whether a specific individual will attempt suicide. The lifetime prevalence of death by suicide in major, chronic psychiatric disorders such as severe major depressive disorder, bipolar illness, and schizophrenia is approximately 10%. Psychiatric disorders comorbid with major depression including substance use disorders, anxiety disorders, impulse disorders, and severe personality disorders (antisocial and borderline) increase risk of suicide. Patients with a history of being emotionally, physically, or sexually abused are at higher risk for suicidal behavior, and as stated earlier, the elderly have a higher rate of completed suicide per suicide attempt than younger patients. Because over half of completed suicides in the United States involve firearms, it is critical to limit access to weapons in those at risk for suicide.

Critical factors that increase risk of suicide include the following:

1. History of previous serious suicide attempts, including jumping, hanging, drowning, or use of firearms
2. History of bipolar illness or major depression with previous history of hospitalization
3. History of schizophrenia or chronic psychosis
4. Comorbid conditions including coexisting anxiety disorders, depressive disorders, and substance use disorders
5. Active substance abuse (implicated in 50% of completed suicides)
6. Active psychosis, including command hallucinations or nihilistic delusions
7. Psychosocial stresses; psychosocial isolation, poverty, discrimination
8. Chronic pain and chronic illness
9. Marked agitation and anxiety associated with depression
10. Feelings of hopelessness, guilt
11. Family history of suicide in first-degree relatives

To further elaborate on this list, keep the following in mind when assessing the patient expressing suicidal ideation: previous attempts increase the likelihood of future attempts by five to six times. Patients with multiple psychiatric conditions appear to be at higher risk than those with uncomplicated depression or anxiety. Anxiety disorders double the risk of suicide attempt (odds ratio [OR], 2.2), but the combination of depression and anxiety greatly increases the risk (OR, 17). The suicide risk is high among schizophrenic patients: up to 10% die by committing suicide. Alcoholics have an increased risk of suicide, with a lifetime risk of 2.2% to 3.4%, and those who have comorbid depression are particularly at high risk. Older men are three times more likely than women to complete suicide, although women attempt suicide four times more often than men. Ninety percent of completed suicides are by white people in the United States. Having a first-degree relative who committed suicide increases the risk 6-fold. Individuals who have never married are at highest risk for completed suicide, followed

in descending order by those who are widowed, separated, or divorced. Abuse and other adverse experiences during childhood increase the risk for suicide in adults. Of all the suicides in the United States, the majority are caused by a firearm. Other leading methods of suicide in the United States are hanging in men and poisoning in women.

### Protective Factors

Family connectedness and social support are protective. Parenthood, particularly for mothers, and pregnancy decrease the risk of suicide. Participating in religious activities and religiosity is associated with lower risk for suicide. A patient who expresses a sense of future orientation is at less risk for suicidal behavior. The goal of the doctor is to explicitly support the “part of the patient that wants to remain alive” and to endeavor to engage the patient in experiencing the suicidal thinking as a symptom of his or her illness and not a full expression of his or her self-experience. Developing a therapeutic alliance with the suicidal patient is an essential element in suicide prevention. Mobilizing supportive interpersonal relationships is another important element in suicide prevention.

Recent epidemiologic studies indicate that rates of suicidal behavior have peaks in adolescence and in the elderly, with the highest risk of suicidal behavior in the elderly. The peak prevalence of suicide in the elderly occurs after the age of 75 years. The elderly have the highest rate of completed suicide per attempt. Risk factors in the elderly that contribute to their vulnerability to suicidal behavior and completed suicide include social isolation, bereavement, chronic physical pain, and chronic illness. Cognitive impairment may increase impulsivity and impair judgment.

Studies of suicidal behavior in children and adolescents indicate risk factors that include preexisting psychiatric disorders, including eating disorders (bulimia and anorexia), a history of aggressive or impulsive behavior, and self-mutilation (self-cutting); other important risk factors in children and adolescents involve a history of sexual, physical, or emotional abuse, a pattern of feeling emotionally isolated from parents, family, and friends, feeling “unheard,” and being bullied.

Adolescents and children with depression have a higher rate of adverse reactions to antidepressants characterized by agitation, insomnia, or hypomania. This may reflect the fact that these depressed adolescents and young adults may be in the depressed phase of a latent bipolar disorder, which makes them vulnerable to such adverse side effects with antidepressants.

Patients with physical disease and chronic pain are at higher risk for suicidal behavior and completed suicide than age-matched physically healthy controls. Particularly prevalent chronic illnesses associated with completed suicide in a recent epidemiologic study of completed suicides in Germany included cancer, heart disease, and chronic pain. Other studies have indicated that patients with end-stage renal disease are at risk for death, not only by choosing to discontinue treatment but by active suicide attempts.

In all of these subcategories of risk for suicidal behavior, two overriding factors increasing risk of suicidal behavior and completed suicide stand out: a history of chronic psychiatric illness including most prominently depression, anxiety, or bipolar disorder and active substance abuse. Sedative abuse, mixed drug abuse, and opiate abuse markedly increase risk for suicide attempts and completed suicide. Substance abuse is highly comorbid with other psychiatric disorders including affective disorders and anxiety disorders.

### Managing Risk of Suicide

Management of the suicidal patient includes treating the modifiable risk factors such as depression, anxiety, panic attacks, psychosis, sleep disorders, and substance abuse; reducing other modifiable risk factors such as impulsivity, aggression, physical pain and illness, and access to lethal means of self-destruction also is of critical importance. Psychiatric hospitalization may be required to manage acute risk factors; careful follow-up posthospitalization is vital because risk of suicide attempts rises in the posthospitalization period.

### Treatment of Depression in Adults

#### Psychotherapy

The two forms of psychotherapy that have been used extensively for treating depression and that have shown efficacy are cognitive behavioral therapy (CBT) and interpersonal therapy (IPT).

CBT focuses on the impact of cognitions on mood and behavior and seeks to modify thinking patterns that reinforce feelings of depression, such as the belief “I am unlovable.” In depression, patients see themselves, their experiences, and their future in negative ways, which in turn sustains and magnifies their depressive symptomatology. Cognitive therapy uses specific treatment strategies to correct these habitual thinking errors found in different psychopathologic states. Treatment helps patients achieve a better integration of cognition (thoughts), emotion, and behavior. Patients treated with a combination of antidepressants and CBT have more sustained recoveries than those who are treated with antidepressant alone.

Interpersonal psychotherapy is a short-term typically 12-week treatment model that focuses on psychoeducation, identifies core conflicts, enhances coping and communication skills, and highlights strategies for improved behavioral adaptation. IPT is useful for patients who face conflicts with significant others or who are having difficulty adjusting to a life transition. The clinical practice guidelines for treatment of depression in the primary care setting recommend interpersonal psychotherapy for short-term treatment of nonpsychotic depression, to remove symptoms, prevent relapse and recurrence, correct causal psychological problems with secondary symptom resolution, and correct secondary consequences of depression. Variants of cognitive behavioral psychotherapy and interpersonal psychotherapy include problem-solving psychotherapy, which appears to be effective according to the Depression Guideline Panel of the

Agency for the Health Care Policy and Research (AHCPR); reminiscence psychotherapy is another specialized psychotherapy focused on treatment of pathologic grief reactions. This treatment is targeted at aiding patients in overcoming loss of loved ones.

Expressive psychotherapy has also been demonstrated to have utility in patients who are working through vulnerability to depression but are no longer acutely disabled by depression as a result of responding to biological treatment. Expressive psychotherapy is based on the model of psychoanalytic psychotherapy and seeks to uncover interpersonal conflicts and intrapsychic emotional experiences that are contributing to vulnerability to depression. Issues around low self-esteem, inhibition of healthy self-esteem, and self-criticism are often explored in this form of psychotherapy.

### Antidepressant Medications

The major classes of drugs used to treat depression are SSRIs, TCAs, MAOIs, and SNRIs.

#### Choice of Antidepressant

SSRIs are often the first choice in primary care because of fewer side effects and less danger with overdose. Patients will respond to the same antidepressant with which they were successfully treated in the past and will respond to the same antidepressant to which a first-degree relative has responded. SSRIs selectively inhibit the reuptake of serotonin in central nervous system (CNS) neurons as well as peripherally, thereby increasing the stimulation of serotonin receptors. SNRIs inhibit the reuptake of serotonin and norepinephrine. Norepinephrine dopamine reuptake inhibitors (NDRIs) inhibit reuptake of norepinephrine and dopamine. MAOIs irreversibly block the enzyme monoamine oxidase (MAO), the enzyme responsible for the oxidative deamination of neurotransmitters such as serotonin, norepinephrine, and dopamine (Table 105.1). Secondary and tertiary amine TCAs tend to block both serotonin and norepinephrine. Their use is limited because of their side effects and lethality in overdose.

#### Overview of Antidepressants

Table 105.1 presents an overview of antidepressants.

#### Drug Interactions

Some of the SSRIs such as fluoxetine and paroxetine inhibit the liver P450 enzymes leading either to increases in the levels of the drugs metabolized by these enzymes (such as increasing the levels of phenytoin or antiarrhythmics) or inhibiting the conversion to the active metabolite of drugs such as tamoxifen to endoxifen and codeine to morphine, thereby leading to ineffective levels of active drug.

#### Discontinuation Syndrome From SSRIs and SNRIs

Discontinuation reactions are more severe and more common with the short-acting drugs such as venlafaxine and paroxetine. Symptoms include vertigo, paresthesias, and shock-like feelings in the upper extremities and the neck.

Other symptoms include myalgias, tremor, myoclonus, ataxia, visual changes, piloerection, nausea, vomiting, and diarrhea. Patients may complain of emotional lability. Symptoms are relieved by taking the antidepressant within a short period of time.

Tapering is recommended for all antidepressants but particularly for shorter-acting venlafaxine and paroxetine over a period of at least 3 months to prevent withdrawal. Relapse of symptoms usually recurs within about 6 to 8 weeks. Patients who have had one episode of depression are treated for 6 to 8 months after they have had a complete remission of symptoms; those who have had two episodes should be treated for 2 to 3 years; and those who have had three or more episodes should have lifelong treatment with antidepressants.

#### Serotonin Syndrome

Serotonin syndrome (SS) is a potentially life-threatening condition associated with increased serotonergic activity in the CNS. The syndrome is characterized by the triad of mental status changes, autonomic hyperactivity, and neuromuscular abnormalities including hyperactivity, tremor, clonus, and hyperreflexia. It is typically caused by combining two or more serotonergic medications. The most common drug offenders are concomitant use with another SSRI, TCAs, MAOIs, triptans, ergot alkaloids, fentanyl, tramadol, amphetamines, levodopa, ondansetron, or granisetron. Most cases are relatively mild and can be managed on an outpatient basis with reduction or discontinuation of the serotonergic agents. In severe cases with more marked symptoms, treatment includes discontinuation of all serotonergic agents, supportive care in the intensive care unit (ICU), hydration, treatment with benzodiazepines, and administration of serotonin antagonists. Resolution usually occurs within 24 hours.

#### Effects of SSRIs and Other Newer Antidepressants on Suicide Risk in Adults

Current studies are inadequate to conclusively prove or disprove the association between the newer antidepressants and suicidal ideation or behavior in adults. There is some evidence that treatment with SSRIs may increase the risk of nonfatal self-harm compared with placebo but not compared with treatment with TCAs. Any absolute increase in the risk of nonfatal harm appears to be very small. At present, there is no compelling evidence indicating that SSRIs and other newer antidepressants increase the risk of suicidal ideation or completed suicide in adults. Given that the SSRIs and newer antidepressants have proven efficacy in the treatment of depression in adults, and that untreated depression is highly correlated with suicide risk, it is strongly recommended to continue use of these medications in the treatment of depressed patients.

Recent data indicate that risk of suicidal ideation and behavior may be slightly increased in patients age <24 years who are begun on antidepressants, but there is no evidence of an increase in completed suicide in that age group; this may reflect the fact that elements of this youthful population group are latently bipolar, and the antidepressant may

**TABLE 105.1** Overview of Antidepressants

Drug	Toxic/Adverse Effects	Comments
SSRIs: Citalopram (Celexa) Sertraline (Zoloft) Fluoxetine (Prozac) Paroxetine (Paxil)	CNS: insomnia, agitation, headaches, drowsiness GI upset, nausea, sexual dysfunction, hyponatremia/SIADH in elderly, impaired platelet aggregation may increase bleeding, increased bleeding in patients taking NSAIDs Citalopram in doses $\geq 40$ mg may cause an increase in the ST interval, especially in patients who have low potassium or magnesium	Serotonin syndrome, a disorder of excess serotonin activity, is caused by combining two or more serotonergic medications; common offenders include tramadol, MAOIs, triptans, levodopa, ergot alkaloids, linezolid, and St. John's wort. SSRI medications have P450 drug interactions and may increase or inhibit the metabolism of drugs to active metabolites, as in tamoxifen to endoxifen. Rapid discontinuation of short-half-life SSRIs (such as paroxetine) may result in a medication discontinuation syndrome. SSRIs are safer in overdosage than tricyclic antidepressants. Discontinuation may occur with short-acting antidepressants
Serotonin norepinephrine reuptake inhibitors: Duloxetine (Cymbalta) Venlafaxine (Effexor) Desvenlafaxine (Pristiq)	Insomnia, GI upset, HA, sexual dysfunction, sustained increase in blood pressure	Avoid use of MAOIs LFT monitoring recommended with duloxetine
Monoamine oxidase inhibitors: Phenelzine (Nardil) Tranylcypromine (Parnate) Isocarboxazid (Marplan) Selegiline	Weight gain, orthostatic hypotension, sexual dysfunction Hypertensive crisis may occur with tyramine-containing foods Interactions with serotonergic drugs lead to serotonin syndrome	Limited use because of drug/food interactions with tyramine-containing foods such as aged cheeses, aged cured meats, marmite, sauerkraut, soy sauce, improperly stored meats, fish, and poultry
<b>Tricyclic Antidepressants</b>		
Tertiary amines: Amitriptyline (Elavil) Imipramine (Tofranil) Doxepin (Sinequan)	Potentially fatal in overdose, increased risk of seizures and arrhythmias, common anticholinergic side effects, weight gain, sedation, sexual dysfunction, orthostatic hypotension	Blood monitoring indicated Contraindicated with use of MAOIs and in patients with recent myocardial infarction
Secondary amines: Nortriptyline (Pamelor) Desipramine (Norpramin)		
<b>Other Antidepressants</b>		
Mirtazapine	Sedation, weight gain, some anti-nausea effects, rare incidence of agranulocytosis	Helpful in depression associated with anxiety, insomnia, weight loss, agitation, nausea, severe depression
Trazodone Vilazodone (Viibryd)	Sedation, hypertension, dry mouth Priapism is a rare side effect	Mild antidepressant used mainly for insomnia; develop tolerance to it
Bupropion (Wellbutrin)	Dopaminergic; activating	No sexual side-effects; no anti-anxiety effect

CNS, Central nervous system; GI, gastrointestinal; HA, heart attack; LFT, liver function test; MAOIs, monoamine oxidase inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs; SIADH, syndrome of inappropriate antidiuretic hormone secretion; SSRIs, selective serotonin reuptake inhibitors.

be stimulating mania, agitation, and/or psychosis. There is no evidence that antidepressants increase suicidal ideation or behavior in the 24 years to 65 years age group, and there is evidence that antidepressants reduce suicidal ideation and behavior in patients age  $>65$  years.

### Psychopharmacologic Approaches to Refractory Depression

Somewhat more than one-third of all patients will have a full antidepressant response to their initial antidepressant trial. Therefore it is not uncommon for clinicians to switch to a different antidepressant class in the nontreatment responsive

patient. Common strategies to deal with refractory depression also include adding antidepressant augmenting medications to standard antidepressants including lithium carbonate, the stimulant methylphenidate, or triiodothyronine thyroid hormone in low dosage. Novel neuroleptics such as aripiprazole, ziprasidone, and olanzapine may also boost response to standard antidepressants. Some patients will respond to combinations of antidepressants such as SSRIs augmented with low doses of TCAs. For the most severe refractory patients MAOI medication may be highly effective. ECT is reserved for the most acute, life-threatening, or highly refractory patients.

### • BOX 105.2 DSM-5 Diagnostic Criteria for a Manic Episode

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).
  - B. During the period of mood disturbance and increased energy or activity three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
    1. Inflated self-esteem or grandiosity
    2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
    3. More talkative than usual or pressure to keep talking
    4. Flight of ideas or subjective experience that thoughts are racing
    5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed
    6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless nongol-directed activity)
    7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
  - C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
  - D. The episode is not attributable to the physiologic effects of a substance (e.g., a drug, of abuse, a medication, other treatment) or to another medical condition.
- Note: A full manic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiologic effect of that treatment is sufficient evidence for a manic episode and therefore a bipolar I diagnosis.
- Note: Criteria A to D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

From American Psychiatric Association (APA): *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: APA; 2013. © 2013 American Psychiatric Association.

## Bipolar Disorder

Recognition of bipolar disorder is important because it is associated with substantial morbidity and mortality, and treatment differs from that of unipolar depression. It is not uncommon for bipolar disorder to be underdetected, as patients tend to present with symptoms primarily of depression, especially in a primary care setting. Depressive symptoms are more frequent over the course of bipolar disorder than manic or hypomanic symptoms, although the latter define the disorder.

Bipolar I disorder is a recurrent disorder that may be familial in nature, although the exact genetic transmission of this disorder is unclear. Bipolar I disorders are defined on the basis of the criteria of DSM-5 (Box 105.2). These are characterized by distinct periods of abnormally and persistently elevated, expansive, or irritable mood lasting for at least 1 week. In addition, at least three of the following symptoms are present: inflated self-esteem or grandiosity, decreased need for sleep, greater talkativeness than usual, racing thoughts or flight of ideas, distractibility, increase in goal-directed activity, and excessive involvement in pleasurable activities that have a high potential for painful consequences, such as spending money or sexual indiscretion. Patients with bipolar II disorder have one or more depressive episodes with at least one hypomanic episode.

Hypomania refers to briefer duration and less severe level of manic symptoms, does not require hospitalization, and is not associated with psychotic symptoms (Box 105.3). Hypomania causes mild functional impairment and can even improve functioning.

Patients with bipolar disorder presenting with depression should be treated with mood stabilizers and not with antidepressants because they can cause patients to become

manic or hypomanic and destabilize their condition. About 25% to 33% of patients presenting with depression have bipolar depression. Patients presenting with both manic and depressive symptoms within the same 24-hour period are described as exhibiting a “mixed” bipolar presentation, and characteristically they exhibit both manic and depressive symptoms throughout their episode.

### Distinguishing Unipolar and Bipolar Depression

Patients with bipolar, compared with unipolar, depression are more likely to have a family history of bipolar disorder, have an earlier age of onset, have had recurrent episodes of depression, and have atypical features of depression such as sleeping too much, eating too much, complaints of fatigue, leaden paralysis in the extremities, and lack of motivation. Their response to antidepressants is characterized by heightened feelings of anxiety, insomnia, and irritability.

Patients presenting with depression should be specifically asked about manic or hypomanic symptoms including the following: “Have you experienced sustained periods of feeling uncharacteristically energetic?” “Have you had periods of not sleeping but not feeling tired?” “Have you felt your thoughts were racing and could not be slowed down?” “Have you had periods where you were excessive in sexual interest, spending money, or taking unusual risks?” The Mood Disorder Questionnaire is a useful screening instrument for bipolar I and bipolar II disorder. It has sensitivity of 0.281 and specificity of 0.972 in a community sample.

Both suicide attempts and completed suicide are very common problems in patients experiencing mixed bipolar episodes or bipolar depression; this fact heightens the importance of diagnosing bipolar spectrum disorders.

### • BOX 105.3 DSM-5 Diagnostic Criteria for a Hypomanic Episode

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day.
- B. During the period of mood disturbance and increased energy and activity, three (or more) of the following symptoms (four if the mood is only irritable) have persisted, represent a noticeable change from usual behavior, and have been present to a significant degree:
1. Inflated self-esteem or grandiosity
  2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
  3. More talkative than usual or pressure to keep talking
  4. Flight of ideas or subjective experience that thoughts are racing
  5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed
  6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
  7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)

- C. The episode is associated with unequivocal change in functioning that is uncharacteristic of the individual when not symptomatic.
- D. The disturbance in mood and the change in functioning are observable by others.
- E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization. If there are psychotic features, the episode is, by definition, manic.
- F. The episode is not attributable to the physiologic effects of a substance (a drug of abuse, a medication, other treatment).

Note: A full hypomanic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiologic effect of that treatment is sufficient evidence for a hypomanic diagnosis. However, caution is indicated so that one or two symptoms (particularly increased irritability, edginess, or agitation following antidepressant use) are not taken as sufficient for diagnosis of a hypomanic episode, nor necessarily indicative of a bipolar diathesis.

Note: Criteria A to F constitute a hypomanic episode. Hypomanic episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

From American Psychiatric Association (APA): *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: APA; 2013. © 2013 American Psychiatric Association.

## Treatment and Prevention of Bipolar Disorder

The treatment of bipolar disorder is divided into two components: management of the acute phase of illness and prevention of recurrence of the illness. The management of the acute manic phase of the illness involves the use of medications that control acute manic symptoms within hours to 1 to 2 days. These medications include lithium carbonate, valproate, and novel neuroleptics such as olanzapine, quetiapine, risperidone, and aripiprazole. High-dose benzodiazepines may be used adjunctively to calm acute mania. For treatment of refractory mania, clozapine, a highly potent antipsychotic medication, may be highly effective in calming acute mania. ECT is also used to treat acute mania, refractory to medications. Lamotrigine, another mood stabilizer, is more commonly used in the depressed phase of the illness and is somewhat less effective for management of acute mania. Acute control of mania commonly requires psychiatric hospitalization. “Triple therapy” for acute mania includes the concurrent usage of a mood stabilizer, a novel neuroleptic, and high dosage of benzodiazepine. A combined regimen of lithium, olanzapine, and clonazepam would be an example of such a regimen.

Once acute control of the mania is established, the emphasis shifts to prevention of recurrent episodes. In this regard lithium is the most effective medication, although valproate is often used in this role as well. The novel neuroleptics may also play a role in preventing subsequent episodes. Preventive treatment of bipolar illness often involves the long-term usage of lithium carbonate; such long-term

usage does run the risk of adverse effect on renal function, requiring consistent monitoring or renal indices.

## Treatment of Bipolar Depression

Patients with bipolar depression are best treated with mood stabilizers such as lithium, lamotrigine, olanzapine-fluoxetine combinations, quetiapine, and lurasidone. There are risks with antidepressant monotherapy treatment because it can cause switches into hypomania or mania, mixed affective states, and rapid cycling between mania and depression. If patients with bipolar depression do not respond to the medications noted previously, clinicians may add low-dose standard antidepressant treatment but must “cover” the antidepressant with a mood stabilizing medication such as lithium or a novel neuroleptic such as risperidone. ECT is often an effective treatment for refractory bipolar depression.

### Lithium

Lithium is approved for both acute treatment and the maintenance treatment of bipolar disorder. It is somewhat more effective in preventing manic episodes, but its substantial reduction in suicide suggests efficacy in depression as well. Common side effects are nausea, vomiting, diarrhea, weight gain, tremor, polyuria, polydipsia, and hypothyroidism. Chronic lithium ingestion has been associated with several different forms of renal injury. Nephrogenic diabetes insipidus is the most common side effect of lithium therapy. Chronic tubular interstitial nephropathy is the predominant

form of chronic renal disease associated with lithium therapy. Additional kidney manifestations of lithium exposure include renal tubular acidosis and hypercalcemia. Lithium is contraindicated in severe cardiovascular or renal disease, dehydration, and sodium depletion. It should be used cautiously with drugs such as diuretics, nonsteroidal antiinflammatory drugs, and angiotensin-converting enzyme inhibitors because they may cause lithium toxicity.

### Lamotrigine

Lamotrigine has efficacy for both acute and maintenance treatment of bipolar depression. It is also efficacious for rapidly cycling bipolar disorder, although rapid cycling bipolar illness (four or more episodes in 1 year) may require combinations of mood stabilizers to contain. Common side effects of lamotrigine are headache, insomnia, fatigue, and dizziness. Rare side effects include Stevens-Johnson syndrome (0.8%).

### Atypical Antipsychotics

Quetiapine and olanzapine with fluoxetine have been shown to have mood stabilizing and antidepressant properties. Main side effects are weight gain, DM, and metabolic syndrome. Lurasidone is effective in the treatment of bipolar depression and has mood stabilizing properties. It has also demonstrated effectiveness in mixed mood states characterized by mania coexisting with depression. Recently, cariprazine has also demonstrated effectiveness in treatment of bipolar depression. Both lurasidone and cariprazine have less metabolic side effects than olanzapine and quetiapine.

## Anxiety Disorders

The disorders of this group are most commonly encountered in the outpatient setting and affect approximately 10% of patients. Patients with anxiety disorders are more impaired in their functioning as compared with patients with DM and hypertension. So many of the symptoms of anxiety such as tachycardia, diaphoresis, shortness of breath, nausea, and chest pain could be confused with cardiac problems. On the other hand, autonomic arousal and anxious agitation may be attributed to stress or anxiety when the symptoms may actually represent a serious medical condition such as pulmonary embolism or cardiac arrhythmia.

Medical causes of anxiety disorders include hyperthyroidism, hypoxemia, pulmonary embolus, vestibular dysfunction, hypoglycemia, encephalitis, and partial complex seizures. Patients with chronic obstructive pulmonary disease are often highly anxious and may benefit from nonbenzodiazepine anxiolytics such as buspirone or hydroxyzine because benzodiazepines depress respiratory drive in chronic obstructive pulmonary disease. Mitral valve prolapse is associated with vulnerability to panic disorder for reasons that are unclear. Anxiety and agitation are common presenting symptoms in patients whose primary disorder is delirium or dementia.

## Panic Disorder

Lifetime prevalence of panic disorder is 1.5% to 3.5% in the general population. The prevalence in primary care settings is 4% to 7%, and it is more common in women. Because patients with panic disorder tend to present with physical symptoms, it takes about eight visits to a clinician to make a diagnosis of panic disorder.

### Clinical Manifestations

Panic attacks are characterized by the sudden onset of intense fear or discomfort and by the abrupt development of some specific somatic, cognitive, or affective symptoms (Box 105.4). Somatic symptoms can include chest pain or discomfort, shortness of breath, tachycardia and palpitations, dizziness, paresthesias, light-headedness, headaches, nausea, abdominal discomfort, sweating, chills and hot flashes, fear of dying, and fear of losing control. In addition, patients have persistent concern about having additional attacks (anticipatory anxiety) and worry about possible implications of the attack such as having a heart attack or losing control, and as a result, they may develop significant avoidance behaviors.

Depression occurs frequently with panic disorder and increases the risk of suicide by 20%. Comorbid asthma, labile hypertension, mitral valve prolapse, and migraine headaches are common in patients with panic disorder.

### Acute Treatment

The goal is to block the panic attack as quickly as possible to prevent the patient from developing avoidance behaviors, anticipatory anxiety, and agoraphobia. The most effective rapid-acting anxiolytic medications are the benzodiazepine group of medications. Alprazolam has approval from the US Food and Drug Administration as an anti-panic medication, but lorazepam and clonazepam may be equally effective in treating acute panic. The effect of the medications begins within 20 to 30 minutes. Therefore it is common practice to initiate treatment with a benzodiazepine combined with an antidepressant. The goal is to gradually taper off the benzodiazepine medication over several weeks after the antipanic efficacy of the antidepressant is established.

Antidepressant medications including the TCAs and SSRI and SNRI antidepressants, as well as MAOI medications, are all effective for the treatment of panic but can take several days, or up to a few weeks, to gain efficacy. SSRI and SNRI medications are the most commonly prescribed because of their relatively less problematic side-effect profile as compared with other antidepressants.

Benzodiazepines should not be prescribed for patients with a history of drug abuse, alcoholism, or addictive tendencies because they are commonly abused in that population. The risk of abuse and dependency is markedly less in patients without such a history. Adverse effects of benzodiazepines include transient cognitive clouding, sedation, and effects on balance and coordination. In general,

### • BOX 105.4 DSM-5 Diagnostic Criteria for Panic Disorder Without Agoraphobia

A. Recurrent, unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes and during which time four (or more) of the following symptoms occur:

Note: The abrupt surge can occur from a calm state or an anxious state.

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, light headed, or faint
9. Chills or heat sensations
10. Paresthesias (numbness or tingling sensations)
11. Derealization (feelings of unreality) and depersonalization (being detached from oneself)
12. Fear of losing control or “going crazy”
13. Fear of dying

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

- B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:
1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, or “going crazy”)
  2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations)
- C. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders).
- D. The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder, in response to reminders of traumatic events, as in posttraumatic stress disorder, or in response to separation from attachment figures, as in separation anxiety disorder).

From American Psychiatric Association (APA): *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: APA; 2013. © 2013 American Psychiatric Association.

benzodiazepines are best used to gain acute relief of symptoms and then tapered off gradually over several weeks after panic symptoms are in good control. There are circumstances in which patients with no history of drug abuse, alcoholism, or addiction may benefit from the judicious more persistent use of low-dose benzodiazepines as an adjunct to antidepressant antipanic medication.

## Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is a common condition with a 1-year prevalence of 3% and lifetime prevalence of 5.7%; the prevalence is 8% in primary care. Patients with GAD tend to present with predominantly somatic symptoms and frequently have comorbid conditions such as panic disorder, major depression (40%–50%), alcohol abuse, and personality disorder. Generalized anxiety disorder commonly presents to the primary care physician's office with cardinal symptoms of somatic distress such as insomnia, headache, nonspecific gastrointestinal distress, persistent worry, and psychologic tension. Unlike the catastrophic presentation of panic disorder, which has an acute onset and gradually abates over 2 to 3 hours, GAD is a chronic, often lifelong condition.

### Clinical Manifestations and Diagnosis

Diagnostic criteria from DSM-5 for GAD (Box 105.5) include excessive worry about a number of events or activities, occurring more days than not, for at least 6 months, that are out of proportion to the likelihood or impact of

the feared events. Worry leads to anxiety, which is associated with physical symptoms of anxiety such as dry mouth, sweating, palpitations, muscle tension leading to tension headaches, low back pain, and fatigue. Patients are easily startled, have difficulty falling asleep, and complain of poor memory and poor concentration. They have little insight into the connection between their reported worries or current life stress and their physical symptoms.

Patients should be screened for depression, medical disorders such as hyperthyroidism, pheochromocytoma, medication side effects, and for substance abuse, especially alcohol abuse.

## Treatment of Generalized Anxiety Disorder

### Drug Therapy

SSRIs, venlafaxine (SNRI), buspirone, and TCAs are effective for the treatment for GAD, but the SSRIs and SNRIs have become the first line of treatment because of their lower side-effect profiles and lower risk for tolerance and a direct effect on the psychic symptoms of worry and anxiety. Benzodiazepines, such as lorazepam or clonazepam, effectively treat the symptoms of GAD; because GAD is a chronic disorder, ideally the clinician will try to minimize to the extent possible the chronic use of benzodiazepines given the side effects of possible cognitive clouding and sedation. In addition, benzodiazepines are to be avoided in patients with a history of drug or alcohol abuse or dependence because this population is at risk for abuse of benzodiazepines. Ideally, a trial of an SSRI or SNRI will be effective and will facilitate tapering off of benzodiazepine. Buspirone is also

### • BOX 105.5 DSM-5 Diagnostic Criteria for Generalized Anxiety Disorder

- A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
- B. The individual finds it difficult to control the worry.
- C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):
- Note: Only one item is required in children.
1. Restlessness or feeling keyed up or on edge
  2. Being easily fatigued
  3. Difficulty concentrating or mind going blank
  4. Irritability
  5. Muscle tension
  6. Sleep disturbance (difficulty falling or staying asleep or restless, unsatisfying sleep)
- D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
- F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder [social phobia], contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

From American Psychiatric Association (APA): *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. Arlington, VA: APA; 2013. © 2013 American Psychiatric Association.

an alternative to benzodiazepines in the treatment of GAD but may take several weeks to gain maximal efficacy; the usual dosage range of buspirone for GAD is 15 to 30 mg per day in divided dosage, but a maximal dosage of 30 mg bid may be required to attain therapeutic response. A course of medication treatment of GAD may involve initiating treatment with low-dose benzodiazepine while concomitantly beginning SSRI, SNRI, or buspirone. Once the nonbenzodiazepines begin to exert efficacy, it is often possible to gradually taper the patient off of benzodiazepine.

### Psychotherapy in the Treatment of Panic Disorder and Generalized Anxiety Disorder

CBT, relaxation, and meditative therapies and behavioral therapies, such as exposure and response prevention, are all well-established psychotherapies for the treatment of anxiety disorders. Optimal treatment for panic disorder and GAD involves the combination of anxiolytic medication and psychotherapy.

It is important to recommend a psychotherapy program to complement medication management in GAD. CBT, meditation and relaxation therapies, and expressive psychotherapy all have demonstrated efficacy in reducing symptomatology. Behavioral therapies and biofeedback may also play a role in treating this disorder.

GAD is generally a persistent, chronic disorder, and the majority of patients do not achieve a full, enduring recovery. Thus ongoing treatment is essential with the goal of gradually minimizing the impact of symptoms on functioning. Lifestyle changes, exercise, adequate sleep, and attention to stress reduction are important elements in managing this disorder.

### Schizophrenia and Related Disorders

Schizophrenia is a severe disorder involving chronic or recurrent psychosis and long-term deterioration in functional

capacity. Psychosis is a break in reality manifested as some combination of delusions, hallucinations, disorganized or illogical thinking, and chaotic behavior. Although psychosis is a hallmark of schizophrenia, it is not pathognomonic for the disorder, and other psychiatric and medical disorders must be ruled out before the diagnosis is made. This is especially important if the first psychotic episode is after the age of 40 years. Schizophrenia is the most significant chronic psychotic disorder. Acute psychosis may be encountered in bipolar disorder and severe major depressive disorders, but these psychotic states are not persistent as in schizophrenia. A closely related condition to schizophrenia is schizoaffective disorder in which there is chronic psychosis but also significant mood alteration with manic or depressive elements. In schizophrenia, mood disorder is not a prominent feature of the illness; mood is bland or “flat,” and oddness, eccentricity, or bizarre behaviors dominant the clinical picture.

### Antipsychotic Medications

Antipsychotic medications are grouped into several distinct classes based primarily on their side-effect profile. All conventional and atypical antipsychotics appear to be equally efficacious in the treatment of psychosis; only clozapine is unique in its efficacy in refractory psychosis. There are no differential effects between the antipsychotic medications on nonpsychotic symptoms such as mania, uncontrolled behaviors, delirium, and poor impulse control. Medications differ in potency, side effects, routes of administration, and cost.

Conventional older antipsychotics include high-potency drugs such as haloperidol (Haldol), perphenazine (Prolixin), fluphenazine (Stelazine), and thiothixene (Navane) as well as low-potency drugs including Thorazine and mesoridazine (Mellaril). These older antipsychotic drugs are characterized by good efficacy but are associated with a high risk for

parkinsonian extrapyramidal side effects (EPS) including rigidity, bradykinesia, tremor, and akathisia (subjective and objective restlessness). In addition, they carry a 5% to 7% per year cumulative risk of tardive dyskinesia, which consists of late-onset choreoathetotic movements of tongue, face, neck, trunk, or limbs. Conventional antipsychotics are also associated with increase in prolactin levels, causing galactorrhea and amenorrhea. Significant QT prolongation is associated with intravenous haloperidol; however, clinically significant QT prolongation with oral use of haloperidol and other conventional antipsychotics occurs infrequently. Because of extrapyramidal side effects of these medications, they should not be given to patients with Parkinson disease or Lewy body dementia.

Atypical antipsychotics include clozapine (Clozaril), olanzapine (Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), ziprasidone (Geodon), aripiprazole (Abilify), and paliperidone (Invega). These drugs (except clozapine) have a low risk of EPS and the related risk of tardive dyskinesia. EPS and tardive dyskinesia are absent with clozapine. These medications are associated with weight gain, increased blood sugars, and metabolic syndrome. Risperidone increases prolactin levels and may cause galactorrhea and amenorrhea in women. Quetiapine is a reasonable choice for the treatment of psychosis in Parkinson disease because it has less extrapyramidal effects than other atypical antipsychotic medications.

There is limited evidence of superior efficacy for any of these drugs except for clozapine, and the only prediction of patient response is prior response to the same agents. Clozapine has demonstrated superior efficacy as compared with other antipsychotic medications in the treatment of refractory psychosis and refractory mania.

Neuroleptic malignant syndrome is a life-threatening neurologic emergency caused by neuroleptic agents, which block dopamine. Symptoms consist of the tetrad of fever  $>38^{\circ}\text{C}$ , which is the defining symptom, extreme muscular rigidity, mental status changes as the first symptom, and autonomic instability. Treatment is to stop the causative agent and other potential contributing psychotropic agents such as lithium, anticholinergic therapy, and serotonergic agents, provide aggressive supportive care in the ICU, administer muscle relaxants (such as dantrolene) to treat malignant hyperthermia and dopaminergic agents (such as bromocriptine and amantadine) to restore dopaminergic tone, and to use benzodiazepines to control agitation. Neuroleptic malignant syndrome can last from days to weeks.

Causative agents are usually “typical” conventional neuroleptics with high potency such as haloperidol and fluphenazine, although all antipsychotics including the atypical antipsychotics and antiemetic agent metoclopramide (Reglan) can also cause neuroleptic malignant syndrome.

Laboratory findings show elevated creatine kinase  $>100,000$  IU/L, leukocytosis, elevated catecholamines, and low serum iron.

## Somatization

Somatization refers to the tendency to experience psychological distress in the form of somatic symptoms and to seek medical help for these symptoms. Emotional responses such as anxiety and depression can initiate and/or perpetuate symptoms. Somatization can be unconscious or conscious and may be influenced by psychological distress or personal gain.

The DSM-5 diagnosis of somatic symptom disorder highlights the patient’s preoccupation with one or more somatic symptoms that dominate his or her thoughts, cause intense anxiety, and become a focus of time and energy. A subgroup of such patients presents with predominant pain as their primary somatic experience.

### Somatization Disorder

Patients with somatization disorder have recurrent multiple somatic complaints beginning before the age of 30 years. The disorder affects mostly women and results in treatment being sought and causes significant impairment in social, occupational, or other important areas of functioning. All of the following can be present at any time during the course of the illness: four pain symptoms; two gastrointestinal symptoms; one sexual symptom; and one pseudoneurologic symptom. It is best managed by collaborative work with an empathic primary care physician and mental health professional. Regularly scheduled appointments with the primary care provider are a cost-effective strategy that lessens “doctor shopping” and frequent visits to an emergency department (ED).

Conversion disorder refers to symptoms or deficits of voluntary or sensory function suggesting a neurologic or general medical condition and associated with psychological factors. Typically, there is sudden onset of a dramatic but physiologically unlikely condition such as paralysis, aphonia, blindness, deafness, or pseudoseizures. The presentation fits the patient’s view of the disorder rather than human physiology.

Pain disorder refers to pain in one or more sites of significant focus or severity, causing significant distress or impairment, and is associated with psychological factors.

Hypochondriasis refers to preoccupation with the fear of having a serious disease based on a misattribution of bodily symptoms or normal functions. The conviction about serious disease can be as severe and as inappropriate as a delusion, putting the diagnosis in the realm of psychosis. Hypochondriasis is often seen in generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, major depressive disorder, and separation anxiety disorder.

Body dysmorphic disorder refers to preoccupation with an imagined or exaggerated defect in physical appearance.

In factitious disorder, patients present with physical symptoms and findings. This is done at a conscious level, but the secondary gain is not obvious. These patients have

some medical knowledge. Wound healing difficulty, excoriations, infection, bleeding, hypoglycemia, and gastrointestinal ailments are common presentations. The most extreme presentation, Munchausen syndrome, occurs in a subgroup of patients who feign disease, move from hospital to hospital, and submit to repeated procedures for illnesses they have voluntarily produced.

Undifferentiated somatoform disorder refers to one or more physical symptoms that cause distress or impairment in functioning at least for 6 months.

### **Treatment of Somatic Symptom Disorders**

Treatment of somatic symptom disorders is complex and often involves a multimodal psychotherapy that is tailored to the individual patient. The psychotherapy component of treatment involves establishing a consistent, emphatic alliance with the patient. The focus of psychotherapy is on understanding the role of the symptoms in the patient's psychologic life and avoiding rejecting or judgmental responses to the patient's difficulties. A range of psychotherapy approaches may be beneficial including cognitive behavioral psychotherapy, behavioral psychotherapies including exposure and response prevention (demonstrating to a patient that physical therapy activities will not cause an imagined, feared injury), and relaxation and meditation techniques. Biofeedback strategies may also be considered. For some patients, an expressive psychotherapy focused on the meaning of the symptoms as a defense against core emotional conflicts in their life may be fruitful after a strong therapeutic relationship is established.

Pertinent to medication management, somatic pain disorders, including musculoskeletal distress, may respond to antidepressant medications such as SSRI, SNRI, or TCAs. Duloxetine (SNRI), sertraline (SSRI), or amitriptyline (tricyclic) all may be useful. Dosage range for treatment of these conditions is in the low to mid range. Other secondary medication choices include gabapentin or low dosage of novel neuroleptics, such as quetiapine.

Somatic symptom disorders present a spectrum of disorders requiring a treatment program specifically tailored to the unique, specific symptoms presented by the patient. The only uniform aspect of these disorders is that they require persistent, empathic treatment by the physician and a flexible, eclectic approach to somatic and psychologic interventions. Somatic symptom disorders are commonly persistent conditions that may yield to long-term multimodal treatment approaches.

### **Delirium**

Nearly 30% of older medical patients experience delirium at some time during their hospitalization. This percentage is even higher in surgical patients. Delirium has an enormous impact on the health of older patients. Patients with delirium have high morbidity and mortality.

### **Clinical Features**

Disturbance of consciousness is manifested by reduced clarity of awareness of the environment. The ability to focus, sustain, or shift attention is impaired, and the patient is easily distracted by irrelevant stimuli. There is a change in cognition that may include memory impairment, disorientation, and language disturbance or the development of perceptual disturbance, which may include illusions or hallucinations. The disturbance develops over a short period of time and tends to fluctuate during the course of the day. The patient may be coherent and cooperative in the morning but at night becomes agitated, attempts to pull out intravenous lines, and wants to leave. Delirium is also associated with disturbance in sleep-wake cycle, daytime sleepiness, agitation, and difficulty falling asleep at night. Psychomotor behavior disturbances may include increased psychomotor activity, which may include groping or picking at the bedclothes, attempting to get out of bed, or decreased activity with sluggishness and lethargy that approach stupor. Variable emotional responses such as anxiety, fear, depression, irritability, anger, euphoria, and apathy can also be seen.

### **Approach to the Patient**

Virtually any medical condition can precipitate delirium in a susceptible person. The history and physical examination will guide most of the investigations. The conditions noted most commonly in prospective studies of the disorder include fluid and electrolyte disturbance (dehydration, hyponatremia, and hypernatremia); infections (urinary tract infection, respiratory tract, skin, and soft tissue); drug and alcohol toxicity; withdrawal from alcohol, barbiturates, benzodiazepines, and SSRIs; metabolic disorders (hypoglycemia, hypocalcemia, uremia, liver failure, and thyrotoxicosis); low perfusion states (shock, heart failure); and postoperative states, especially in the elderly.

### **Management**

Important issues in management of delirium involve providing medical care that reverses the underlying medical insult to the patient; the clinician may need to discontinue medications such as opiates or benzodiazepines that may exacerbate behavioral dysfunction. Attention to environmental issues in-hospital could include maximizing staff continuity, providing clocks and calendars to facilitate reality orientation, encouraging family members to visit, and providing personal items at the bedside. Placing the patient close to the nursing station may be helpful.

Medication management involves facilitating sleep and normal diurnal functioning. Low dosage of an atypical antipsychotic medication may help facilitate sleep and normalize behavior. Medication management issues

include the use of medications that may be delivered parenterally or intravenously; if the patient is able to swallow, medication in liquid form is often useful. For example, risperidone is a novel neuroleptic available in liquid form. Medications that are worth considering

include intramuscular olanzapine, haloperidol, or ziprasidone. Haloperidol may be given through an intravenous route. In general, the use of benzodiazepines should be limited to patients experiencing alcohol or sedative-hypnotic withdrawal delirium.

## Chapter Review

### Questions

1. A 76-year-old man presents to the hospital with urinary retention and is found to be septic from a urinary tract infection. He is confused and agitated with paranoid ideation. He is exhibiting visual hallucinations, as characterized by his seeing “bugs on his bed sheets and the walls.” He balls his fists and attempts to strike one of the nurses. He has a history of advanced Parkinson disease and is on a dopamine agonist. Which of the following medications would be the most appropriate to manage his behavioral dysfunction?
  - A. Haloperidol
  - B. Quetiapine
  - C. Risperidone
  - D. Aripiprazole
2. A 29-year-old woman is brought to the ED with the following chief complaints: difficulty breathing, lightheaded dizziness, a fear of dying, and a fear of going crazy. The onset of this episode was sudden and without a precipitant. She is experiencing tingling in her hands. An electrocardiogram is normal. She reports a history of recurrent depression on three previous occasions and episodic attacks similar to her current presentation. All laboratory studies are normal, and the patient is much improved after 45 minutes in the ED. Which of the following would be the most optimal medication management on an outpatient basis?
  - A. Begin a trial of bupropion.
  - B. Begin a course of long-term benzodiazepine preventive treatment.
  - C. Initiate a time-limited course of an SSRI and a benzodiazepine.
  - D. Initiate a time-limited course of benzodiazepine while also beginning a long-term antidepressant treatment with an SSRI.
3. A 33-year-old man presents to your office with sad mood, lack of energy, loss of interest, lack of enjoyment (anhedonia), and early morning awakening. He acknowledges being tearful. He reports a history of periods of increased energy, diminished sleep, press of speech, flight of ideas and markedly increased productivity, and goal-directed activity. He states that these shifts in mood may occur “three to four times a year”; at times he reports he may have periods of sad mood and lack of energy interspersed with episodes of increased activity and socially intrusive behavior within the same day. Which of the following medication regimens is not an appropriate intervention?
  - A. Lithium carbonate
  - B. Lamotrigine
  - C. Fluoxetine
  - D. Lurasidone
4. You are asked to consult on an 83-year-old woman in a nursing home. She is medically stable, with normal laboratory studies. She appears tense, preoccupied, and makes poor eye contact. On interview, she initially is silent but eventually admits to hearing voices telling her that she deserves to die and should jump off the roof. What is the most appropriate immediate step you should take to manage this clinical situation?
  - A. Reassure the patient that she will recover, and begin antidepressant medication.
  - B. Arrange for a psychiatric consultation the next day, and begin an antianxiety medication.
  - C. Place the patient on one-to-one constant observation, begin an antipsychotic medication, and obtain a stat psychiatry consultation to consider next steps possibly including ECT.
  - D. Begin an intensive psychotherapy program conducted by a psychiatric clinician at the nursing home while awaiting a psychiatric consultation.
5. A 35-year-old male with a history of hypertension, type 2 diabetes, and bipolar disorder presents for his yearly physical examination. His medications include metformin, lisinopril, lithium, and a new medication begun 4 months ago. On physical examination, his weight has increased by 30 lb in the past 4 months. His hemoglobin A<sub>1c</sub> is 10.6%. Which of the medications listed below is the most likely to have caused the weight gain?
  - A. Depakote
  - B. Olanzapine
  - C. Lamictal
  - D. Topiramate

## Geriatrics

SUZANNE EVA SALAMON

**G**eriatric medicine is the subspecialty of internal medicine that focuses on the care of patients age >65 years. As life expectancy increases and the Baby Boom generation reaches old age, there will be a significant increase in this population. In the United States, the number of Americans >65 years is projected to more than double from 46 million currently to >98 million by 2060. This group accounts for 14.1% of the total population. This number is expected to reach over 72 million by 2030, or almost one in every five Americans. The population age  $\geq 85$  years is projected to increase the most, from 5.8 million in 2010 to 8.7 million in 2030. There will never be enough geriatric specialists to care for this group of patients, so all health care providers must be aware of the key principles of geriatrics.

The effects of normal aging and disease-related changes common in older adults necessitate a unique approach when caring for this group. There are several geriatric syndromes encountered regularly in older adults. These include frailty, multimorbidity, polypharmacy, dementia, delirium, late-life depression, urinary incontinence, and falls.

### Frailty and Multimorbidity

Frailty is not synonymous with aging but is a clinical syndrome of weakness, low energy, decreased walking speed, decreased physical activity, and weight loss, often seen in combination with illness and decreased functional reserve. Various diagnostic criteria exist to define frailty and objectively characterize the signs and symptoms. Frailty is important to recognize because frail older adults are at higher risk of poor outcomes including prolonged hospitalizations, increased risk of falls, greater functional decline, and mortality. A comprehensive geriatric assessment can identify the modifiable precipitating factors that cause frailty and improve the core manifestations of frailty, especially physical activity, exercise tolerance, strength through resistance exercise, and nutrition. Precipitants can include depression, dementia, acute illness, pain, immobility, hospitalization, and multiple chronic illnesses and medications.

The number of chronic medical conditions is a strong predictor of frailty and is also known as the multimorbid state. Multimorbidity refers to the presence of multiple chronic medical conditions, where the impact of illness is

greater than the sum of each individual condition. Over 50% of older patients have three or more chronic medical problems. Caring for patients with multimorbidity challenges the concept of clinical practice guidelines, which often focus on individual diseases without considering other coexisting illnesses and the impact of each treatment on the individual as a whole. Clinicians caring for patients with multimorbidity face complex clinical management decisions, inadequate evidence, and time constraints that hinder provision of efficient care. When caring for older patients with multimorbidity, providers must choose therapies that incorporate patient preference while also factoring risks, benefits, quality of life, prognosis, and complexity.

### Polypharmacy

Polypharmacy is the use of several drugs at the same time. The average older person uses five to seven prescription drugs and several over-the-counter drugs. As the number of medications increase, the number of adverse effects and drug–drug interactions also increase. A common example is the interaction between warfarin and antibiotics. Thirty percent of hospital admissions are linked to polypharmacy and are estimated to cause 106,000 deaths per year at a cost of \$85 billion. Adverse drug events are reported to be preventable in 27% of ambulatory care settings and 42% of long-term care settings. Older adults are more sensitive to the effects and side effects of medications because of altered pharmacokinetics (i.e., changes in body composition) and altered pharmacodynamics (i.e., changes in the body's response to drugs). Creatinine values that are within “normal” laboratory reference range may indicate significant renal insufficiency. Therefore the glomerular filtration rate must be calculated and used as a guide when prescribing renally cleared medications.

The Beers Criteria, updated in 2012, are a list of potentially inappropriate medications to avoid or to use with extreme caution in older adults because of either ineffectiveness or high risk for adverse events. These include benzodiazepines, muscle relaxants, and certain analgesics (Table 106.1). Medications with high anticholinergic properties (antihistamines, antispasmodics, antimuscarinics, and some antidepressants and antipsychotics) should be avoided or

**TABLE 106.1** Examples of Medications to Avoid or Use With Caution in Older Adults, According to the 2012 Beer's Criteria

Drug	Reason
Anticholinergics and antihistamines such as diphenhydramine (Benadryl) and hydroxyzine (Atarax and Vistaril)	Confusion, sedation, constipation, urinary retention, and dry mouth
Benzodiazepines, especially long-acting formulations such as diazepam (Valium), clonazepam (Klonopin), and chlordiazepoxide (Librium)	All benzodiazepines increase risk of cognitive impairment, delirium, falls, fractures, and motor vehicle accidents. Older adults have increased sensitivity and slower metabolism with long-acting agents.
Skeletal muscle relaxants and antispasmodics such as carisoprodol (Soma) and cyclobenzaprine (Flexeril)	Highly anticholinergic properties that can cause confusion, sedation, constipation, and weakness as well as questionable effectiveness
Gastrointestinal antispasmodic drugs such as dicyclomine (Bentyl) and hyoscyamine (Levsin)	Highly anticholinergic properties that can cause confusion, sedation, constipation, and weakness as well as questionable effectiveness
Antimuscarinic agents (for treatment of urinary incontinence) such as oxybutynin	Highly anticholinergic properties that can cause confusion, sedation, constipation, and weakness. Should be avoided in patients with dementia or constipation.
Barbiturates	Sedation and physical dependence
Digoxin (Lanoxin) in doses >0.125 mg/d unless required	Toxic effects at higher doses caused by reduced renal clearance
Tricyclic antidepressants such as amitriptyline (Elavil) and doxepin (Sinequan)	Highly anticholinergic and can cause orthostatic hypotension
Long-acting sulfonylureas such as glyburide	Greater risk of severe prolonged hypoglycemia
SSRI antidepressants	Use with caution. May cause or exacerbate SIADH (and hyponatremia) and increase risk of falls. Paroxetine (Paxil) has strong anticholinergic properties. Fluoxetine (Prozac) has a long half-life and can cause agitation and sleep disturbance from CNS stimulation.
NSAIDs, non-COX selective	GI bleeding and peptic ulcer disease, especially in those at high risk: those age >75 years or taking corticosteroids, oral anticoagulants, or antiplatelet agents. Indomethacin has the most adverse effects of all the NSAIDs.

COX, Cyclooxygenase; CNS, central nervous system; GI, gastrointestinal; NSAIDs, nonsteroidal antiinflammatory drugs; SIADH, syndrome of inappropriate antidiuretic hormone secretion; SSRI, selective serotonin-reuptake inhibitors.

used with extreme caution because of their risk of confusion, delirium, sedation, falls, constipation, and urinary retention. As a rule, medications should be started in older adults at the lowest possible dose, titrated slowly, and regularly evaluated for effectiveness and side effects.

Medication lists should be frequently reviewed so that unnecessary drugs can be eliminated. A medication review should be performed at least annually and every time a medication is changed or started. Nonadherence may be as high as 50% in older adults, so ask about difficulties taking medications and adverse events, review the refill history, and whenever possible have the patient bring all his or her actual medications to the visit. Transitions of care are a particularly dangerous time for older adults because of the high risk of medication errors, omissions, and commissions. Careful medication reconciliation is critical at every transition of care.

## Dementia

### Background

Dementia is a disorder that is characterized by a decline in cognition involving one or more cognitive domains (learning and memory, language, executive function, complex attention, perceptual-motor, social cognition) significant enough to interfere with routine activities of daily life.

### Epidemiology

Dementia is common and increases with age, occurring in approximately 10% of adults age >65 years and increasing to 50% of adults age >90 years. There are many forms of dementia (Box 106.1). Alzheimer disease (AD) is the most common type, accounting for 60% to 80% of dementias. In

### • BOX 106.1 Causes of Dementia

- Alzheimer disease
- Vascular dementia
- Mixed dementia
- Dementia with Lewy bodies
- Frontotemporal dementia
- Depression
- Infection (e.g., syphilis, HIV, or encephalitis)
- Parkinson disease
- Vitamin B<sub>12</sub> deficiency
- Hypothyroidism
- Creutzfeldt-Jakob disease (prion disease)
- Subdural hematoma
- Normal-pressure hydrocephalus
- Alcohol-related dementia

2012 5.2 million adults age >65 years had AD, accounting for almost \$84 billion in annual costs caring for this group. Non-Alzheimer dementias include vascular (multiinfarct) dementia (15%–20%), dementia with Lewy bodies (DLB), and Parkinson disease. Some research suggests that vascular and mixed dementia are more prevalent than previously believed. Less than 10% of dementias are caused by reversible conditions (e.g., hypothyroidism or B<sub>12</sub> deficiency), and even when treated, the underlying cause often turns out to be AD or vascular dementia.

### Pathophysiology

AD is defined by neuritic amyloid plaques and neurofibrillary tangles, leading to neuronal cell loss and alterations in neurotransmitter function. The *APOE E4* allele on the *APOE* gene appears to be a risk factor for AD, but its role is not yet fully defined. Age is the greatest risk factor for the development of dementia. Other risk factors include family history and Down syndrome. The other dementias involve lesions localized to specific cortical or subcortical areas of the brain.

### Clinical Presentation

Normal aging may cause a decline in some memory along with slower recall time for newly learned information and slowed ability to learn new information. There may also be subtle word-finding difficulty and trouble recalling names of people. However, with normal aging there is no functional impairment, and scores on objective tests are within the normal range.

Mild cognitive impairment (MCI) is a distinct type of objective cognitive impairment that does not qualify as dementia because there is no functional impairment. Patients with MCI will have subjective complaints of cognitive decline in at least one domain along with noticeable and measurable deficits, but the deficits have no effect on social and occupational functioning. Some patients with MCI (thought to be around 10% per year) will develop dementia, and some will improve. Medications used to treat dementia are not effective in treating MCI.

Identifying the specific form of dementia has important implications in prognosis and treatment (Table 106.2). AD is distinguished by memory impairment with at least one of the following: aphasia (language disturbance), apraxia (difficulty performing simple motor activities in the presence of normal motor function), agnosia (difficulty recognizing familiar objects), or executive dysfunction. Memory loss is the most common initial presentation, often reported by a family member rather than the patient. It is often incorrectly dismissed as part of normal aging. In the early stage of AD, symptoms include difficulty in learning new information, getting lost while driving to familiar places, or changes in mood manifested as suspicion or hostility. By the middle stage of AD, patients are unable to perform activities of daily living and develop eating problems, incontinence, and motor impairment. In the late stage of AD, memory loss is severe, and afflicted patients will often become mute, immobile, develop recurrent infections, and often display behavioral disturbances such as agitation, depression, hallucinations, and delusions. End-stage AD qualifies for hospice care.

Vascular dementia is associated with microvascular disease as small strokes destroy brain tissue. Risk factors include smoking, hypertension, diabetes, and heart disease. Patients with vascular dementia classically exhibit a stepwise deterioration that prominently affects gait and speech, although in practice the deterioration is more subtle and progressive rather than stepwise. Mixed dementia refers to a combination of AD along with evidence of microvascular disease. Frontotemporal dementia (FTD) presents initially with changes in personality such as disinhibition or apathy and executive dysfunction. DLB is associated with extrapyramidal motor symptoms similar to Parkinson disease but in addition is noted for fluctuating levels of attention and visual hallucinations. Patients with DLB notably have increased sensitivity to neuroleptics with worsening of the extrapyramidal symptoms when exposed to antipsychotics. Dementia is common in patients with Parkinson disease, but in contrast to DLB, the parkinsonian features occur before the development of cognitive dysfunction.

### Diagnosis

The diagnosis of dementia is a clinical diagnosis. The history obtained from the patient and caregivers is the most important part of the evaluation for suspected dementia. Cognitive testing is another important part of the evaluation and can be done by a primary care provider, neurologist, or through more extensive neuropsychologic testing. The most frequent screening tests of cognition in the primary care office are the mini-mental state examination (MMSE) and Montreal cognitive assessment (MoCA), which take about 5 to 10 minutes to administer. A score of <26 out of 30 suggests impairment. Level of education influences the tests. The MoCA is more sensitive and specific than the MMSE for detecting early dementia and mild cognitive impairment. Patients should also be evaluated for depression,

**TABLE 106.2** Specific Characteristics of Non-Alzheimer Dementia

Symptom	Disorder
Abrupt, stepwise deterioration	Vascular dementia
Prominent behavioral changes such as apathy and disinhibition	Frontotemporal dementia
Progressive gait disorder	Vascular dementia, Parkinson disease, normal-pressure hydrocephalus
Extrapyramidal signs before the development of cognitive dysfunction	Parkinson disease
Extrapyramidal signs after the development of cognitive dysfunction	Dementia with Lewy bodies
Fluctuation in consciousness	Dementia with Lewy bodies
Visual hallucinations	Dementia with Lewy bodies
Neuroleptic sensitivity	Dementia with Lewy bodies and Parkinson disease

which has symptoms that can overlap with dementia. A careful neurologic examination and routine blood assays including thyroid function and vitamin B<sub>12</sub> should be performed. Imaging with a noncontrast head CT or MRI may be considered to rule out vascular disease, normal-pressure hydrocephalus, or subdural hematomas. Neuroimaging is often not necessary but could be considered for those age <65 years or those who have focal neurologic deficits, rapidly progressive symptoms, acute onset, or history of recent fall and/or head trauma. Functional neuroimaging with fluorodeoxyglucose positron emission tomography, single-photon emission CT, or perfusion MRI is sometimes used to differentiate FTD from AD, although this is an evolving topic.

The US Preventive Services Task Force (USPSTF) concludes that there is insufficient evidence to recommend for or against routine screening for dementia in all older adults, although there should be a low threshold for testing when there are concerns about cognitive decline, change in behavior, or other warning signs.

## Treatment

There is no cure for AD, but there are medications that may help slow the disease and manage behaviors. Cholinesterase inhibitors help restore the loss of the neurotransmitter acetylcholine, which is decreased in AD. The US Food and Drug Administration (FDA) has approved donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne) for use in mild-to-moderate AD, although these drugs have been used with varying effect in other forms of dementia as well. Cholinesterase inhibitors may improve cognitive scores, moderately improve behavioral disturbances, and maintain independence. However, the effect is usually small and followed by eventual decline. There may be a greater role for treatment with cholinesterase inhibitors in AD and DLB versus vascular dementia or FTD. Side effects from cholinesterase inhibitors include nausea,

vomiting, diarrhea, and weight loss. A separate medication option is memantine (Namenda), an N-methyl-D-aspartate antagonist, FDA approved as an add-on to cholinesterase inhibitors for moderate-to-severe dementia. Although common practice in the United States is to add memantine to donepezil for treatment of more advanced disease, the evidence of benefit is unclear. For example, a 2012 randomized placebo controlled trial did not find that the addition of memantine to donepezil improved cognition or function, although either treatment alone did appear helpful. In general, the clinical improvement with medication treatment is modest at best. Patients and families should be counseled on the treatment options and be provided realistic expectations, with clinical reevaluation to determine if further treatment is indicated and tapering of medications if there continues to be a decline despite maximal treatment.

Neuropsychiatric symptoms common in dementia should first be managed with nonpharmacologic therapies such as exercise, music, old movies, and redirection. Nonpharmacologic treatment is often more effective than medication. A careful history and examination should attempt to rule out delirium, infection, pain, constipation, sensory impairment, depression, or other common triggers for behavioral disturbances. If necessary, atypical antipsychotics at low doses can be effective for the management of psychosis or agitation. However, even newer atypical antipsychotic medications can produce side effects of parkinsonism, tardive dyskinesia, sedation, and anticholinergic effects. In addition, there is a “black box label” warning for possible increased risk of death in older demented patients. Therefore antipsychotic medications should be used carefully and at low doses and frequently assessed for effectiveness and side effects.

Management of the demented patient also includes advanced care planning (documentation of advanced directives and health care proxy), addressing caregiver stress, and ensuring safety (driving and wandering).

**TABLE 106.3 Etiology of Delirium**

Risk Factors	Causes

## Delirium

### Background

Delirium is an acute change in mental status defined by a fluctuating course and the inability to maintain attention. Delirium is common, especially in hospitalized patients, and is frequently missed. Delirium leads to increased morbidity, mortality, loss of independence, institutionalization, and almost \$7 billion in annual costs.

### Epidemiology

Rates of delirium vary depending on precipitating factors and predisposing risk factors. The overall prevalence of delirium in community dwellers is only 1% to 2%, but 10% to 30% of elderly presenting to emergency departments are delirious. Rates are highest in the hospital setting with up to 53% of older adults developing delirium postoperatively, and in the intensive care units up to 87% are delirious. The 1-year mortality rate in people with delirium is as high as 40%. Unfortunately, delirium is often unrecognized; only 20% of cases are recognized by physicians and only 50% by nurses.

### Pathophysiology

The exact mechanism of delirium is poorly understood, but it is felt to signify generalized disruption in higher cortical function. Cholinergic deficiency, dopaminergic excess, and cytokines are hypothesized to play a role. Two-thirds of people who develop delirium have underlying dementia or other predisposing risk factors (Table 106.3).

### Clinical Presentation

The hallmark of delirium is an acute change in mental status developing over hours or days that fluctuates with periods of lucid intervals along with the inability to maintain attention. Patients will often display incoherent and disorganized

speech or thoughts. Altered consciousness can present with either hyperactive delirium with agitation and restlessness, hypoactive delirium with lethargy and a decreased level of motor activity, or a mixture of the two. Global cognitive deficits involving memory, language, and disorientation can occur. Characteristic alterations in the sleep cycle as well as hallucinations and emotional disturbances are also common.

### Diagnosis

The diagnosis of delirium is primarily clinical and is made using the confusion assessment method (CAM). The CAM is a validated bedside screening tool that requires the following: (1) acute change in mental status with a fluctuating course and (2) inattention with either (3) disorganized thinking or (4) altered level of consciousness.

### Treatment

The etiology of delirium is usually multifactorial (see Table 106.3) and is often reversible if the underlying causes are corrected. However, hospitalized patients with dementia who develop delirium may have irreversible damage as evidenced by increased rates of cognitive deterioration that is maintained for at least 5 years after hospitalization with delirium. Thus prevention and early treatment of delirium are critical. Many factors can cause delirium, but medications very often play a key role. Examples of medications that can cause delirium include anticholinergic medications (antihistamines, antispasmodics, antimuscarinics), benzodiazepines, opioid analgesics, and sleeping pills. Delirium can also be an atypical presentation for many diseases in older adults, including infection (urinary tract or pneumonia), electrolyte and metabolic disturbances, hypoxia, urinary retention, constipation, and pain. Screening for alcohol or drug use is important to rule out withdrawal or intoxication.

Supportive care should focus on maintaining hydration, nutrition, and mobilizing the patient as soon as possible to

prevent additional complications as well as stopping any potentially harmful drugs. Behavioral symptoms are often the most challenging complication of delirium to manage, especially in an agitated, confused patient. Nonpharmacologic methods should be used, which include frequent orientation, reassurance, and family involvement. Physical restraints and nighttime interruptions should be avoided. Unnecessary lines and tubes, especially Foley catheters, should be removed as soon as possible. Pharmacologic treatment should be used only for the agitated patient at risk of harm to self or others. Antipsychotics such as haloperidol can be used for acute agitation and should be used in low doses of 0.25–1.0 mg orally or intramuscularly, not to exceed 3 mg in a 24-hour period. When patients are able to take oral medications, atypical antipsychotics can be used in low doses and given at regular intervals as needed. Typical regimens include risperidone (0.5 mg twice daily), olanzapine (2.5–5 mg daily), and quetiapine (12.5–25 mg twice daily). These drugs should be used sparingly because of the adverse side effects mentioned previously. The best treatment for delirium is prevention by recognizing patients at high risk and minimizing risk factors.

## Late-Life Depression

### Background

Depression in older adults is common yet often undetected and undertreated. Symptoms can present differently in older adults because of the coexistence of chronic medical disorders, memory loss, pain, and alcohol or substance abuse. Untreated depression is associated with poor quality of life, nonadherence to medical treatment, functional decline, and increased morbidity and mortality. The risk of suicide underlies the importance of recognizing and treating depression because older men have the highest rate of successful suicide of any age group.

### Epidemiology

Over 10% of adults age >65 years presenting to primary care physicians have clinically significant depression. Hospitalized and institutionalized older adults have even higher rates. Depression is more common in women, those with chronic medical disorders, insomnia, stressful life events, functional decline, and social isolation.

### Pathophysiology

Previous psychiatric disorders continue to be a risk factor for depression in later life. Chronic medical conditions and functional decline contribute to the new development of depression after the age of 65 years. Studies suggest that cerebrovascular disease and vascular risk factors may play a role in the development of depression caused by microvascular ischemic changes.

## Clinical Presentation

Late-life depression can present differently from adult depression. Older adults with depression are less likely to express feeling sad and are said to have “depression without sadness.” Anxiety, hopelessness, anhedonia, sleep disturbances, and weight loss are more prominent features in late-life depression. Cognitive symptoms such as psychomotor retardation or executive dysfunction are more common and can mimic symptoms of dementia. Symptoms of depression are often mistaken for medical ailments and should be considered if there is poor response to treatment regimens.

## Diagnosis

Major depression as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5), requires the presence of a depressed mood or loss of interest with at least four additional symptoms nearly every day for more than 2 months (Box 106.2). Presence of <5 symptoms is consistent with minor depression. Screening tests such as the Patient Health Questionnaire–2 (“Over the last 2 weeks, have you (1) had little interest or pleasure in doing things? (2) Felt down, depressed, or hopeless?”) or the Geriatric Depression Scale are simple bedside questionnaires that can be used to help identify patients with depression. Additional evaluation should include a medication review, measurement of thyroid function, and screening for memory loss and alcohol or substance abuse.

## Treatment

Effective therapy for mild to moderate depression usually involves use of antidepressants. Selective serotonin-reuptake inhibitors (SSRIs) are considered first-line treatment. Most SSRIs are equally effective, with gastrointestinal upset the most common adverse effect. Citalopram now has a maximum dose of 20 mg for patients age >60 years because of the risk of QT prolongation and torsades, and it should be avoided in patients with congenital QT syndrome or bradycardia. Fluoxetine (Prozac) should be avoided in older adults because of its long elimination half-life. Other antidepressants are available,

### • BOX 106.2 Diagnostic Criteria for Major Depression<sup>a</sup>

1. Depressed mood
2. Markedly diminished interest or pleasure
3. Weight loss or decreased appetite
4. Insomnia or hypersomnia
5. Psychomotor agitation or retardation
6. Fatigue or decreased energy
7. Feelings of worthlessness or guilt
8. Inability to concentrate or make decisions
9. Recurrent thoughts of death or suicide

<sup>a</sup>Must have ≥5 symptoms, nearly every day for at least 2 weeks, and symptoms must include either depressed mood or diminished interest.

and their unique side effect profiles can be used to tailor medications to the individual needs. Mirtazapine (Remeron) is a serotonergic and noradrenergic antidepressant with potential beneficial side effects of sedation and appetite stimulation when used at low doses. Bupropion (Wellbutrin) can cause anxiety and insomnia and therefore may be useful in patients with fatigue or lethargy. Serotonin-norepinephrine reuptake inhibitors (SNRIs) such as duloxetine (Cymbalta) and venlafaxine (Effexor) are useful for patients with coexisting neuropathic pain, although SNRIs may be less well tolerated in frail older adults than SSRIs. Monotherapy is preferred to minimize side effects and drug interactions. Starting doses should be lower for older adults although full adult doses will usually be required for adequate response. Treatment response may take up to 12 weeks, although partial improvement will often be seen after 4 weeks of treatment. Antidepressant treatment should be continued for at least 6 to 12 months or longer to prevent recurrence. Other antidepressants such as tricyclic antidepressants and monoamine oxidase inhibitors are used less frequently because of their potential serious side effects of cardiac conduction defects, myocardial infarction, and orthostatic hypotension.

Structured psychotherapy is another valid treatment option that studies show to be as effective as pharmacotherapy for mild-to-moderate depression. Psychotherapy is also useful in conjunction with pharmacotherapy in severe or chronic forms of depression.

Electroconvulsive therapy (ECT) is effective for the treatment of severe depression in older adults resistant to other treatments or in patients at risk of serious harm because of psychotic features, suicidality, or severe malnutrition. Severe or persistent depression, the presence of mania or psychotic features, and suicidality are indications for referral to a psychiatrist.

## Urinary Incontinence

### Background

Urinary incontinence is a common and potentially disabling problem in older adults yet often goes unrecognized and untreated. Patients are often reluctant to mention this problem, and busy practitioners often do not inquire about it. Incontinence can lead to depression, anxiety, falls, skin infections, sleep disturbance, caregiver burden, and social isolation and is a major reason for institutionalization.

### Epidemiology

Up to 30% of those age  $\geq 65$  years are affected by urinary incontinence. The prevalence increases with age. Women are 2 to 3 times more likely to be affected until the age of 80 years, when men are just as likely to experience incontinence.

### Pathophysiology

Incontinence is often multifactorial. Changes in the lower urinary tract, central nervous system, cognition, mobility,

and volume status all play a role in its development. The supporting muscles of the pelvic floor are often weakened by lack of estrogen, previous vaginal deliveries, or pelvic irradiation. These changes commonly result in detrusor muscle weakness, bladder overactivity, and bladder outlet obstruction. Disruption in the nervous system by stroke, Parkinson disease, or normal-pressure hydrocephalus, for example, can also lead to incontinence. Limited mobility, decreased manual dexterity, and cognitive dysfunction can lead to incontinence even in the absence of actual physiologic abnormalities. Comorbidities including severe constipation, diabetes, and congestive heart failure also contribute.

### Clinical Presentation

There are four basic types of incontinence, although symptoms often overlap (Table 106.4).

Urge incontinence is the most common and is also known as overactive bladder. It presents with the sudden need to urinate, often with leakage of moderate-to-large amounts of urine. Urinary frequency and nocturia are common. Men often have additional symptoms related to prostatic enlargement. Women with urge incontinence may also have symptoms of stress incontinence, which is referred to as mixed incontinence.

Stress incontinence is characterized by leakage of urine with increased intraabdominal pressure exacerbated by coughing, sneezing, position change, or exercise. It is more common in women and is often associated with weakened pelvic floor muscles.

Overflow incontinence is seen with urinary retention because of detrusor muscle weakness or bladder outlet obstruction (in men commonly from prostate hypertrophy, in women from prolapse which blocks the urethra). Symptoms include decreased urinary output, weak stream, and hesitancy in addition to dribbling, frequency, and nocturia.

Functional incontinence refers to the inability to reach the toilet in time. Causes include medications (e.g., diuretics), impaired mobility (e.g., arthritis and stroke), environmental obstacles, and psychiatric or cognitive disorders.

### Diagnosis

Because patients often do not report symptoms of urinary incontinence, care providers should screen for this disorder with routine questions directly inquiring about incontinence. A physical examination should include a pelvic examination to evaluate for anatomic or atrophic changes, a rectal examination to rule out impaction, and a neurologic examination to rule out evidence of a focal neurologic deficit. Mobility, cognition, and volume status should be assessed. Additional diagnostic tests should include a postvoid residual by bladder ultrasound and a urinalysis. Further urodynamic studies can be performed by a urologist or gynecologist when the diagnosis is unclear.

**TABLE 106.4 Urinary Incontinence**

Type	Symptoms	Treatment
Stress	Small amount of urine loss with increased abdominal pressure (such as cough, laugh, exercise)	Pelvic muscle exercise, scheduled voiding, topical estrogens if atrophic vaginitis, surgical options, or pessary
Urge	Moderate-to-large amount of urine loss with inability to delay urination and often associated with urgency and frequency	Scheduled voiding, antimuscarinic drugs
Mixed	Combination of stress and urge incontinence symptoms	Combination of aforementioned treatments
Overflow	Leakage of small amount of urine with distended bladder and hesitancy, frequency, or dribbling	Removal of obstruction, treatment of prostatic enlargement, scheduled voiding, catheterization, pessary
Functional	Incontinence caused by inability or unwillingness to toilet	Behavioral interventions, scheduled voiding

## Treatment

Treatment options for incontinence depend on the type of incontinence as well as the preferences of the patient. Not all incontinence can be cured, but even a reduction in occurrence can greatly improve quality of life.

Nonpharmacologic methods of management include the use of bedside commodes and urinals and changing the timing of diuretics. Bladder training includes Kegel exercises, which involve repetitive contractions and relaxations of the pelvic floor muscles to strengthen them. This is especially useful in stress or mixed incontinence. Regular toileting at fixed intervals can also be helpful in staying dry.

Topical estrogens may help with symptoms of stress incontinence related to atrophic vaginitis. Incontinence related to prolapse may respond to pessaries or other urologic procedures.

Pharmacotherapy can be used in conjunction with behavioral interventions. Urge and mixed incontinence respond to antimuscarinic drugs, which decrease bladder wall muscle contractions, such as oxybutynin (Ditropan), solifenacin (Vesicare), and tolterodine (Detrol). Current evidence does not support the superiority of any one type; however, all share similar anticholinergic side effects including dry mouth, constipation, and urinary retention. These drugs may also induce delirium or worsen symptoms of dementia and so should be used with caution and started at low doses.

Men with prostatic enlargement and voiding symptoms including incontinence often respond to either alpha-adrenergic antagonists alone or in combination with 5-alpha-reductase inhibitors. Alpha-adrenergic antagonists such as alfuzosin (Uroxatral), terazosin (Hytrin), tamsulosin (Flomax), and doxazosin (Cardura) are commonly associated with orthostatic hypotension. Terazosin and alfuzosin exhibit less of this effect. 5-alpha-reductase inhibitors such as finasteride (Proscar) are testosterone antagonists that are well tolerated other than potential sexual side effects.

Urinary catheters are indicated for urinary retention with high postvoid residual volume or if skin wounds, pressure sores, and irritation result from the incontinence. Intermittent catheterization is preferred over chronic indwelling catheters because of risk of infection.

## Falls

### Background

Falls are common in older adults and are associated with fractures, functional decline, and death. In addition, falls and fear of falling are associated with loss of self-confidence and anxiety and are a major reason for nursing home admission. Costs from falls account for 6% of all medical expenditures in older adults. The incidence of falls can be decreased by identifying precipitating factors coupled with targeted interventions.

### Epidemiology

The incidence and severity of falls increase with age. Over one-third of community-dwelling adults age >65 years fall each year, and the rate of falls increases in nursing homes and hospitals to 50%. Ten percent of falls result in serious injury, with nursing home residents suffering serious injury almost 25% of the time. Unintentional injuries are the fifth leading cause of death in older adults, with falls underlying the majority of such injuries.

### Risk Factors

Falls usually occur from a combination of factors, including decreased strength, visual deficits, gait and balance problems, arthritis, cognitive impairment, and medications. Orthostatic hypotension appears to play a role in many falls and can be caused by medications, postprandial hypotension,

fluid or blood loss, autonomic dysfunction, or adrenal insufficiency. Falls also occur because of environmental factors such as poor lighting, loose carpets, and lack of bathroom safety equipment. However, these factors result in falls because of underlying pathophysiologic abnormalities in the patient that make it difficult for him or her to compensate for the environmental hazard. Except for overwhelming hazards such as an icy sidewalk or an external force strong enough to knock anyone over, a fall should never be attributed to an extrinsic factor without assessing why the patient was unable to adapt to it. For the same reason, the term “mechanical fall” should be avoided, because it implies that the fall was not caused by the patient’s underlying condition, and therefore nothing needs to be done about it.

Medications can be particularly dangerous in older adults; the more medications one takes, the higher the risk of falling. Medications particularly associated with falling include neuroleptics, SSRIs, tricyclic antidepressants, benzodiazepines, anticonvulsants, class 1A antiarrhythmics, antihypertensives, diuretics, and diabetic medication.

## Evaluation

The evaluation of a patient with a history of falls requires a thorough assessment of risk factors including a history of previous falls and a medication review. Special attention should focus on medications associated with falls and any new or altered medications. Levels of drugs such as phenytoin (Dilantin) should also be tested when appropriate.

The “Get Up and Go” is a good screening tool to assess for balance and gait. This requires the patient to stand from a seated position without using his or her arms, walk 10 to 20 feet, turn, and return to his or her seat. Postural (orthostatic) vital signs should be checked. Underlying neurologic diseases such as Parkinson disease, stroke, or dementia should be ruled out. A targeted neurologic examination should include tests of proprioception, muscle strength, and balance (Romberg examination). Vision testing as well as a detailed examination of the feet and footwear is also recommended.

Basic laboratories include a complete blood count, measurement of serum electrolytes, blood urea nitrogen, creatinine, glucose, vitamin B<sub>12</sub>, and assessment of thyroid function. Neuroimaging is indicated if there is evidence of a focal neurologic deficit, history of head trauma, or evidence of a central nervous system process. Cardiac workup with an electrocardiogram (EKG), echocardiogram, or evaluation for arrhythmias is warranted only if there is clinical evidence for such an underlying diagnosis, especially if there is a history of syncope.

## Management

The approach to preventing further falls requires a targeted intervention based on identified risk factors and physical examination findings. Falls that are not caused by an underlying cardiovascular or neurologic disorder can be classified

into four treatment categories: leg muscle weakness, poor balance/instability, medication toxicity, and hypotension.

Patients who demonstrate leg muscle weakness on physical examination and the “Get Up and Go” test should be referred to a physical therapist for quadriceps strengthening and resistance training.

Poor balance or instability responds well to balance training by a physical therapist. Assistive devices such as canes and walkers may also be indicated and should be properly fitted by a therapist. Patients should be referred to a podiatrist if there is poor foot care or if better-fitting footwear such as wide-soled shoes are indicated. Referral should be made to an ophthalmologist if there is evidence of poor vision to ensure proper corrective lenses or treatment of other reversible vision loss such as cataracts. A standardized home safety evaluation by an occupational therapist can identify environmental hazards such as throw rugs, slippery bathtubs, and poor lighting. An occupational therapist may also make specific recommendations such as the installation of stair rails and bathroom safety equipment such as grab bars. Programs such as tai chi and balance classes at senior centers have been shown to decrease the incidence of falls.

After all medications have been thoroughly reviewed, any unnecessary or problematic medications should be tapered and discontinued if possible. Special attention should be paid to the elimination of psychotropic medications. Reducing the number of medications to <4 is shown to reduce the risk of falling, so the benefits of each medication should be weighed against the risk of falling.

Orthostatic and postprandial hypotension should be treated based on the underlying cause. For example, reducing antihypertensive medications or dividing them into morning and evening dosing may diminish orthostatic hypotension. Separating medications from meals may reduce postprandial hypotension. Patients should be educated about the need to rise slowly from a seated or lying position. They should also be encouraged to maintain adequate volume status. Patients with autonomic dysfunction may respond to thigh-high or waist-high support stockings or to medications such as fludrocortisone or midodrine.

Patients at risk of falling should have osteoporosis screening as well as adequate calcium and vitamin D supplementation in doses of 800 to 1000 U/d to reduce the risk of fracture. Patients who live alone should have personal emergency-response systems (e.g., Lifeline) to ensure prompt treatment should they continue to fall.

## Hypertension in the Older Adults

Systolic blood pressure gets higher with age and increases the risk of stroke, heart failure, and cardiovascular and overall mortality. The goals of blood pressure treatment are still controversial. Although a goal of 120/80 mm Hg is supported by results from the Systolic Blood Pressure Intervention Trial (SPRINT) study, higher systolic blood pressures in the 140 to 160 mm Hg range may be acceptable in elderly patients, especially frail patients, to avoid the potential side

effects of medications such as orthostatic hypotension and falls. Because of possible overtreatment “white-coat hypertension,” it is recommended that patients do home-monitoring of blood pressures before deciding to start medications. As well, gradual lowering of blood pressure to assess how well the patient tolerates both antihypertensive medications and the effects of lower blood pressure is recommended.

If blood pressure therapy is warranted, comorbid medical conditions should be taken into consideration in medication selection. Initial treatment should be diuretics, long-acting calcium channel blockers, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers starting with the lowest dose. Beta-blockers are not recommended as first-line drugs unless there are other indications. If more than one medication is needed and compliance is not a problem, separating doses into morning and evening doses may help avoid hypotension.

For patients in the long-term care setting who are frail with multiple comorbidities, there is controversy as to the benefits of pharmacologic therapy, considering the high incidence of orthostatic hypotension and falls in this group.

## Pain Management in Older Adults

Persistent pain is common in adults age >65 years. Types of pain are often divided into somatic (arthritis, postoperative, fracture, bone metastases), visceral (renal colic, constipation), and neuropathic (radiculopathy, postherpetic neuralgia, diabetic neuropathy, poststroke syndrome). Once a workup has determined the cause of the pain, treatment can be initiated.

Patients with dementia may not be able to verbally express pain. For these patients, a Faces Pain Scale chart with six faces ranging from happy to severe pain may be helpful if he/she can point to the one that best represents pain. Pain may be expressed as agitation or insomnia, and a mild analgesic such as acetaminophen may be helpful.

Nonpharmacologic therapy can be helpful for persistent pain. This includes physical activity, tai chi, range-of-motion exercises, yoga, acupuncture, and massage.

Pharmacologic therapy can be challenging. Local therapy should be tried first (local steroid injections, ultrasound, topical preparations such as diclofenac gel, over-the-counter capsaicin, or lidocaine patches). Acetaminophen is generally used as first-line therapy, with the maximum dose of 3000 mg/24 h. Nonsteroidal antiinflammatory drugs (NSAIDs) are generally more effective than acetaminophen but are associated with more adverse events, including gastrointestinal bleeding, fluid retention, hypertension, renal insufficiency, and delirium and should be used carefully, if at all. Opioids are generally reserved for short-term acute pain, such as bone fracture, postoperative pain, kidney stones, and so on. Tramadol can be helpful but can lower the seizure threshold and can lead to serotonin syndrome in patients taking other serotonin agonists. Neuropathic pain seen in postherpetic neuralgia, diabetic neuropathy, and radiculopathies may respond to anticonvulsants such as

gabapentin and pregabalin. Antidepressants such as duloxetine may also be useful.

Because of potential side effects of these medications, start at the lowest doses and treat for the shortest time possible. Meperidine should be avoided because of potential delirium.

## Health Screening in Older Adults

Preventive health measures should be individualized and consider a patient’s life expectancy, general health, cognitive status, and functional status. Many preventive health measures are underused (e.g., immunizations, screening for depression, falls risk), and cancer screening tends to be overused by patients with many comorbidities.

Cancer screening is beneficial in reducing cancer mortality if the cancer is detected early enough that it decreases morbidity or death. The most recent USPSTF screening guidelines for older adults are as follows:

Breast cancer: biennial mammograms for women age 50 to 74 years. May also be helpful in healthy women age >74 years.

Colon cancer: fecal occult blood test, sigmoidoscopy, or colonoscopy for ages 50 to 75 years.

Cervical cancer: no screening age >65 years if they have had normal Pap smears and are not at high risk for cervical cancer.

Prostate cancer: no prostate-specific antigen age >75 years.

Lung cancer: annual low-dose CT for ages 55 to 80 years with a 30 pack-year smoking history and who currently smoke or have quit within past 15 years.

Other screening:

Abdominal aortic aneurysm (AAA): one-time ultrasound for AAA in men age 65 to 75 years who have ever smoked.

Osteoporosis: bone density scan in women age >65 years.

Vaccinations:

Influenza: every year.

Pneumococcal: pneumococcal conjugate vaccine 13 and pneumococcal polysaccharide vaccine 23 at least 1 year apart, age ≥65 years.

Tetanus/acellular pertussis/diphtheria: Tdap every 10 years.

Herpes zoster: once age >60 years.

Lifestyle counseling:

Exercise or physical therapy and vitamin D to prevent falls in those at increased risk of falling.

Ask about tobacco use.

## Perioperative Issues in the Elderly

More than one-half of all surgical procedures are done in people age >65 years. These include cataracts, joint and bone problems, vascular issues, and cancers. Likewise, postoperative morbidity and mortality are more common in people age >65 years.

Preoperative assessment is important to try to reduce complications. EKG findings of ischemia, left ventricular hypertrophy, or left bundle branch block suggest a higher risk of cardiac complications and death. An ejection fraction of <35% is related to a higher rate of heart failure postoperatively. In general, anticoagulant therapy can continue through surgery for skin surgery, dental extractions, and cataract surgery. Delirium is common postoperatively and can last for several months. Preoperative risk factors for delirium include age >70 years, cognitive impairment, limited physical function, alcohol abuse, abnormal electrolytes, and a hematocrit <30.

Some of the problems that occur and require careful monitoring include keeping patients at bed rest for too

long, using catheters longer than needed, dehydration, and medications that can contribute to delirium.

Postoperative complications include hypertension, arrhythmias, and heart failure. Because postoperative deep venous thrombosis and pulmonary embolism occur, patients should receive prophylaxis for these while bedridden. Kidney function can decline following even brief decreases in cardiac output and medications toxic to the kidney. Immobility, constipation, and bladder outlet obstruction are common occurrences. Pain control may require short-term use of narcotics, but the doses as well as the length of treatment should be kept as low as possible. Because narcotics can cause constipation, laxatives and stool softeners are often given at the same time.

## Chapter Review

### Questions

- A 79-year-old woman with osteoporosis, hypertension, and recurrent falls presents to her primary care provider for a routine follow-up accompanied by her daughter. The patient has no specific concerns, but her daughter is concerned about recent behavioral problems. Specifically, she reports that her mother has reported seeing visions of her deceased relatives. On further questioning the daughter reports that her mother's memory has declined over the past several years. She has required help with finances and managing the house but assumed this was part of normal aging. On physical examination, she is noted to have some cogwheeling and gait instability as well as inattention and executive dysfunction on brief cognitive screening tests. She has no previous history of depression or other psychiatric disorders. What would be the best approach to caring for this patient?

  - Do a lumbar puncture to rule out encephalitis.
  - Administer low-dose neuroleptic for periods of agitation.
  - Initiate treatment with an SSRI.
  - Discuss with the patient and her caregiver options for ensuring proper supervision and safety at home.
- An 85-year-old man with dementia is admitted to the hospital after a fall and found to have a hip fracture. Within 24 hours he underwent successful operative repair under general anesthesia. In the postanesthesia care unit he was agitated and more confused from baseline and was administered several doses of lorazepam. On the second day of his admission he was no longer agitated, but by the third day the medical team noticed that he was less interactive and unable to maintain attention and was developing dehydration from lack of appetite. What is the next appropriate intervention?

  - Consult surgery for placement of a feeding tube.
  - Initiate therapy with an SSRI for depression.
  - Discontinue all opiates, and administer scheduled acetaminophen.
  - Order noncontrast head CT.
  - Perform a thorough medication review.
- An 82-year-old woman with hypertension, diabetes, and osteoporosis presents to her primary care office after a recent hip fracture. On further questioning, you learn that she has had several recent falls. The first fall occurred as she was walking outside and tripped on the sidewalk. Another fall occurred in the bathroom when she lost her balance transferring out of the shower. A medication review reveals that she is not taking any new medications and is currently taking calcium 500 mg 3 times daily, vitamin D 400 IU twice daily, alendronate 70 mg weekly, aspirin 81 mg daily, lisinopril 20 mg daily, and glimepiride 2 mg daily. She has no episodes of hypoglycemia and denies syncope or palpitations. Physical examination reveals no orthostasis, no focal neurologic deficit, negative Romberg, and is otherwise unremarkable except for impaired proprioception bilaterally. She is wearing appropriate shoes and corrective lenses, and on the "Get Up and Go" test she can stand from a seated position without using her arms, although she does exhibit unsteadiness while walking. What is the best approach to preventing further falls?

  - Reduce the dose of lisinopril.
  - Refer to physical therapy for quadriceps strengthening.
  - Refer to physical therapy for balance-training exercises and possible assistive device.
  - Order vitamin B<sub>12</sub> level.
  - C and D
- A 73-year-old woman with hypertension complains of urinary incontinence. She reports involuntary leakage of variable amounts of urine, usually associated with urinary frequency and urgency and inability to delay voiding in time to make it to the bathroom. Physical examination, including a pelvic and rectal examination, is unremarkable. A urinalysis and postvoid residual are also unremarkable.

What is the best approach to treating this patient's incontinence?

- A. Topical estrogen
  - B. Bladder training with regularly scheduled voiding
  - C. Antimuscarinic drugs
  - D. Intermittent catheterization
  - E. Surgical bladder neck suspension
5. An 89-year-old woman with hypertension, dyslipidemia, coronary artery disease, congestive heart failure, and atrial fibrillation is admitted to the hospital after her family discovered her dehydrated and malnourished at home. She has been living alone for the past 2 years because her husband died and was functionally independent until the past several months, when she seemed more forgetful and began requiring help from her family. She began making errors in her checkbook and paying bills late and seemed in general slower. She has lost 10 lb mainly from skipping meals. She is on several medications, but none are new or changed, although she has recently been

forgetting doses. She has no history of psychiatric disorders, and initial workup reveals no significant underlying pathology. Cognitive testing reveals mild executive dysfunction and overall lack of effort on testing.

What is the next step to appropriately care for this patient?

- A. Order noncontrast head CT.
- B. Begin therapy with donepezil.
- C. Pursue oncologic workup.
- D. Pursue evaluation to determine underlying cause of delirium.
- E. Perform screening for depression.

### Answers

- 1. D
- 2. E
- 3. E
- 4. B
- 5. E

# Palliative Care

JOHN D. HALPORN AND JAMES A. TULSKY

**P**alliative care, and the medical subspecialty of palliative medicine, is specialized medical care for people living with serious illness. It focuses on providing relief from the symptoms and stress of a serious illness. The goal is to improve quality of life for both the patient and the family.

Palliative care is provided by a team of palliative care doctors, nurses, social workers, and others who work together with a patient's other doctors to provide an extra layer of support. It is appropriate at any age and at any stage in a serious illness and can be provided along with curative treatment. (This definition is from the Center to Advance Palliative Care, listed in references.) Hospice is a particular type of palliative care for patients with a limited life expectancy (usually  $\leq 6$  months); hospice always includes the provision of palliative care, but palliative applies to a broader range of illnesses, disease trajectories, and prognoses not included in hospice care. Palliative care is recognized as an increasingly important component of medical care for cancer and chronic disease that can improve quality of life, extend survival in some cases, and seeks to match patients' medical care with their individual beliefs and values. Increasing palliative care use has promise in the reduction of unwanted and ineffective care.

Palliative care is commonly understood to be delivered at a specialty level by fellowship-trained, board-certified practitioners in a hospital or hospice setting; however, the vast majority is primary palliative care delivered by general internists, primary care physicians, hospitalists, and medical specialists as an integral part of their work. Basic management of pain, depression, anxiety, and other symptoms as well as discussing prognosis, goals of care, suffering, and code status are primary palliative care tasks common to all physicians. Specialty-level palliative care includes management of complex and refractory symptoms, existential distress, and conflict regarding goals of care.

This chapter presents the two most important facets of palliative care practice: communication about goals of care and common symptom management.

## Communication

High-quality communication between patients and physicians about diagnosis, prognosis, treatment decisions, and goals of care enhances patient satisfaction and clinical

outcomes by helping patients adapt to living with serious illness. It enables them to make choices that best promote or preserve their quality of life. This communication is often stressful for the patient, family, and physician and is frequently avoided or delayed because of this stress and providers' lack of knowledge and experience. Specific and effective skills can be learned through study, reflection, and practice; three essential techniques are presented here.

## Ask-Tell-Ask

Ask-Tell-Ask is a helpful technique to present new information that promotes understanding through building on what the patient already knows about his or her illness. It allows the physician to watch the patient's reception of information, informing where to go next in the conversation and signals when the patient is reaching his or her fill. Ask-Tell-Ask can be applied broadly to an entire visit or to the specific issue of how the patient's health and disease are today.

## Deepening the Conversation

- |      |   |
|------|---|
| Ask  | <p>"What have the doctors told you about what's going on with your illness?"</p> <p>"What is your understanding of the success of your treatment so far?"</p> <p>"What is the most important thing to talk about today?"</p>  |
| Tell | <p>Provide a brief piece of new information.</p> <p>"Your examination and tests show your heart and lungs are working better on the new medicines."</p> <p>"Results from the current scan show your cancer has progressed despite treatment."</p> <p>"I think it is time to have a nurse come to your house once a week to help with your wound."</p> |
| Ask  | <p>"Check in to learn what he or she took away from your "tell."</p> <p>"To make sure I explained things well, can you tell me what you now understand about your treatment plan?"</p> <p>"What is going through your mind right now?"</p>  |

Similar to the second “Ask” step above, it is usually necessary to check in with the patient regarding the best next step for conversation; physicians often cannot tell what is most important to him or her at that moment. Simple open-ended questions give the patient some control over this direction, and they reveal the patient’s current “location.” Allowing silence after the question, without elaboration or topic change by the physician, is helpful for the patient to provide a rich response and to display emotion. Common examples are:

- “What are your thoughts about what we have discussed today?”
- “What are you thinking about the next few months?”
- “How are you handling this disease these days?”

## Responding to Emotion

Physicians should expect patients and families to show strong emotions when discussing difficult topics such as the sharing of serious news or planning goals of care in advanced illness. Although challenging and anxiety provoking, this response from patients is normal; effective techniques exist that will help the patient feel heard and will advance the conversation forward. The NURSE acronym illustrated subsequently describes five common skills that can be used in response to emotion. They are not expected to be used together or in sequence but rather provide different approaches to demonstrating one’s empathy for the patient and continuing the conversation.

N	Name	Naming a patient’s emotion notes what is happening in the encounter, shows the patient that you are attuned to what he or she is experiencing, and may help the patient gain more insight into the situation. For example, “It sounds like you are worried that the cancer may be recurring.” To name an emotion may require that physicians read nonverbal clues that patients display. It is important that when using naming, the physician is suggestive, not declarative. “I wonder if you’re feeling angry” or “Some people in this situation would be angry,” rather than “I can see you’re angry about this.” People don’t like being told what they are feeling.
U	Understand	The most effective empathic statements link the “I” of the doctor to the “you” of the patient: “I sense how upset you are feeling about the results of the CT scan.” It is not necessary to have had the experience to empathize, but it is necessary to put yourself in the patient’s position and to communicate that understanding back to the patient. A sensitive appreciation of the patient’s predicament or feelings is an important prerequisite for responding in a way that builds the relationship. By making an “understand” statement the physician is telling the patient that he or she gets what he or she is going through and he or she is aligned with him or her. This can be very simple such as “It must be hard as you think about the effect your chemotherapy has had on your kids” and serves to validate patient emotions. Paradoxically, saying “I cannot imagine what it is like to (X)” is a good way to show you understand.
R	Respect	This can be a nonverbal response, involving facial expression, touch, or change in posture, but a verbal response is helpful because it can be more explicit in giving patients the message that their emotions are not only allowable but also important. Acknowledging and respecting a patient’s emotions is an important step in showing empathy. In terms of how much to do on this step, consider matching the intensity of your acknowledgment to the patient’s expression of emotion; a strong emotion deserves a strong acknowledgment. Praising the person’s coping skills is a good way to show respect. “I am very impressed with how well you’ve cared for your mother during this long illness. You have been a Godsend for her.” This really makes people feel good about themselves and implies respect.
S	Support	Several types of supporting statements are possible. Physicians can express concern, articulate their understanding of a patient’s situation, express willingness to help, make statements about partnership, and most importantly, acknowledge the patient’s efforts to cope. Given that many dying patients fear abandonment, making statements, if truthful, that you will be there for the patient is very useful, for example, “I’ll be with you during this illness, no matter what happens.”
E	Explore	Distressed patients frequently do not share their emotions or what they are thinking directly or clearly. In these situations, the simple statement “Tell me more” can be extremely effective to open people up more and help them articulate what was, at first, hard to say.

## Goals of Care Discussion

A goals of care discussion is a specific kind of physician-patient conversation that serves important purposes in the patient's care—clarifying the ill patient's hopes and wishes for his or her future, allowing the physician to align with the patient's values, and planning future care that is concordant with these goals. Goals of care discussions apply to all important care decisions, and they should not be limited to provider-patient-family conflicts or specific decisions such as resuscitation status or elements of a POLST (physician order for life-sustaining treatment). The discussion is appropriate at every encounter involving a decision, and it is extremely important early in an illness to enable aligned and appropriate care from the beginning. Ideally, discussions should take place between the patient and his or her trusted long-term provider with the themes and choices evident in the medical record for others to follow in subsequent hospital or specialist encounters. Finally, physicians should follow a “talking map” or mental model to enhance the consistency and timeliness of the discussion. The REMAP model is one such technique illustrated here.

### REMAP Model

Reframe why the status quo isn't working	You may need to discuss serious news (e.g., a scan result) first. “Given this news, it seems like a good time to talk about what to do now.” “We're in a different place.”
Expect emotion and empathize	Use one of the NURSE statements: “It's hard to deal with all this.” “I can see you are really concerned about [x].” “Tell me more about that—what are you worried about?” “Is it ok for us to talk about what this means?”
Map out the future	“Given this situation, what's most important for you?” “When you think about the future, are there things you want to do?” “As you think toward the future, what concerns you?”
Align with the patient's values	“As I listen to you, it sounds the most important things are (x,y,z).”
Plan medical treatments that match patient values	“Here's what I can do now that will help you do those important things. What do you think about it?”

## Pain

Pain as a symptom is the physical sensation of actual or imagined tissue damage (imagined refers to neuropathic mechanisms where the sensation is present without a precipitating tissue injury). For most patients with life-limiting illness, pain is a frequent component of their disease; in cancer, pain is nearly universal in recurrent or advanced disease and is greatly feared by patients. Landmark results from the SUPPORT (the Study to Understand Prognosis and Preferences for Outcomes and Risks of Treatments) study showed 50% of conscious patients with serious illness who died in the hospital reported severe pain about half of the time during the hospital stay. Patient and family perceptions of the origin and meaning of pain and beliefs about pain relief and pain medication all color the patient's and doctors' experience. Accurate diagnosis and treatment of pain are essential to patient quality of life and his or her ability to be cared for by family at home. Logistic, financial, and regulatory barriers to effective pain relief are many, and women, minority, poor, aged, and nursing home groups are at increased risk of undertreatment. Attitudes and misconceptions about the importance and meaning of pain symptoms and treatments (especially opioid medication) commonly lead to undertreatment and misunderstandings about the use and goals of pain treatment.

### Pain Assessment

Pain assessment requires careful attention to the patient's history, review of systems, physical examination, and diagnostic data. A complete characterization of pain includes mechanism (somatic, visceral, or neuropathic), severity, location, referral pattern, timing, and aggravating and relieving features. Recognizing pain syndromes such as trigeminal neuralgia, bone pain from tumor, or peripheral neuropathy allows for specific treatments with known medication strategies. Unexplained pain in a patient with illness should always raise concern for disease spread, additional complications, or sometimes a new diagnosis. Empirically treating pain without understanding its pathogenesis is unfortunately common and leads to delayed diagnosis, missed opportunities for treatment, ineffective treatment, and overuse of pain medications.

Palliative care requires expertise with common analgesics in intravenous (IV), oral (po), and topical forms as well as skills in patient education and risk management. For most serious illness-related pain, management is rarely an occasional prescription for intermittent pain medication; instead a practice of regular follow-up visits, with systems in place to comply with state and national regulations, monitor prescriptions, and survey for appropriate opioid use, is a standard practice.

### Initial Opioid Prescribing

Pain treatment in serious illness, particularly cancer, frequently requires opioids early on for severe symptoms. Initial treatment following step one of the familiar World Health Organization's

**TABLE 107.1** Pharmacodynamic Properties of Common Opioids

	Form	Onset (Minutes)	Peak (Minutes)	Duration (Hours)
Morphine	Oral – IR	15–60	30–60	3–4
	Oral – ER	2–4 hours		8–12
	IV	1–5	3–4	3–4
Oxycodone	Oral – IR	10–15	30–60	3–4
	Oral – ER	2–4 hours		8–12
Hydromorphone	Oral – IR	15–30	30–60	3–4
	IV	1–2	5–20	3–4
Fentanyl	Oral transmucosal	5–15	20–30	1–2
	Transdermal patch	<12 hours	12 hours	48–72
	IV	<1	5–15	0.5–2

*ER*, Extended release; *IR*, immediate release; *IV*, intravenous.

pain ladder with acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) is indicated for mild and intermittent symptoms; with appropriate monitoring, these strategies can be effective for months or years in slow-moving diseases. More severe pain and steadily escalating symptoms require opioids for control, and common strong short-acting agents (oxycodone, morphine, and hydromorphone) are routinely used initially in an as-needed regimen. These three agents are similarly effective for somatic and visceral pain but with different potencies; equivalent oral starting doses of each agent are oxycodone 5 mg, morphine 7.5 mg, and hydromorphone 2 mg (1.875 mg to convert exactly). Each reaches peak effect between 30 and 60 minutes and has a 3- to 4-hour effective duration. Choosing between these agents is not done for efficacy but for different tolerability and compatibility with other medical issues, detailed in [Table 107.1](#). Adjustment in dosage depends on the degree of relief from each dose, for example, 5 mg of oxycodone may result in pain decrease from 8/10 to 6/10, whereas 10 mg brings it from 8/10 to 4/10. Frequency of dosing depends on how long episodes of pain last. Does the pain return or increase in severity at the end of the 3-hour duration of the medication? When patients take more of their as-needed doses (up to 8 times per day for an every-3-hours-as-needed prescription) it indicates frequent or nearly constant pain and should be a prompt to consider long-acting opioids.

### Long-Acting Opioids

As pain worsens in severity and duration, patients have better relief with a long-acting agent for basal pain control with as-needed doses of short-acting agents added for incident or fluctuating pain. Common long-acting agents are oral extended-release forms of morphine and oxycodone in 2 or 3 times daily dosing or a topical fentanyl patch that provides 48 to 72 hours of coverage. Long-acting agents should make

up approximately 70% of total daily opioid intake, and as-needed doses should be 10% to 15% of the total daily dose of opioid every 3 to 4 hours. See example 1 below.

#### Example 1: Opioid Escalation

Outpatient taking morphine 15 mg tabs every 3 hours as needed for pain with 7 daily doses on average.

1. Daily po morphine = 7 doses × 15 mg/dose = 105 mg po morphine daily
2. Long-acting morphine: using the most convenient available pill size of 30 mg gives an extended release morphine dose of 30 mg 3 times daily for 90 mg daily total
3. Short-acting morphine: breakthrough dosing is 10% to 15% of 105 mg daily total or 15 mg every 3 hours as needed
4. Note that no 50% to 75% safety factor reduction is required because there is no conversion between opioids

#### Opioid Conversion

In hospitalized patients, physicians often must convert between different routes of delivery and opiate type; for example a patient admitted with sudden onset of pain and vomiting from progressive pancreatic cancer with biliary obstruction will require intravenous hydromorphone for initial relief, followed by introduction of a long-acting oral agent once oral intake is reestablished, and then transition from IV hydromorphone to an oral short-acting as-needed agent before discharge ([Table 107.2](#)). Conversion of total daily opioid requirement is accomplished by constructing a proportion between equianalgesic amounts of different opioids and then calculating a destination dose of the new drug (see Example 2). On conversion between opioids, a 25% to 50% reduction in total dose of the new agent is recommended to account for incomplete cross-tolerance between drugs caused by individual variation in absorption, drug sensitivity, metabolism, and secretion.

**TABLE 107.2 Equianalgesic Doses of Common Opioids**

Opioid	IV Route	PO Route
Morphine	10	30
Oxycodone		20
Hydromorphone	1.5	7.5
Fentanyl	0.1 mg IV dose 25 µg/h patch equivalent to 50 mg of oral morphine in 24 h	

IV, Intravenous; PO, oral.

$$\frac{\text{Old opioid from table}}{\text{New opioid from table}} = \frac{\text{Old opioid dose/24 h}}{X} \quad X = \frac{\text{New opioid dose}}{24 \text{ h}}$$
**Example 2: Equianalgesic Conversion**

Opioid conversion: hospitalized patient receiving 2 mg IV hydromorphone every 6 hours and 10 mg of oral oxycodone 3 times daily with good pain control. Convert this to a long-acting and short-acting morphine regimen for discharge.

- Daily IV hydromorphone = 4 doses/d × 2 mg/dose = 8 mg IV hydromorphone daily
- Daily po oxycodone = 3 doses/d × 10 mg/dose = 30 mg po oxycodone daily
- Convert to daily po morphine doses

$$\frac{1.5 \text{ mg IV hydromorphone}}{30 \text{ mg po morphine}} = \frac{8 \text{ mg IV hydromorphone per day}}{X}$$

X = 160 mg po morphine per day from hydromorphone

$$\frac{20 \text{ mg po oxycodone}}{30 \text{ mg po morphine}} = \frac{30 \text{ mg po oxycodone per day}}{Y}$$

Y = 45 mg po morphine per day from oxycodone

- Total daily po morphine dose with safety factor  
50% to 75% of (160 mg + 45 mg) = 100 mg – 150 mg daily po morphine
- Extended-release morphine—60 mg twice a day or 120 mg daily total. Note this is the nearest approximation with available pill size and remains within the 50% to 75% safety factor
- Breakthrough dose = 10% to 15% of 120 mg daily total dose = 15 mg po every 3 hours as needed

**Opioid Toxicity**

Common opioid toxicities are nausea, somnolence, delirium, itching, constipation, and ataxia. All but constipation are usually worse on starting or increasing the opioid, but in some cases the side effect will continue past the first several days, and the patient will require a change in agent. There is enough variation in activity and clearance of the

different opioids that an alternate agent can provide relief with tolerable side effects. Constipation occurs with all opioids and requires concurrent use of osmotic and stimulant laxatives; these should be started on a standing basis with all new opioid prescriptions. Polyethylene glycol is a very effective single daily dose treatment. New agents are available for opioid-induced constipation that target the specific mesenteric plexus effects of opioids; these include methylnaltrexone and lubiprostone and can be helpful in severe cases.

The principle danger with acute exposure to opioids is suppression of the respiratory drive, inhibiting respiratory triggers of both hypercarbia and hypoxia. Opioid-naïve patients and those with additional causes of somnolence from metabolic derangement, neurologic injury, or medications such as benzodiazepines or alcohol are most at risk. It is important for physicians to monitor level of consciousness, oxygenation, and particularly capnography in the patient with acute pain treated with new or escalating doses of opioids, particularly when doses are IV and “stacked” at frequency intervals less than the drug’s time to peak effect. Finally, very high doses of opiates present a risk of neuroexcitatory side effects of myoclonus and hyperesthesia. These unusual developments are very uncomfortable and require reduction in total opioid dosing or rotation to a different opioid, or both; palliative care or anesthesia-pain consultation is helpful in these cases.

**Buprenorphine and Methadone**

Several less common opioids deserve mention for their utility in pain management and frequent use in long-term opioid dependence. Methadone is a unique agent because of its antagonism of the N-methyl-D-aspartate receptor in addition to the classic effects on mu, delta, and kappa receptors; this provides additional benefit in cases of neuropathic pain and hyperesthesia caused by other opioids. Particular risks with methadone include a long and variable half-life of up to 60 hours causing delayed emergence of somnolence and respiratory depression as well as prolongation of QT interval. Methadone for pain management is usually dosed in 2 or 3 times daily regimens and can be prescribed by all licensed physicians; consultation or review with a pain or palliative care specialist is recommended given the unique challenges in methadone use. Patients on methadone maintenance for opioid dependence can be given additional short-acting opioids for acute pain while continuing their once daily methadone maintenance dose. To avoid overdose, it is critically important to confirm the current dose and last administration of methadone with their maintenance program before providing this in the inpatient setting. Buprenorphine is a partial opioid agonist/antagonist commonly used to treat opioid dependence where it reduces opioid craving, offers mild analgesic effects, and blocks further opioid receptor activation by illicit (or prescribed) opioids. It is available as a long-acting skin patch for pain; for abstinence treatment it is prescribed as a 3-times daily sublingual film.

**TABLE 107.3** Mechanisms of Nausea and Associated Medications

Mechanism	Associated Conditions	Avenues for Relief	Useful Agents and Receptor Class
Chemoreceptor trigger zone	Chemotherapy Drugs, toxins, cytokines	Remove inciting agent Block CTZ activation	5HT3: ondansetron NK-1: aprepitant D2: metoclopramide, chlorpromazine, haloperidol, olanzapine
GI injury, distention, toxins, and inflammation	Gastroparesis, gut edema, tumor, mucosal inflammation	Relieve distention and inflammation, diuresis	5HT3 and D2 agents above ACH: scopolamine
Hepatic insufficiency	Loss of functioning liver because of tumor or cirrhosis, biliary obstruction, hepatic congestion from CHF	Reduce ongoing liver inflammation or injury, improve biliary drainage, reduce venous pressure	Diuresis Corticosteroids D2: haloperidol, olanzapine
Vestibular dysfunction, brain lesions	Tumor invasion, drug or radiation toxicity	Reduce vestibular and balance sensitivity, reduce swelling and inflammation	ACH: scopolamine Histamine: meclizine Dexamethasone
Higher cortical: anxiety, fear, conditioning	Anxiety disorders	Pharmacologic and behavioral strategies	Lorazepam Olanzapine Relaxation Behavioral techniques

*5HT3*, 5-Hydroxytryptamine type 3; *ACH*, acetylcholine; *CHF*, congestive heart failure; *CTZ*, chemoreceptor trigger zone; *D2*, dopamine 2; *GI*, gastrointestinal.

## Adjuvant Pain Medications

Some pain syndromes require additional medications and modalities for effective treatment, and this strategy may even allow opiate dose reduction. Acetaminophen up to 3000 mg daily and NSAIDs (ibuprofen up to 2400 mg daily) can be extremely effective in inflammatory and bone pain if the agents are compatible with the patient's illness and other medications. Neuropathic pain can be effectively treated with gabapentin, pregabalin, amitriptyline, venlafaxine, or duloxetine, often in combinations of several agents together. Denosumab and bisphosphonates can help with vertebral compression fracture pain, either osteoporotic or from tumor infiltration, and calcitonin nasal spray is helpful for osteoporotic compression fractures.

## Procedural Pain Interventions

Anesthesia-pain specialists can perform regional nerve blocks by injecting local anesthetic (marcaine), steroid, and sometimes a temporary (1–3 months) nerve ablative agent such as ethanol or phenol. Common sites of effective nerve blocks are celiac or hypogastric plexus for abdominal pain, intercostal and paravertebral blocks for chest wall and abdominal wall pain, and trigeminal block for facial symptoms. Pain blocks are relatively easy to perform under fluoroscopic guidance, they have few to no side effects, and they can offer significant and prolonged relief allowing decreases in opioid dose.

## Nausea and Vomiting

Nausea is a very common symptom in most serious illnesses with several independent mechanisms and associated targets

for treatment. Nausea is a disabling and discouraging symptom that leads to rapid weight loss, inactivity, isolation, and depressive symptoms.

## Nausea Mechanisms

Nausea has three routes of nervous system input, and each directly stimulates the medullary vomiting center to cause vomiting, mediated by vagus discharge. The chemoreceptor trigger zone in the fourth ventricle area postrema is sensitive to many exogenous (and some endogenous) substances; it is also sensitive to compression and mediates nausea response to increased intracranial pressure. Gut-mediated nausea is transmitted by vagus afferent signals and begins with mechanoreceptor and chemoreceptor stimulation in the liver, stomach, peritoneum, and intestines. This response is triggered by stimuli such as vascular edema from congestive heart failure, excessive osmotic load, physical distension from obstruction or paresis, and specific toxins. Higher cortical stimuli produce nausea and vomiting through vestibular and ophthalmic input in visual and motion-related nausea and from multiple inputs related to fear and anxiety.

## Nausea Treatment

Control strategies for nausea and vomiting are shown in [Table 107.3](#), divided by mechanism. Often several agents are necessary to control severe symptoms. For mechanical obstruction causing continued vomiting, such as gastric outlet tumor or small bowel obstruction, gastric decompression and drainage are necessary by a nasogastric, percutaneous, or enteroenteral route.

**TABLE 107.4** Common Dyspnea Mechanisms and Associated Disease Processes

Mechanism	Disease Process	Example Diseases
Increased respiratory drive	Metabolic disturbance, respiratory insufficiency	Hypoxia, hypoxemia, acidemia
	Increased cardiac filling pressures	CHF, aortic stenosis
	Loss of lung volume	Effusion, tumor, surgery, COPD
	Inadequate perfusion	Anemia, CHF, COPD
	Psychiatric symptom overlap	Anxiety, panic
Decreased ventilatory function	Neuromuscular compromise	ALS
	Chest wall and diaphragm dysfunction	Tumor infiltration, pleural effusion
	Bronchial constriction/obstruction	COPD
	Fibrosis	Idiopathic pulmonary fibrosis

ALS, Amyotrophic lateral sclerosis; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease.

## Dyspnea

Dyspnea is an extremely distressing sensation associated with suffocation and fear of dying imminently. Cardiac, pulmonary, neurologic, and rheumatologic diseases as well as cancer cause increasing dyspnea in later stages. Treating the pathophysiologic cause of dyspnea is the essential first step; pulmonary edema, bronchoconstriction, and many other physiologic contributors listed in Table 107.4 can be improved or reversed resulting in improvement in shortness of breath. Careful evaluation and diagnosis are essential to allow these effective treatments.

Oxygen is an essential tool for relief in dyspnea in the presence of hypoxia, but it is not useful for symptoms when oxygenation is normal. A breeze or fan directed at the face is a useful nonpharmacologic measure for any level of oxygenation. Opioids are very effective in relieving the sensation of dyspnea by dampening the response to input from mechanoreceptors and chemoreceptors in the lungs and chest, relaxing the pulmonary vasculature, and allowing the brain's respiratory center to tolerate both hypoxia and hypercarbia without increasing respiratory drive. By these mechanisms, opioids can allow the patient to tolerate respiratory insufficiency with comfort. Often a low dose of opioid (morphine 0.5 mg IV or 5 mg of po morphine elixir every 3 hours as needed) is very effective in improving dyspnea. Advise patients and families that increasing use of opioids to tolerate dyspnea with decreasing respiratory function is not a viable state for continued survival, and respiratory failure, intubation, or death will ultimately result. Finally, benzodiazepines are helpful to reduce the heightened anxiety accompanying dyspnea with the recognition that sedation and slowed respiratory drive will be compounded by these agents.

## Anorexia

Anorexia, diminished appetite, or aversion to food is frequently overshadowed by nausea; it will often require

additional intervention when the nausea sensation is controlled with the aforementioned measures. Anorectic agents often cannot address the dramatic catabolism and profound aversion to food in aggressive cancer, chronic infection, and advanced chronic obstructive pulmonary disease (COPD) or heart failure; patient expectations about "reversal" of weight loss or "return" of appetite should be discussed to set realistic expectations. Available measures include corticosteroids for an immediate but time-limited boost in appetite and ability to tolerate food. Longer-term agents include megestrol acetate, dronabinol, and mirtazapine, which can alter metabolic balance and improve taste, smell, and interest in food, both mechanisms leading to weight gain. Depression and anxiety states often worsen both nausea and anorexia and improve with targeted psychiatric agents.

## Fatigue

Fatigue is the symptom of difficulty or inability to be physically active, reduced endurance for physical activity, and mental fatigue limiting memory, concentration, or mood stability. It is a ubiquitous symptom in advanced disease leading to patients being homebound, bedbound, isolated, and depressed. Poor nutrition, weight loss, active metabolic or oncologic disease, pain, nausea, depression, and cardiac and pulmonary insufficiency can all leave patients without enough energy to maintain their age-appropriate activity. The best interventions are directed at the underlying physiology (nutrition, chemotherapy, and peripheral perfusion) and are the only measures that can bring long-term relief from significant fatigue. The best evidence for fatigue symptom relief is for gentle regular exercise, which results in optimization of available perfusion, increases appetite, produces endorphins, and combats the sense of inertia that ill patients commonly have. Psychostimulants have been disappointing in their lack of effect for physical fatigue symptoms although they are specifically helpful for somnolence and poor concentration when related to opiates.

## Summary

Patients, and doctors, often believe that suffering from illness, particularly at the end of life, is usual and to be expected. Palliative care, with its exquisite attention to symptoms, goals, and quality of life, offers hope that the experience of illness can be somewhat comfortable and

peaceful in physical, spiritual, and emotional realms. Improving this process is the aim of palliative care, particularly the primary palliative work done by internists in all capacities. This essential role of the physician as provider of comfort and trusted advisor is a profoundly important and deeply satisfying bulwark of medical practice.

## Chapter Review

### Questions

1. A 39-year-old woman has advanced breast cancer and new bony metastatic disease in the L3 and L4 vertebral bodies without neural encroachment or neurologic compromise. There is no pathologic fracture evident on radiology scans. Her severe pain has been stabilized in the hospital using dexamethasone, NSAIDs, and opiates. She is on IV hydromorphone at a continuous dose of 0.6 mg/h, and she receives 0.4-mg IV bolus doses for breakthrough pain with an average of 5 per day. She is due for discharge and outpatient radiation therapy. What is the most appropriate dose of po morphine on discharge?
  - A. Morphine-extended release 100 mg bid with morphine immediate release 30 mg every 3 hours as needed
  - B. Morphine-extended release 100 mg 3 times daily with morphine immediate release 15 mg every 3 hours as needed
  - C. Morphine-extended release 30 mg 3 times daily with morphine immediate release 30 mg 3 times daily as needed
  - D. None of the above
2. A 72-year-old woman with cor pulmonale, peripheral edema, and ascites has developed progressive nausea and anorexia without vomiting over the past 3 weeks. Her weight has increased over this period without the development of dyspnea; her examination shows increased pedal edema, anasarca, and ascites. Which regimen will best relieve her nausea?
  - A. Diuretics, antihistamines, cognitive-behavioral therapy
  - B. Diuretics, therapeutic paracentesis, prochlorperazine
  - C. Dexamethasone, ondansetron, prochlorperazine
  - D. Scopolamine, therapeutic thoracentesis
3. A 69-year-old man with advanced COPD (forced expiratory volume in 1 second = 0.8 L, dependent on home oxygen) fell at home and sustained fractures of his right lateral 4th, 5th, and 6th ribs. He was admitted to the intensive care unit earlier today for somnolence, respiratory failure, and pain control. He is currently on a bilevel positive airway pressure device with a continuous infusion of hydromorphone for pain. He is drowsy and uncomfortable but currently stable from a respiratory and hemodynamic standpoint. You are the hospitalist covering this patient; his wife and adult children have arrived to talk about his condition. After introducing yourself and getting agreement to talk about the patient's prognosis and ongoing care, what is the best starting question for this meeting?
  - A. Should we insert a breathing tube and attach him to a ventilator if he cannot breathe well enough by himself?
  - B. I wonder if you are feeling angry about your father's/husband's condition?
  - C. Talking to his other physicians and reading the chart lead me to recommend that we should not continue this aggressive treatment.
  - D. What is your understanding of your father/husband's current condition?

### Answers

1. A
2. B
3. D

ANN L. PINTO

## Questions

1. A 65-year-old woman comes to the office because her brother has been diagnosed with stage IV lung cancer. She wants to be screened for lung cancer herself. She smoked one pack of cigarettes daily for 40 years and quit 8 years ago.

Which of the following discussion points about lung cancer screening in asymptomatic current or former heavy smokers is true?

- A. Yearly screening chest x-rays (CXR) reduce lung cancer mortality.
  - B. Annual low-dose CT (LDCT) scanning results in a 20% relative reduction in lung cancer mortality.
  - C. Most lung cancers detected by LDCT are stage III or IV.
  - D. Five percent of LDCT scans had positive findings.
  - E. Fifty percent of the positive screens in LDCT represent cancer.
2. A 42-year-old male complains of fatigue, low libido, and erectile dysfunction. Examination is notable for gynecomastia. Laboratory results are notable for total testosterone 180 mg/dL, repeat 160 mg/dL. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are normal.

What do you recommend as a next step?

- A. Testosterone replacement therapy
  - B. Pituitary evaluation
  - C. Sildenafil
  - D. Relationship counseling
  - E. Semen analysis
3. An 81-year-old female with an ischemic cardiomyopathy and ejection fraction (EF) 15% is admitted to the hospital with pulmonary edema for the fourth time this year. Despite aggressive diuresis, she remains volume overloaded with declining renal function. She wants to go home, but her son disagrees and wants her care to be pursued more aggressively. You recommend a palliative care consultation.

Which of the following is true regarding palliative care in patients with advanced heart failure?

- A. Patients should be referred when curative therapies have been exhausted.
  - B. Palliative care requires discontinuation of active treatment.
  - C. The onset of functional decline in heart failure correlates strongly with 6-month prognosis.
  - D. Palliative care focuses on the psychosocial needs of patients and families in addition to their physical needs.
4. A 65-year-old professor presents after a colleague found him wandering, unable to find his office. His wife reports two episodes when he thought that one of his former graduate students was at the dinner table and that during sleep he often thrashes around violently. One year ago, he was awarded a major prize for his research. On examination, the patient is orthostatic, with slowed speech, some limb rigidity, and a shuffling gait. He has marked difficulty with the clock drawing test. Laboratories including vitamin B<sub>12</sub>, thyroid-stimulating hormone (TSH), and rapid plasma reagin are normal. Based on these findings, the most likely diagnosis is:
    - A. Alzheimer disease
    - B. Parkinson disease
    - C. Lewy body dementia
    - D. Multiinfarct dementia
    - E. Normal pressure hydrocephalus
  5. A 27-year-old male presents to the emergency department (ED) with a food impaction. In the preceding months, he has had worsening heartburn and difficulty swallowing that did not respond to over-the-counter (OTC) omeprazole. His medical history is significant only for eczema. Based on this history, what is the most likely diagnosis?
    - A. *Candida* esophagitis
    - B. Achalasia
    - C. Diffuse esophageal spasm
    - D. Gastroesophageal reflux disease
    - E. Eosinophilic esophagitis

6. A 58-year-old male presents with neck pain that radiates down his left arm. Despite high-dose nonsteroidal antiinflammatory drugs (NSAIDs), he rates his pain as 8/10 in severity. He has a history of hypertension and chronic headaches. Medications include imipramine, lisinopril, and trazodone. You diagnose a cervical radiculopathy, refer him for physical therapy, and prescribe tramadol for pain. Four hours later, he is brought to the ED with mental status change, agitation, and fever to 104°F. On examination, he has dilated pupils, rigidity, hyperreflexia, and spontaneous clonus.  
The most likely diagnosis is:
- Intracerebral hemorrhage
  - Bacterial meningitis
  - Anticholinergic toxicity
  - Serotonin syndrome
  - Neuroleptic malignant syndrome
7. A 68-year-old male presents for follow-up after a hospital admission for decompensated congestive heart failure (CHF). His medical history is notable for coronary heart disease (CAD) with an ischemic cardiomyopathy and EF of 30%. He notes dyspnea with mild exertion and worsening lower extremity edema. Which of the following medications does not have a mortality benefit in patients with class III CHF?
- Aliskiren
  - Candesartan
  - Metoprolol
  - Enalapril
  - Spironolactone
8. A 19-year-old female with a history of intrauterine device (IUD) placement 3 weeks ago presents with complaints of crampy lower abdominal pain and dyspareunia. She is afebrile. Her examination is notable for cervical friability and bilateral adnexal tenderness. Pregnancy test is negative.  
What treatment do you recommend?
- Ceftriaxone 125 mg intramuscularly (IM) plus azithromycin 1 g (orally) po  $\times$ 1
  - Ciprofloxacin 500 mg bid (twice a day) plus metronidazole 500 mg bid  $\times$ 14 d
  - Ceftriaxone 250 mg IM plus doxycycline 100 mg bid plus metronidazole 500 mg bid  $\times$ 14 d
  - Drug regimen in answer C plus removal of the IUD
9. A 33-year-old female presents to establish care. Her medical history is significant for Hodgkin disease diagnosed at age 16 and treated with ABVD (adriamycin, bleomycin, vinblastine, dacarbazine) plus mantle irradiation. She has been free of disease since completion of therapy. She feels well and has no complaints. Which of the following screening tests is indicated in this 33-year-old woman?
- Annual mammograms
  - Annual breast MRI
  - Echocardiogram every other year
  - Annual TSH
  - A, B, C, D
  - B, C, D
10. A 52-year-old male presents for follow-up of hypertension. He feels "great," works full-time, and is training for a half marathon. He takes lisinopril 40 mg, hydrochlorothiazide 25 mg, amlodipine 10 mg, and naproxen 500 mg bid.  
On examination, body mass index (BMI) is 24, blood pressure (BP) is 162/96 mm Hg, and heart rate is 66 beats per minute. Cardiac examination: normal rate and rhythm with no additional sounds. No carotid, abdominal, or renal bruits. Pulses 2+ with no peripheral edema. Laboratory results: creatinine 1, potassium (K) 3.6, hemoglobin A<sub>1c</sub> 5.6, low-density lipoprotein (LDL) 106, TSH 1.37, urinalysis (UA) normal.  
He reports 100% medication compliance. An ambulatory monitor confirms hypertension, which does not improve with discontinuation of naproxen. What is the most likely diagnosis?
- Renal artery stenosis
  - Hyperaldosteronism
  - Pheochromocytoma
  - Cushing syndrome
  - Obstructive sleep apnea (OSA)
11. A 68-year-old male complains of urgency, frequency, and awakening 3 times a night to urinate. He denies hesitancy or weak stream. He has cut back on caffeine and alcohol with no improvement in his symptoms. On examination his prostate is moderately enlarged, smooth, and symmetric. Postvoid residual is 30 mL. UA is unremarkable, and renal function is normal. The best first choice of medication for him would be:
- Tamsulosin
  - Oxybutynin
  - Finasteride
  - Sildenafil
  - Botulinum toxin
12. Which of the following patients should be treated for latent tuberculosis (TB) infection?
- A 58-year-old male starting hemodialysis with purified protein derivative (PPD) 10 mm
  - A 27-year-old student from Uganda with PPD 5 mm
  - A 34-year-old injection drug user with cough and weight loss
  - A 24-year-old suburban teacher with PPD 10 mm
  - A 45-year-old healthy spouse of a patient with active pulmonary TB and negative PPD
13. Disease X has a prevalence of 10% in your clinic. If you have a test for X that is 90% sensitive and 90% specific, what fraction of patients with a positive test truly have disease X?
- 50%
  - 67%

- C. 75%  
D. 90%
14. A 52-year-old female presents with hot flashes, sleep disruption, and vaginal dryness that began 1 year ago. She is healthy, with no medical history except for vaginal hysterectomy for menorrhagia 5 years ago. There is no family history of cancer or venous thromboembolism. She wonders about hormone replacement therapy (HRT) but has heard that this is dangerous. You discuss risks and benefits of HRT. Which of the following statements regarding her options for HRT is true?
- Compounded bioidentical hormones provide a better safety profile than synthetic estrogen preparations.
  - Low-dose conjugated equine estrogens plus medroxyprogesterone acetate would be a good choice for her.
  - HRT reduces the risk of developing dementia in addition to alleviating vasomotor symptoms.
  - Transdermal estrogen alone is contraindicated because of increased risk of breast cancer.
  - HRT is not associated with weight gain.
  - A vaginal estrogen preparation would be a good choice for her.
15. A 24-year-old male camp counselor from Connecticut presents with 3 days of intermittent fever as high as 104°F, malaise, myalgias, and headache. Examination reveals a temperature of 101.7°F and a palpable spleen tip. Laboratory testing: white blood cells 3.3, hematocrit 32.3, platelets 84, alanine aminotransferase 135, aspartate aminotransferase 106, total bilirubin 2.8, direct bilirubin 0.3, creatinine 0.9. The most likely diagnosis is:
- Tick-borne relapsing fever
  - Lyme disease
  - Rocky Mountain spotted fever
  - Human granulocytic anaplasmosis
  - Babesiosis
16. Polymerase chain reaction (PCR) confirms your diagnosis of babesiosis in the preceding patient. What is the best treatment for him?
- Doxycycline
  - Cefuroxime
  - Amoxicillin-clavulanic acid
  - Azithromycin plus atovaquone
  - Clindamycin plus quinine
17. A 62-year-old male with hypertension, dyslipidemia, and prediabetes is found to have persistent elevation of transaminases (2× upper limit of normal). His only medication is lisinopril. He does not drink alcohol. BMI is 35 with notable central adiposity. There are no stigmata of advanced liver disease. Hepatitis serologies are negative, transferrin saturation is normal, and testing for autoimmune liver disease is negative. Ultrasound shows diffuse hepatic steatosis. In addition to weight loss, what is the most appropriate pharmacologic intervention?
- Pioglitazone
  - Vitamin E
  - Atorvastatin
  - Ursodeoxycholic acid
  - Metformin
18. A 35-year-old female presents with complaints of “spider bites” on her legs. Her examination is notable for clear lungs, ankle swelling, and dusky, tender nodules on her lower extremities. A CXR shows bilateral hilar adenopathy but is otherwise clear. Which should be the next step in her management?
- Chest CT
  - NSAIDs
  - Biopsy of leg nodules
  - Steroids
  - Mediastinoscopy
19. A 65-year-old female presents with 2 weeks of progressive knee pain that began after an evening of dancing at a wedding. Pain is worse with climbing stairs. On examination there is swelling and tenderness about 2 inches below the joint, medially. The most likely diagnosis is:
- Prepatellar bursitis
  - Osgood-Schlatter syndrome
  - Iliotibial band syndrome
  - Anserine bursitis
  - Patellar tendinitis
20. A 47-year-old male presents after a spell of left arm weakness that lasted 10 minutes then resolved spontaneously. His medical history is significant for hypertension and hyperlipidemia. His neurologic examination is completely normal. MRI brain/MR angiography head and neck showed no infarct or hemodynamically significant stenosis. Echocardiogram was normal, and 48-hour event monitor showed no arrhythmia. Which of the following is the best option for long-term secondary prevention of stroke in this patient who has had a transient ischemic attack (TIA)?
- Warfarin
  - Ticlopidine
  - Acetylsalicylic acid (ASA)
  - Cilostazol
  - ASA + clopidogrel
21. A 44-year-old male presents with pain in his hands and morning stiffness. He also notes some erectile dysfunction. He has recently been diagnosed with diabetes and is being evaluated for abnormal liver function tests. On examination he has notable bony enlargement of second and third metacarpals but no active synovitis. What testing is most likely to be diagnostic?
- Antinuclear antibody
  - Transferrin saturation

- C. Anticyclic citrullinated peptide antibody  
 D. Rheumatoid factor  
 E. No laboratory testing needed
22. A 24-year-old woman presents with dysuria and frequency without fever, back pain, or vaginal discharge. She takes no medication and has no drug allergies. Her examination is notable only for mild suprapubic tenderness. What do you recommend as the best next step?  
 A. Ciprofloxacin 250 mg bid × 3 d  
 B. Amoxicillin 500 mg tid (three times per day) × 7 d  
 C. Nitrofurantoin (extended-release) ER 100 mg bid × 5 d  
 D. Urine culture with antibiotic choice determined by sensitivities  
 E. Nucleic acid amplification test for gonorrhea (GC)/chlamydia
23. A 21-year-old college student presents to your office complaining of fever, cough, sneezing, and watery eyes. His medical history is unremarkable, and he has had all childhood immunizations. He takes no medications and has no allergies. Examination is significant for a temperature of 104°F, conjunctival injection, clear lungs. You also note white spots on a red background on the buccal mucosa. Which of the following is true regarding this case?  
 A. The patient should be placed on contact precautions.  
 B. Antiviral medication reduces the duration of illness.  
 C. Encephalitis is the most common cause of associated death.  
 D. Diarrhea is a common complication.  
 E. Postexposure prophylaxis with ciprofloxacin should be provided for susceptible contacts.

### Answers

1. B.  
 National Lung Screening Trial
- Enrolled 53,000 asymptomatic high-risk smokers
    - Age 55–64 years
    - >30-pack year history of smoking
    - Currently smoking or quit within the last 15 years
  - Annual screening for 3 years versus annual screening by x-ray
  - Median follow-up 6.5 years; study terminated early because of benefit
  - Results:
    - 20% relative reduction in lung cancer mortality; 6.7% reduction in all-cause mortality
    - 24% of scans had positive findings, 95% of which were not cancer
  - Most cancers (70%) were stage I or II
- (The National Lung Screening Trial Research team. Results of initial low-dose computed tomographic screening for lung cancer. *N Engl J Med.* 2013; 368:1980.)

2. B.  
 Secondary hypogonadism  
 Reproducibly low testosterone with an inappropriately low/normal FSH and LH indicates a pituitary problem.  
 Pituitary evaluation:
  - Prolactin
  - Other tests of pituitary function
  - Iron studies (r/o hemochromatosis)
  - Pituitary MRI
 Exclude excessive exercise, eating disorder.  
 Semen analysis is not required unless fertility is desired. (Basaria S. Male hypogonadism. *Lancet.* 2014; 383:1250–1263.)
3. D.  
 Advanced heart failure is the leading cause of hospitalization for people age >65 years in the United States. It is a terminal illness characterized by decompensations and recoveries, often with failure to achieve prior level of functioning. The 1-year mortality for heart failure patients is high but individually unpredictable; as a result, patients and their families often lack understanding of their poor prognosis. The burden of symptoms is often underappreciated; studies have shown that patients with advanced heart failure would be willing to “trade” half their remaining life to have an improvement in quality of life.  
 Palliative care:
  - Focuses on maximizing quality of life (both physical and psychosocial) and does not preclude therapies designed to prolong survival
  - Can be initiated at any time during course of patient’s illness
  - Is predicated on shared decision making according to patient’s goals and wishes
  - Educates patients and families about the future and encourages advanced care planning
  - Provides an easy transition to hospice care when needed
 (Goodlin SJ. Palliative care in congestive heart failure. *J Am. Coll. Cardiol.* 2009;54(5):386–396; Allen LA, Stevenson LW, Grady KL, et al. American Heart Association; Council on Quality of Care and Outcomes Research; Council on Cardiovascular Nursing; Council on Clinical Cardiology; Council on Cardiovascular Radiology and Intervention; Council on Cardiovascular Surgery and Anesthesia. Decision making in advanced heart failure: a scientific statement from the American Heart Association. *Circulation* 2012;125:1928–1952; Lewis EF, Johnson PA, Johnson W, et al. Preferences for quality of life or survival expressed by patients with heart failure. *J. Heart Lung Transplant.* 2001; 20:1016–1024.)
4. C.  
 Lewy body dementia
  - Early deficits in visuospatial and executive functioning (memory loss more predominant in Alzheimer)

- Visual hallucinations
  - Rapid-eye movement sleep disorder, acting out dreams
  - Parkinsonism symptoms, especially bradykinesia and stiffness
    - Onset of dementia and parkinsonism <1 year apart suggests Lewy body dementia
    - If parkinsonism precedes dementia by >1 year, more likely to be Parkinson disease dementia
  - Cognitive fluctuations with variable attention/alertness
  - Autonomic dysfunction (often presenting as orthostasis and frequent falls)
  - Duration typically shorter than Alzheimer disease and there can be rapid decline
5. E.  
Eosinophilic esophagitis
- Male preponderance (M:F 3:1)
  - Peak incidence: childhood or third to fourth decade
  - Patients typically have a history of atopy
  - Most common presentation is solid food dysphagia
  - Food impaction is common (33%–50% of patients)
  - Diagnosis: esophagogastroduodenoscopy with biopsy showing eosinophils plus lack of response to proton-pump inhibitor
  - Treatment:
    - Swallowed inhaled corticosteroids
    - Dietary modification
  - Relapse is common if treatment is discontinued
- (Dellon ES, Gonsalves N, Hirano I, et al. American College of Gastroenterology. ACG clinical guideline: evidenced based approach to the diagnosis and management of esophageal eosinophilia and eosinophilic esophagitis (EoE). *Am J Gastroenterol.* 2013; 108:679–692.)
6. D.  
Serotonin syndrome
- Precipitated by use of serotonergic drugs
    - Selective serotonin reuptake inhibitors/serotonin-norepinephrine reuptake inhibitors, monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants, trazodone, opiates including tramadol, many drugs of abuse (cocaine, Ecstasy), OTC medications (St. John's wort, L-tryptophan), some antibiotics (linezolid, ciprofloxacin)
    - More likely when more than one serotonergic drug is used
    - MAOIs are particularly dangerous in this regard
  - Symptoms can vary from mild to life threatening and are often missed/attributed to other causes
  - Symptoms usually develop within 24 hours of initiation/dose change of culprit drug, commonly <6 hours
    - Can occur weeks after discontinuation of drug (especially with drugs with long half-life such as fluoxetine)
    - Neuroleptic malignant syndrome typically develops more slowly (days to weeks)
  - Symptoms: fever, altered mental status, rigidity, spontaneous clonus, hyperreflexia, autonomic instability
  - Hunter criteria (formalized diagnostic criteria)
    - Serotonergic agent: dose change, overdose, interaction *plus* one of the following:
      - Spontaneous clonus
      - Inducible clonus and agitation or diaphoresis
      - Ocular clonus and agitation or diaphoresis
      - Ocular clonus or inducible clonus
      - Tremor and hyperreflexia
      - Hypertonia and temperature >38°C and ocular clonus or inducible clonus
7. A.  
Relevant clinical trials:
- Aliskiren + enalapril led to more adverse effects versus enalapril alone without decrease in death or heart failure (HF) hospitalization. Aliskiren alone did not meet criteria for noninferiority versus enalapril (ATMOSPHERE [The Aliskiren Trial to Minimize Outcomes in Patients with Heart Failure] 2016)
  - Angiotensin-converting enzyme (ACE) inhibitors improve mortality in patients with symptomatic and asymptomatic left ventricular dysfunction (CONSENSUS [Cooperative North Scandinavian Enalapril Survival Study], SOLVD [Studies of Left Ventricular Dysfunction])
  - Beta-blockers improve survival in patients with systolic dysfunction (NYHA [New York Heart Association] II-IV), usually after stabilization on a diuretic and an ACE inhibitor (MERIT-HF [Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure])
  - Angiotensin receptor blocker use in ACE-inhibitor intolerant patients improves survival in patients with HF and reduced EF (CHARM [Candesartan in heart failure—assessment of reduction in mortality and morbidity]-Alternative)
  - Spironolactone has a mortality benefit in patients with class III or IV HF (RALES [Randomized Aldactone Evaluation Study])
8. C.  
Pelvic inflammatory disease
- Ascending infection of the female upper genital tract
  - Major cause of infertility and ectopic pregnancy
  - Polymicrobial infection: *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, gram-negative facultative organisms, anaerobes, and streptococci
  - Negative endocervical GC/chlamydia testing does not rule out upper tract infection and treatment regimens need to cover these
  - Presentation: lower abdominal or pelvic pain
  - Dyspareunia, intermenstrual or postcoital bleeding, vaginal discharge, dysuria also common
  - Onset during/immediately post menses is suggestive

- Treat if any one: uterine, adnexal, or cervical motion tenderness
- Increasing resistance of *N. gonorrhoeae* to fluoroquinolones precludes use
- Ceftriaxone is preferred (dose: 250 mg) plus doxycycline to cover *C. trachomatis*
- Some trial data to suggest azithromycin are less reliable (but still an option for patients who may not be compliant with 2-week course of doxycycline)
- Need for anaerobic coverage not definitive, but most guidelines recommend addition of metronidazole (also covers *Trichomonas*)
- IUDs do not need to be removed unless failure to improve
- Always screen for HIV/other sexually transmitted diseases

## 9. E.

Surveillance for late complications in survivors of childhood cancers

Secondary malignancies—most common are solid tumors

- Latency 10 years; risk persists 30+ years posttreatment
- Risk: 20% at 20 years
- Younger age at diagnosis/poorer prognosis
- Risk varies with regimen/location of radiation field and inversely proportional to age at diagnosis
- Breast, lung, gastrointestinal and skin most common

Screening for secondary malignancies:

- Breast cancer
  - Annual mammograms and breast MRIs starting at age 25 years or 8 years posttreatment (whichever is latest)
  - Increased risk of bilateral and contralateral metachronous cancers
- Skin cancer: annual skin examinations
- Lung cancer: controversial
- Colon cancer: no recommendation

Surveillance for cardiovascular complications

- High-risk treatment regimens
  - Mediastinal irradiation
  - Cardiotoxic chemotherapy (e.g., adriamycin)
- Increased risk of early CAD, valvular disease, left ventricular dysfunction, and arrhythmia
- Screening echocardiogram/electrocardiogram every 2 years (for this case)

Thyroid complications

- Increased cancer risk
- Increased risk of hypothyroidism: should be checked annually.

Clinical guidelines for follow-up according to specific treatment regimens: Children's Oncology Group Long-Term Follow-up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancer; [www.survivorshipguidelines.org](http://www.survivorshipguidelines.org).

## 10. B.

Resistant hypertension/hyperaldosteronism

- Resistant hypertension is hypertension that is not controlled despite use of three antihypertensives at 50% or more of maximal dosing, one of which is a diuretic
- 5% to 10% of patients with hypertension
- Must exclude confounding diagnoses first:
  - Medication noncompliance
  - Medications/substances that cause hypertension (oral contraceptive pills, NSAIDs, stimulants, alcohol, cocaine)
  - White coat hypertension
  - Thyroid disease
- Consider secondary causes of hypertension including:
  - Hyperaldosteronism
  - OSA
  - Renal artery stenosis
  - Hypercortisolism
  - Pheochromocytoma

Hyperaldosteronism

- Common causes of secondary hypertension (20%)
- Excess production of aldosterone
  - Functional adrenal adenoma (Conn syndrome)
  - Bilateral adrenal hyperplasia
- Hypokalemia is textbook, but 50% of cases are normokalemic
- Screen: elevated aldosterone to plasma renin activity (>20:1)
- Treatment: surgery for adenomas versus mineralocorticoid antagonist for hyperplasia

For this case: OSA less likely given normal BMI, high energy. No symptoms or examination findings to suggest pheochromocytoma or hypercortisolism. Renal artery stenosis is less likely given absence of diabetes, low LDL, and normal examination findings.

## 11. B.

This patient has lower urinary tract symptoms that are bothersome and have not responded to conservative measures. Bladder storage phase symptoms of urgency, frequency, and nocturia are consistent with overactive bladder, in contrast to voiding phase symptoms of incomplete emptying, weak stream, hesitancy/intermittency, which are more consistent with bladder outlet obstruction. Although this patient has an enlarged prostate, he has no symptoms of bladder outlet obstruction, and his postvoid residual is not increased. The first choice of medication for overactive bladder in the absence of bladder outlet obstruction is an anticholinergic such as oxybutynin.

## 12. A.

Latent TB infection (LTBI)

- 11 million people in the United States have LTBI; 5% to 10% will reactivate if not treated

- Reactivation most common cause of new TB cases in United States
- Screen those at high risk for new infection or reactivation
  - Recent conversion, HIV+, immunosuppressed, patients on hemodialysis, close contacts
- Tuberculin test: when to treat
  - 5 mm: HIV+, immunosuppressed, close contacts, abnormal CXR
  - 10 mm: intravenous drug users, patients on hemodialysis, patients with hematologic/head and neck cancer, residents/employees of congregate housing, recent arrivals from high prevalence areas
  - 15 mm: low risk

For this case:

- A 58-year-old male starting dialysis with PPD 10 mm
  - Hemodialysis patients are at high risk for reactivation and should be treated
- A 27-year-old student from Uganda with PPD 5 mm
  - Borderline positive test and likely acquired from early exposure; low risk of reactivation
- A 34-year-old injection drug user with cough, weight loss
  - He has symptoms of active pulmonary TB and should be tested with sputum acid-fast bacilli testing
- A 24-year-old suburban teacher with a PPD of 10 mm
  - Low-risk patients should not be tested but, if they are, should not be treated unless PPD >15 mm
- A 45-year-old healthy spouse of patient with active pulmonary TB and a negative PPD
  - This patient is at high risk of contracting TB and should be retested in 8 to 10 weeks after he or she was last exposed

13. A.

	Diseased	Not Diseased	
Test positive	9	9	18
Test negative	1	81	82
	10	90	100

Sensitivity: proportion of patients with disease who test positive  $9/10 = 90\%$

Specificity: proportion of patients without disease who test negative  $81/90 = 90\%$

Positive predictive value: proportion of patients with positive test who have the disease  $9/18 = 50\%$

14. E.

The Women's Health Initiative (WHI) trial clearly noted adverse effects of HRT in women age >60 years. However, most women with menopausal symptoms are in their 40s and 50s. Reevaluation of WHI data by age showed:

- Women in their 50s taking HRT had lower all-cause mortality than women who did not.

- Unopposed estrogen regimens do not appear to increase breast cancer risk (and may possibly lower it) in women age <60 years, menopausal <10 years.
- Healthy women age <60 years, menopausal <10 years, taking HRT <5 years have very low absolute risk of complications.

HRT should not be taken for disease prevention, only for management of bothersome symptoms.

Regarding case patient:

- Bioidentical hormones are not approved by the US Food and Drug Administration.
- This patient does not have a uterus and therefore does not need progesterone.
- Effect of HRT on risk of dementia is not proven, and HRT should not be taken for disease prevention.
- Unopposed estrogen regimens do not appear to increase breast cancer risk (and may possibly lower it) in women age <60 years, menopausal <10 years.
- HRT is not associated with weight gain.
- Vaginal estrogen does not prevent vasomotor symptoms.

15. E.

Babesiosis

- Causative organism: *Babesia microti* in the United States
- Coinfection with Lyme common
- Asymptomatic to severe/life-threatening infection
- Asplenic/immunocompromised patients are at high risk
- Symptoms: fever (typically high), sweats, myalgias, arthralgias
- Laboratory testing: transaminitis, hemolytic anemia, thrombocytopenia are common
- Confirmatory testing: PCR or thin smear showing "Maltese cross" inclusions

16. D.

Treatment of babesiosis

- Mild disease: atovaquone + azithromycin
- Severe disease: clindamycin + quinine

17. C.

Nonalcoholic fatty liver disease

- Spectrum of illness:
  - Nonalcoholic fatty liver: no inflammation, low risk of progression to cirrhosis
  - Nonalcoholic steatohepatitis (NASH): + inflammation ± fibrosis, 20% will progress to cirrhosis
  - NASH cirrhosis: 2% to 3% will develop hepatocellular cancer
- Risk factors: diabetes mellitus (DM), high BMI/visceral obesity, metabolic syndrome
- Increased mortality: CAD most common cause
  - This patient should have aggressive risk factor management; statins should not be avoided
- Multiple medication trials without clear benefit
  - Pioglitazone improves aminotransferases but long-term safety concerns (HF, bladder cancer, bone loss)

- Vitamin E improves aminotransferases in patients without DM but possible increase in all-cause mortality, increased prostate cancer risk
- Metformin, ursodeoxycholic acid have not been shown to have benefit

(Chalasan N, Younossi Z, Lavine JE, et al. The diagnosis and management of non-alcoholic fatty liver disease: practice guideline by the American Association for the Study of Liver Diseases, American College of Gastroenterology, and the American Gastroenterological Association. *Am J Gastroenterol*. 2012;107:811–826.)

18. B.

Sarcoidosis (presenting as Lofgren syndrome)

- Idiopathic granulomatous disease
- Incidence: 10 to 20 in 100,000; more common in African Americans
- Can affect any organ: lungs, skin, eye most common; cardiac has high morbidity
- Common presenting symptoms
  - Nonproductive cough, chest pain, dyspnea (50%)
  - Constitutional symptoms (30%)
  - Ocular (20%); uveitis is most common ocular symptom
  - Skin: erythema nodosum, lupus pernio, skin lesions on scars/tattoos
- Clinical course: asymptomatic to life threatening
- Many patients do not require treatment and unclear if treatment alters progression or prognosis
- Diagnosis of exclusion
  - Differential diagnosis includes cancer (especially lymphoma) and infection (TB, fungal)
  - Biopsy showing noncaseating granulomas and exclusion of other granulomatous disease with compatible clinical/radiologic findings
- Exceptions to need for biopsy
  - Lofgren syndrome (this case)
    - Fever, erythema nodosum, ankle swelling, bilateral hilar lymphadenopathy
    - NSAID-responsive
    - No biopsy unless failure to improve
  - Asymptomatic bilateral hilar adenopathy
  - Heerfordt syndrome (uveoparotid fever)

(Nelson HD, Zakher B, Cantor A, et al. Risk factors for breast cancer for women aged 40 to 49 years: a systematic review and meta-analysis. *Ann Int Med*. 2012;156(9):635–648; Carmona EM, Kalra S, Ryu JH. Pulmonary sarcoidosis: diagnosis and treatment. *Mayo Clin Proc*. 91:946–954; Valeyre D, Prasse A, Nunes H, et al. Sarcoidosis. *Lancet*. 2014;383:1155.)

19. D.

Anserine bursitis

- Overuse injury
- Inflammation of bursa located between proximal anteromedial tibia and conjoined tendon (“goose foot” tendons)

- Risk factors: tight hamstrings, valgus knee deformity, flat feet, female gender, obesity, repetitive activities, osteoarthritis (OA)
- Treatment: icing, stretches, NSAIDs

20. C.

Secondary prevention of stroke in patient with TIA

- There are 690,000 cases of stroke annually in the United States with high associated morbidity; in addition, there are 240,000 cases of TIA annually. Both groups are at high risk for recurrence.
- Antiplatelet agents are useful for secondary prevention; current American Heart Association/American Stroke Association guidelines recommend:
  - ASA (low doses as effective as high doses)
  - ASA + dipyridamole
  - Clopidogrel
  - On average, risk of stroke reduced by 22% with these agents
- Long-term use of ASA + clopidogrel led to an increased risk of bleeding with no reduction in vascular risk (MATCH [Molecular Analysis for Therapy Choice] trial).
- Ticlopidine is effective for prevention but is associated with significant side effects (severe neutropenia, rash, diarrhea) that make it less desirable.
- Warfarin should not be used in patients with a noncardioembolic TIA/stroke.
- Cilostazol has shown some promise in early trials in Asia, but there is insufficient evidence to recommend it at this time.

21. B.

Hemochromatosis

- Iron overload and hemosiderin deposition as a result of mutations in human hemochromatosis gene
- Prevalence 1 in 200 to 500 in the United States
- Symptoms:
  - Early: arthropathy, fatigue, impotence
  - Late: diabetes, cirrhosis, cardiomyopathy
- Polyarticular/symmetric arthritis:
  - classic finding second/third metacarpophalangeal bony enlargement without inflammation
  - Hemochromatosis arthropathy typically presents earlier than OA; median onset 40s in men and 50s in women
- Screen: iron/total iron-binding capacity (>60% men, >50% women); positive screens should be followed with genetic testing

22. C.

Acute uncomplicated cystitis

- Culture not necessary for uncomplicated cases
- Complicated urinary tract infections: pregnant, male, immunosuppressed or otherwise at increased risk of infection (e.g., poorly controlled DM), or with genitourinary tract abnormality (structural or functional)

- 80% *Escherichia coli*, 10% other gram-negative rods (GNRs), remainder g(+) especially *Staphylococcus saprophyticus*
- Base treatment on local resistance, allergy, cost
  - Local resistance rate >20% is considered cutoff for empiric antibiotic use.
  - Hospital resistance data may skew community estimates.
  - Hospitalized patients have disproportional complicated infections and may not represent outpatient setting.
- Fluoroquinolones (FQs) are highly effective but cause “collateral damage”; reserve use for more serious infections
  - FQ use linked with infection with methicillin-resistant *Staphylococcus aureus*, FQ<sup>R</sup> GNRs (*Pseudomonas*)
  - Issues with tendinitis, QT-prolongation/drug interactions as well
- Amoxicillin/ampicillin should not be used
- IDSA guideline acute cystitis/pyelonephritis (Gupta K, Hooton TM, Naber KG, et al. Infectious Diseases Society of America; European Society for Microbiology and Infectious Diseases. International clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: A 2010 update by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases. *Clin Infect Dis*. 2011;52:e103–e120.)

## 23. D.

Measles (rubeola)

- Incubation period: 10 to 12 days postexposure
- Prodrome: fever (often high), cough, coryza, conjunctivitis, Koplik spots
- Maculopapular rash: 2 to 4 days after onset of fever
- Starts at head and proceeds downwards to trunk and then extremities
- Contagious 4 days before/4 days after rash develops
- Attack rate for susceptible patients is 90%
  - 1 dose measles, mumps, rubella (MMR) 90% protective
  - 2 doses MMR 97% protective
- Diagnosis is clinical with confirmation by PCR of nasopharyngeal swab/serologies
- Treatment is supportive; antivirals do not help
- Patients should be placed in respiratory isolation
- 30% of cases have complications
  - Most common: otitis media, diarrhea
  - Pneumonia most common cause of death
  - Rare: encephalitis, seizure, death (0.2%)
- Vaccination of susceptible contacts within 72 hours of exposure
- Intravenous immunoglobulin for high risk/immunocompromised up to 6 days postexposure
- Report to local health authority or Centers for Disease Control and Prevention immediately
- No association between MMR vaccine and autism

# 109

## Internal Medicine Summary

REBECCA A. BERMAN AND CHARLES A. MORRIS

The purpose of this chapter is to provide a review, from across the breadth of internal medicine, of currently recommended health screening strategies. As advances in medical technology continue to push the ability to detect, treat, and impact disease states, there is increasing attention to the utility of screening and its role in periodic health assessments. The concept of disease prevention through early detection has inherent attractiveness; yet evidence to support vast numbers of screening initiatives has been lacking. As laid out in a landmark article from 1968, effective screening is predicated on several major tenets:

1. The condition should be an important health problem.
2. There should be a recognizable latent or early symptomatic stage.
3. The natural history of the condition should be adequately described and understood.
4. There should be an accepted treatment for patients with recognized disease.
5. There should be a suitable screening test applicable during this latent phase.
6. The test should be acceptable to the population.
7. The cost of detection (both of false positives and false negatives) as well as treatment should be economically acceptable.

Whereas many screening tests meet the aforementioned criteria, clear evidence that screening improves mortality for a given disease can be more elusive. Studies to assess the efficacy of screening interventions are susceptible to several types of biases. Lead-time bias, particularly common in studies of cancer screening, refers to early cancer detection and diagnosis that, in the absence of an effective treatment, may increase survival without a mortality benefit (Fig. 109.1). Studies of cancer screening are also vulnerable to length-time bias. This occurs when screening, performed at a fixed interval, preferentially detects slower-progressing tumors while rapidly progressive cancers develop between screening episodes. Consequently, screened populations may appear to have improved clinical outcomes. Overdiagnosis bias, in which screening allows the detection of clinically indolent forms of disease that otherwise might not require intervention or affect mortality, may partly explain apparent benefits of screening for other solid organ malignancies (Fig. 109.2). In general, randomized controlled trials rather

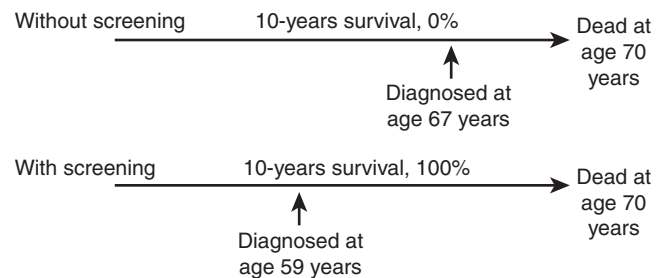

than observational studies help avoid these pitfalls and most accurately assess mortality benefits.

In the United States, there are several sources for physicians to obtain up-to-date practice guidelines on evidence-supported health screening information. The US Preventive Services Task Force (USPSTF) under the auspices of the Agency for Healthcare Research and Quality provides regularly updated reviews of the evidence to support a number of preventative services and grades this evidence with recommendations A to D and I (Box 109.1 and Table 109.1). The American College of Physicians (ACP) also provides guidelines and consensus statements of screening and preventative services based on detailed reviews of the literature. In addition, screening recommendations are produced by various subspecialty professional societies (such as the American Gastroenterological Association recommendations on colorectal cancer screening as endorsed by the American Cancer Society [ACS] or the Centers for Disease Control and Prevention [CDC] recommendations on HIV screening).

This chapter reviews current health screening recommendations for cancer and cardiovascular disease, lifestyle issues including substance use, and common infectious diseases.

### Cancer Screening

According to the ACS it is estimated that 595,690 people will die from cancer-related mortality in 2016; cancer is the second most common cause of death in the United States. Lung, breast, prostate, and colorectal cancers

• **Fig. 109.1** Lead-time bias. (From Welch HG, Woloshin S, Schwartz LM, et al. Overstating the evidence for lung cancer screening: The International Early Lung Cancer Action Program (I-ELCAP) Study. *Arch Intern Med.* 2007;167:2289–2895.)

• **Fig. 109.2** Overdiagnosis bias. (From Welch HG, Woloshin S, Schwartz LM, et al. Overstating the evidence for lung cancer screening: The International Early Lung Cancer Action Program (I-ELCAP) Study. *Arch Intern Med.* 2007;167:2289–2295.)

### • BOX 109.1 USPSTF Ratings of Strength of Recommendations

- The USPSTF strongly recommends that clinicians provide [the service] to eligible patients. The USPSTF found good evidence that [the service] improves important health outcomes and concludes that benefits substantially outweigh harms.
- The USPSTF recommends that clinicians provide [this service] to eligible patients. The USPSTF found at least fair evidence that [the service] improves important health outcomes and concludes that benefits outweigh harms.
- The USPSTF makes no recommendation for or against routine provision of [the service]. The USPSTF found at least fair evidence that [the service] can improve health outcomes but concludes that the balance of benefits and harms is too close to justify a general recommendation.
- The USPSTF recommends against routinely providing [the service] to asymptomatic patients. The USPSTF found at least fair evidence that [the service] is ineffective or that harms outweigh benefits.
- The USPSTF concludes that the evidence is insufficient to recommend for or against routinely providing [the service]. Evidence that the [service] is effective is lacking, of poor quality, or conflicting and the balance of benefits and harms cannot be determined.

USPSTF, United States Preventative Services Task Force.  
From Agency for Healthcare Research and Quality. *Preventative Services Recommended by the USPSTF.* Washington, DC: U.S. Department of Health and Human Services.

account for nearly 50% of cancer deaths. Importantly, mortality of breast, colon, cervical, and prostate cancer has decreased; screening is likely responsible for at least a portion of this decline (although mortality from lung cancer has decreased largely because of a decreased prevalence of smoking).

## Breast Cancer

Mammography remains the standard of care for breast cancer screening, with a maximal benefit that increases with age. Evidence supports a small but clinically significant mortality reduction from screening for breast cancer, particularly among women age  $\geq 50$  years. For women between the ages of 40 and 50, whereas the relative risk reduction from mammography is similar, the absolute benefit from screening is much smaller with high risks of false-positive screens. Published guidelines reflect this debate. The USPSTF recently changed their recommendation to biannual screening for women age 50 to 74 years. For women age 40 to 49 years, USPSTF calls for an assessment of the individual patient's risk profile and an understanding of the potential benefits and harms of screening. The ACS recommends mammography every 1 to 2 years starting at 45 years (with women age  $\geq 40$  years able to opt-in to screening), whereas the ACP recently reviewed the literature and updated their own clinical practice guidelines, recommending that any decision to screen women age 40 to 49 years take into account the risk of false-positive results and an individual's unique risk profile.

In an effort to improve the test characteristics of mammography, several large trials have examined the role of MRI as a screening modality. These studies confirm that high-risk women (defined as a cumulative lifetime risk of  $\geq 15\%$ , including those with inherited predispositions of *BRCA-1* and *BRCA-2*) benefit from the increased sensitivity of MRI screening. Sensitivity of MRI to detect invasive cancer was significantly improved compared with that for mammography, 79.5% versus 33%. Considering these data, the ACS currently recommends MRI screening for high-risk women. The Gail Model (available online at <http://www.acs.org>) is one of several prospectively validated models for calculating

**TABLE 109.1** USPSTF A and B Recommendations

Topic	Description
Abdominal aortic aneurysm screening: men	The USPSTF recommends one-time screening for abdominal aortic aneurysm by ultrasonography in men age 65–75 years who have never smoked.
Alcohol misuse: screening and counseling	The USPSTF recommends that clinicians screen adults age $\geq 18$ years for alcohol misuse and provide persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce alcohol misuse.
Aspirin preventive medication: adults age 50–59 years with a $\geq 10\%$ 10-year cardiovascular risk	The USPSTF recommends initiating low-dose aspirin use for the primary prevention of cardiovascular disease and colorectal cancer in adults age 50 to 59 years who have a $\geq 10\%$ 10-year cardiovascular risk, are not at increased risk for bleeding, have a life expectancy of at least 10 years, and are willing to take low-dose aspirin daily for at least 10 years.
Blood pressure screening in adults	The USPSTF recommends screening for high blood pressure in adults age $\geq 18$ years. The USPSTF recommends obtaining measurements outside of the clinical setting for diagnostic confirmation before starting treatment.
Breast cancer screening	The USPSTF recommends screening mammography for women, with or without clinical breast examination, every 1–2 years for women age $\geq 40$ years.
Cervical cancer screening	The USPSTF recommends screening for cervical cancer in women age 21–65 years with cytology (Pap smear) every 3 years or, for women age 30–65 years who want to lengthen the screening interval, screening with a combination of cytology and human papillomavirus testing every 5 years.
Chlamydia screening: women	The USPSTF recommends screening for chlamydia in sexually active women age $\leq 24$ years and in older women who are at increased risk for infection.
Cholesterol abnormalities screening: men $\geq 35$ , women $\geq 45$	The USPSTF strongly recommends screening men age 35 years and women age $\geq 45$ years for lipid disorders.
Cholesterol abnormalities screening: men age $< 35$ years and women age $< 35$ years	The USPSTF recommends screening men age 20–35 years for lipid disorders if they are at increased risk for coronary heart disease.
Colorectal cancer screening	The USPSTF recommends screening for colorectal cancer starting at age 50 years and continuing until age 77 years.
Depression screening	The USPSTF recommends screening for depression in the general adult population, including pregnant and postpartum women and adolescents age $\geq 12$ years. Screening should be implemented with adequate systems in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up.
Diabetes screening	The USPSTF recommends screening for abnormal blood glucose as part of cardiovascular risk assessment in adults age 40–70 years who are overweight or obese. Clinicians should offer or refer patients with abnormal blood glucose to intensive behavioral counseling interventions to promote a healthful diet and physical activity.
Falls prevention in older adults: exercise or physical therapy	The USPSTF recommends exercise or physical therapy to prevent falls in community-dwelling adults age $\geq 65$ years who are at increased risk for falls.
Falls prevention in older adults: vitamin D	The USPSTF recommends vitamin D supplementation to prevent falls in community-dwelling adults age $\geq 65$ years who are at increased risk for falls.
Folic acid supplementation	The USPSTF recommends that all women planning or capable of pregnancy take a daily supplement containing 0.4–0.8 mg (400–800 $\mu\text{g}$ ) of folic acid.

**TABLE 109.1** USPSTF A and B Recommendations—cont'd

Topic	Description
Gonorrhea screening: women	The USPSTF recommends screening for gonorrhea in sexually active women age $\leq 24$ years and in older women who are at increased risk for infection.
Healthy diet and physical activity counseling to prevent cardiovascular disease: adults with cardiovascular risk factors	The USPSTF recommends offering or referring adults who are overweight or obese and have additional CVD risk factors to intensive behavioral counseling interventions to promote a healthy diet and physical activity for CVD prevention.
Hepatitis B screening: nonpregnant adolescents and adults	The USPSTF recommends screening for hepatitis B virus infection in persons at high risk for infection.
HCV infection screening: adults	The USPSTF recommends screening for HCV infection in persons at high risk for infection. The USPSTF also recommends offering one-time screening for HCV infection to adults born between 1945 and 1965.
High blood pressure in adults: screening	The USPSTF recommends screening for high blood pressure in adults age $\geq 18$ years. The USPSTF recommends obtaining measurements outside of the clinical setting for diagnostic confirmation before starting treatment.
HIV screening	The USPSTF recommends that clinicians screen for HIV infection in adolescents and adults age 15–65 years. Younger adolescents and older adults who are at increased risk should also be screened. All pregnant women should be screened.
Intimate partner violence screening: women of childbearing age	The USPSTF recommends that clinicians screen women of childbearing age for intimate partner violence, such as domestic violence, and provide or refer women who screen positive to intervention services. This recommendation applies to women who do not have signs or symptoms of abuse.
Lung cancer screening	The USPSTF recommends annual screening for lung cancer with low-dose computed tomography in adults age 55–80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years. Screening should be discontinued once a person has not smoked for 15 years or develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery.
Obesity screening and counseling: adults	The USPSTF recommends screening all adults for obesity. Clinicians should offer or refer patients with a body mass index of $\geq 30$ to intensive, multicomponent behavioral interventions.
Osteoporosis screening: women	The USPSTF recommends screening for osteoporosis in women age $\geq 65$ years and in younger women whose fracture risk is equal to or greater than that of a 65-year-old white woman who has no additional risk factors.
Sexually transmitted infections counseling	The USPSTF recommends intensive behavioral counseling for all sexually active adolescents and for adults who are at increased risk for sexually transmitted infections.
Skin cancer behavioral counseling	The USPSTF recommends counseling children, adolescents, and young adults age 10–24 years who have fair skin about minimizing their exposure to ultraviolet radiation to reduce risk for skin cancer.
Tobacco use counseling and interventions	The USPSTF recommends that clinicians ask all adults about tobacco use, advise them to stop using tobacco, and provide behavioral interventions and FDA-approved pharmacotherapy for cessation to adults who use tobacco.

*Continued*

**TABLE 109.1 USPSTF A and B Recommendations—cont'd**

Topic	Description
Syphilis screening: nonpregnant persons	The USPSTF recommends screening for syphilis infection in persons who are at increased risk for infection.
Syphilis screening: pregnant women	The USPSTF recommends that clinicians screen all pregnant women for syphilis infection.

CVD, Cardiovascular disease; FDA, US Food and Drug Administration; HCV, hepatitis C virus; USPSTF, US Preventive Services Task Force.  
 Modified from *USPSTF A and B Recommendations*. US Preventive Services Task Force. June 2016. <http://www.uspreventiveservicestaskforce.org/Page/Name/uspstf-a-and-b-recommendations>.

lifetime breast cancer risk and can facilitate shared decision making between physician and patient. Because mammography can still detect breast cancers that are missed by MRI, high-risk women should be screened with both modalities.

### Cervical Cancer

The introduction of cervical cancer screening with the Papanicolaou (Pap) test has led to a dramatic reduction in the incidence of invasive of cervical cancer. Recently revised guidelines for Pap testing recommend starting to screen women at the age of first sexual activity or 21 years, whichever is first. Cytology-only screening is recommended for women age 20 to 29 years, which may be performed every 3 years. Over 99% of cervical cancer may be attributed to infection with human papilloma virus (HPV), which is the highest attributable risk for any common malignancy. In light of this association there has been considerable interest in the use of viral probes as a standalone or adjuvant screening tool. HPV assays demonstrate a significantly higher sensitivity than Pap testing. For women age >30 years, there are two options. Screening can be done every 3 years using cytology-only testing. If HPV testing is done in conjunction with cytology-based testing then the recommended interval is every 5 years. When used in conjunction with Pap tests, the additional sensitivity of HPV assays can provide a useful tool with which to triage those with abnormal cytology for colposcopy. Because the majority of HPV infections resolve without intervention, HPV probes may prove useful as stand-alone screening tests once a woman is of sufficient age that HPV detection likely reflects persistent infection.

### Prostate Cancer

The benefit from prostate cancer screening is controversial. Since the advent of prostate specific antigen (PSA) for screening, prostate cancer mortality in the United States has declined, although this may be in part to overdiagnosis bias discussed earlier. There was a dramatic increase in incidence of prostate cancer in the early 1990s shortly after PSA testing became available, the majority of which was localized disease. After 13 years of follow-up, the European Randomized Study of Screening of Prostate Cancer showed a small

absolute reduction in prostate cancer mortality of 1.28 per 1000 men and 27 men treated over that time interval to avoid one prostate cancer death. The Prostate, Lung, Colorectal and Ovarian (PLCO) cancer screening trial showed no difference in mortality between the PSA screening and control groups. Based on this finding the USPSTF revised their recommendations for PSA-based prostate cancer screening of men of any age to category “D.” However, these recommendations have come under fire, most recently in an editorial in the *New England Journal of Medicine* in 2016 that found that the control arm of the PLCO was contaminated such that 90% of participants in the control arm actually received a PSA test at some point during the study. Based on these findings, the USPSTF is revisiting its guidelines. The ACS recommends screening starting at age 50 years (or at age 45 years for high-risk men including African Americans and those with a family history of prostate cancer or age 40 years in those with multiple family members diagnosed at a young age) but only after a discussion of the risks and benefits. The American Urological Association recommends no routine screening for average risk men age <54 years and shared decision making for men age 55 to 69 years recognizing that this is the group with the largest potential benefit. In an effort to improve the test characteristics of the PSA, some have advocated using free PSA values or PSA velocity, although the utility of these strategies remains unclear. Velocity may be useful to identify those with lower absolute PSA values who may have clinically significant cancer (e.g.,  $\geq 0.35$  ng/mL/y if total PSA <4 ng/mL); similarly, in older patients with PSA values >4 ng/mL, a velocity >1.25 ng/mL/y may help to exclude those with clinically indolent cancers. However, clinical decision making based on PSA velocity has not yet demonstrated a mortality benefit in a prospective, randomized trial.

### Colorectal Cancer

Routine screening for colorectal cancer (CRC) for age 50 to 77 years (or earlier with a high-risk personal or family history of colon cancer or adenomatous polyps) may be performed by several different strategies. For those age 77 to 85 years, this should be an individual decision, taking into account overall health and prior screening. New guidelines as of June 2016 suggest seven different options for screening: annual fecal

occult blood, annual fecal immunochemical testing (FIT), colonoscopy every 10 years, flex sigmoidoscopy (sig) every 5 years, CT colonography (so-called virtual colonoscopy) every 5 years, flex sigmoidoscopy every 10 years + FIT every year, or FIT stool DNA testing every 1 or 3 years. Of note, the recommendations do not rank amongst these seven options; however, in an accompanying editorial in JAMA, closer reading of the guidelines suggests that in terms of a combination of life expectancy gains and health care resource utilization, the top four screening tests are colonoscopy, FIT for occult blood, sigmoidoscopy plus FIT, and CT colonography. The large number of screening options are intended to drastically improve current colon cancer screening rates, which currently hover around one-fourth of eligible patients.

## Controversies in Screening Lung Cancer

Lung cancer is the most common cause of cancer-related mortality in the United States, with an estimated 158,080 Americans expected to die from lung cancer in 2016, accounting for approximately 25% of all cancer deaths. Unfortunately, early studies of screening high-risk patients with chest radiology and sputum cytology failed to demonstrate a mortality benefit despite detection of an increased number of malignant lesions. The International Early Lung Cancer Action Program (I-ELCAP) study showed that the majority of asymptomatic lung cancers identified by low-dose spiral CT were early-stage disease. In 2011 the National Lung Screening Trial demonstrated that annual CT scan screening of former or current heavy smokers resulted in a 20% relative reduction in mortality. Based on these data in 2013 the USPSTF updated their guidelines to recommend annual low-dose CT screening for patients age 55 to 80 years with a 30-pack year history who either currently smoke or quit within the last 15 years. Patients should be able and willing to have lung surgery and not have “health problems that substantially limit life expectancy.”

## Cardiovascular Screening

### Hypertension

The Joint National Commission on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) defines stage I hypertension as systolic blood pressure >140 mm Hg and/or a diastolic pressure >90 mm Hg. Most recent estimates indicate that over one-quarter of Americans have hypertension, a leading cause of cardiovascular morbidity and mortality. JNC7 recommends screening all adults for high blood pressure, a recommendation also endorsed by the USPSTF and the American Heart Association (AHA). The USPSTF recommends screening for high blood pressure in adults age  $\geq 18$  years and recommends obtaining measurements outside of clinic for confirmation before starting treatment. The JNC8 guidelines have markedly changed the blood pressure goals and the approach to treatment (this is discussed in more detail

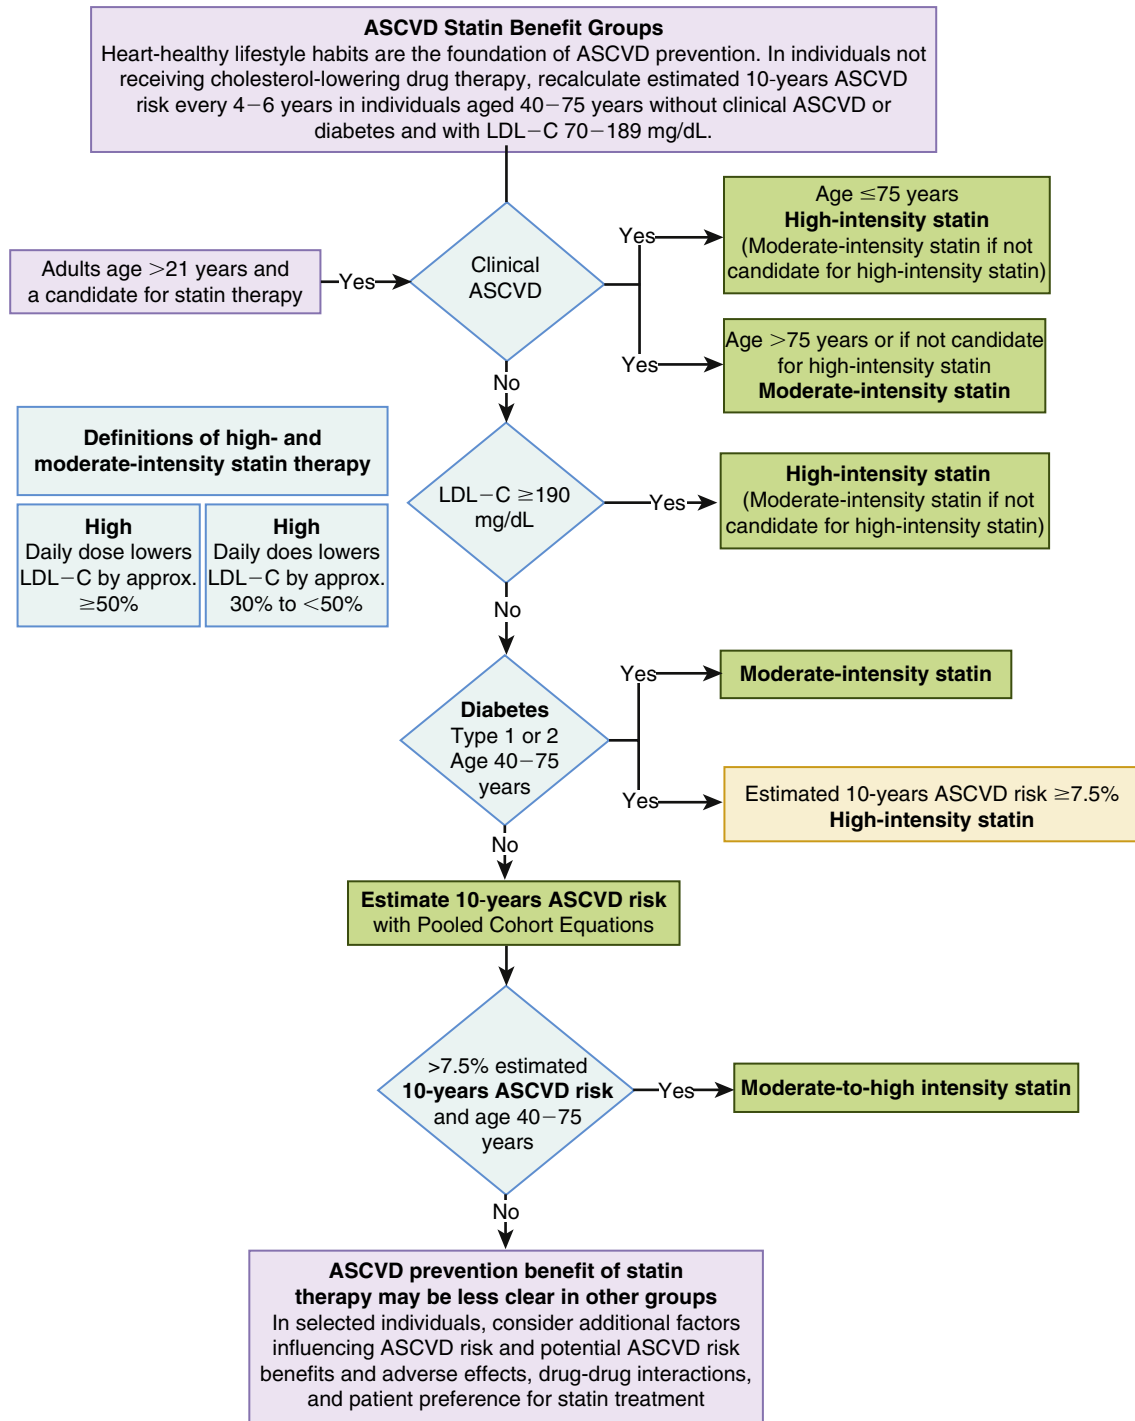

in Chapter 86). The Systolic Blood Pressure Intervention Trial (SPRINT) published in 2015 is very likely to change these guidelines again. In SPRINT, 9361 subjects age >50 years were randomized to either intensive treatment (systolic blood pressure <120 mm Hg) or standard treatment (systolic blood pressure <140 mm Hg). The trial reported a significant reduction in the intensive arm of the primary composite endpoint of myocardial infarction, other acute coronary syndromes, stroke, heart failure, or death from cardiovascular causes. Remarkably, there was also a significant 25% reduction in all-cause mortality in the intensive-treatment group.

### Abdominal Aortic Aneurysms

Abdominal aortic aneurysms (AAA) are common, with an estimated prevalence of 8% among elderly men. These aneurysms pose considerable risk to affected individuals because rupture is associated with a mortality rate as high as 90% in selected populations. The US Department of Veterans Affairs (VA) ran a large randomized controlled trial of over 67,000 veterans for AAA screening versus routine care. Those with AAA >5.4 cm received surgery, and mortality was reduced by 42% in screened versus unscreened populations. Although open repair of these aneurysms carries an operative mortality of approximately 4%, newer endovascular repair techniques have also strengthened the argument in favor of early detection. Because abdominal vascular ultrasonography demonstrates favorable test characteristics of high sensitivity and specificity, and surgical repair of AAAs  $\geq 5.5$  cm decreases AAA specific mortality, the USPSTF has issued a grade B recommendation for one-time screening for AAA by ultrasonography for current or former male smokers age 65 to 75 years. Coverage for this screening benefit is variable, although as of 2014, Medicare does provide coverage for men who have smoked more than 100 cigarettes and men and women with a family history of AAA.

### Cholesterol/Lipid Screening

Epidemiologic studies have convincingly demonstrated that high levels of low-density lipoprotein (LDL) cholesterol are atherogenic and that elevated levels increase the risk of both first and recurrent cardiovascular events. In addition, clinical trials have confirmed that lowering cholesterol by pharmacologic therapy, especially with hydroxymethylglutaryl-CoA reductase inhibitors, decreases coronary heart disease (CHD) incidence and mortality. The National Cholesterol Education Program and Adult Treatment Panel III (ATP III), which were last updated in 2004, have now been replaced by the American College of Cardiology and AHA cholesterol guidelines developed in conjunction with the National Heart, Lung, and Blood Institute. The guidelines represent a departure from ATP III because they abandon specific target levels of LDL cholesterol (Fig. 109.3). Rather the new guidelines focus on defining groups for whom LDL lowering is proven to be most beneficial. According to the

• **Fig. 109.3** 2013 American College of Cardiology/American Heart Association recommendation for statin therapy for atherosclerotic cardiovascular disease (ASCVD) prevention. *LDL*, Low-density lipoprotein. (From Stone NJ, Robinson J, Lichtenstein AH, et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines. *J Am Coll Cardiol.* 2014; 63(25 Pt B):2889–2934. Errata in *J Am Coll Cardiol.* 2015;66(24):2812 and *J Am Coll Cardiol.* 2014;63(25 Pt B):3024–3025.)

guideline, in these patient groups, atherosclerotic cardiovascular disease (ASCVD) risk reduction “clearly outweighs the risk of adverse events.” The groups are:

1. Individuals with clinical ASCVD;
2. Individuals with primary elevations of LDL-C >190 mg/dL;
3. Diabetes patients age 40 to 75 years with LDL-C 70 to 189 mg/dL and without clinical ASCVD; and
4. Individuals without clinical ASCVD or diabetes with LDL-C 70 to 189 mg/dL and estimated 10-year ASCVD risk >7.5%.

The guidelines are discussed in more detail in [Chapter 86](#) and are referenced in the Additional Reading. Guidelines issued by the USPSTF recommend screening all men for dyslipidemia at age 35 years or at age 20 years if there are cardiovascular risk factors. Screening women with cardiovascular risk factors is endorsed at age 45 years or starting at age 20 years if there are cardiovascular risk factors.

### Controversies in Cardiovascular Screening

With the advent of newer cardiovascular imaging including high-resolution and multirow detector CT, nuclear imaging, and ultrasonography, there has been growing interest in incorporating these modalities into screening algorithms for both occult CHD and peripheral vascular disease. In 2006 the Screening for Heart Attack Prevention and Education guidelines were released advocating an imaging-based screening protocol rather than one based on established methods of lipid measurement. However, randomized controlled trial data are lacking for these screening strategies, and they remain unendorsed by major professional societies. In 2010 the AHA released updated guidelines on screening for cardiovascular disease emphasizing a tailored approach for patients in which a global risk score would determine the appropriateness of further testing including imaging-based modalities. In December 2007 the USPSTF has given a “D” rating to screening for asymptomatic carotid stenosis.

### Diabetes Mellitus

Diabetes mellitus is increasingly common, with an estimated national prevalence of 9.3%. The USPSTF updated its guidelines in 2015 to recommend screening for abnormal blood glucose in overweight adults age 40 to 70 years. The American Diabetes Association recommends screening all asymptomatic adults age  $\geq 45$  years with either a hemoglobin A<sub>1c</sub> ( $\geq 6.5$ ), a fasting blood sugar ( $\geq 126$ ), or oral glucose tolerance test at age 45 years ( $\geq 200$ ) or earlier if overweight and with other cardiovascular risk factors. They recommend repeating at least every 3 years.

### Lifestyle Factors

#### Obesity

According to the most recent data from the National Health and Nutrition Examination Survey, almost two-thirds of

adults in the United States are overweight (a body mass index [BMI] = 25–29.9), and almost one-third are obese (BMI  $\geq 30$ ). The USPSTF gives a B recommendation for screening adults for obesity.

### Alcohol and Tobacco Abuse

The Alcohol Use Disorders Identification Test is the most studied screening tool for detecting alcohol-related problems in primary care settings. It is sensitive for detecting alcohol misuse, abuse, or dependence and can be used as a stand-alone screening tool. The four-item CAGE (feeling the need to Cut down, Annoyed by criticism, Guilty about drinking, and need for an Eye-opener in the morning) is the most popular screening test for detecting alcohol abuse or dependence in primary care.

Physicians should remember that even brief tobacco cessation counseling (3 min or less) for patients who smoke has been proven to increase tobacco abstinence rates; because of this the USPSTF gives screening for tobacco use their highest “A” rating. The 5-A behavioral framework is a useful strategy for engaging patients who smoke in a discussion about tobacco cessation:

1. Ask about tobacco use.
2. Advise to quit through clear personalized messages.
3. Assess willingness to quit.
4. Assist to quit.
5. Arrange follow-up and support.

### Infectious Disease/Sexually Transmitted Disease

Chlamydia is the most common sexually transmitted infection in the United States, with an estimated prevalence of 4% to 5% nationally although these estimates vary greatly depending on the target population. If untreated, chlamydia may lead to cervicitis, urethritis, pelvic inflammatory disease, chronic pelvic pain, and infertility. Because the vast majority of both men and women are asymptomatic during chlamydial infection, identification based only on symptomatic patients is problematic. The USPSTF gives an “A” rating to screening sexually active women age  $\leq 24$  years or older women who are at higher risk. The age cutoff is based largely on population studies showing that prevalence of chlamydial infection is inversely correlated with age. Current screening tools include amplified and nonamplified gene probes that allow rapid, accurate detection of infection. Although newer urine-based assays may be performed in men as well, the utility of screening men is less clear as long-term consequences of untreated male infection are less well defined. For this reason, screening men is not universally recommended. Gonococcal infections are the second most common sexually transmitted disease, and screening is also recommended for young women by the USPSTF.

Because of a rise in syphilis cases, new 2016 USPSTF guidelines recommend grade A evidence for screening in asymptomatic high-risk individuals including men age  $\leq 29$  years, men who have sex with men, patients with HIV, history of incarceration, certain racial and ethnic minorities, and in geographic areas of high prevalence.

## Human Immunodeficiency Virus

Recently released estimates of HIV incidence in the United States for 2006 suggest that rates are much higher than previously projected. An estimated 56,300 new HIV infections occurred in 2006, higher than the previous estimate of 40,000 annual new infections. Just over half of these new infections occurred in men having sex with men, but high-risk heterosexual contact accounted for 31% of new infections. African Americans, although comprising 13% of the US population, accounted for 45% of the new HIV infections. Given the advances in treatment of HIV and the transformation of infection into a chronic disease, there has been renewed interest in screening for HIV infection among asymptomatic persons. In 2005 the USPSTF issued an “A” recommendation for screening high-risk individuals, including men who have had sex with men and men and women having unprotected sex with multiple partners. In 2006 the CDC issued revised guidelines recommending HIV screening for all adults, adolescents, and pregnant women at least once and more frequently depending on an individual’s risk.

## Chapter Review

### Questions

1. A 37-year-old man presents to his primary care physician for a routine physical examination. His only medical history includes seasonal allergies for which he uses intranasal fluticasone. He does not smoke cigarettes or drink alcohol. There is no family history of colorectal cancer although his mother did have two adenomatous polyps at age 55 years. When should he undergo his first screening colonoscopy?
  - A. Now
  - B. Age 40 years
  - C. Age 45 years
  - D. Age 50 years
2. A 66-year-old male asymptomatic patient with a history of hyperlipidemia, diabetes, and hypertension presents for routine screening. He has a 15 pack-year history and quit 30 years ago. He drinks one glass of red wine daily. He goes on long walks daily for exercise. He gets his flu shot annually, and he received the pneumococcal vaccine last year. He had a normal colonoscopy 5 years ago. He is on amlodipine and allopurinol. His vital signs are stable,

## Osteoporosis

Age-related bone loss is often asymptomatic, and the morbidity of osteoporosis is secondary to the fractures that occur. Common sites of fracture include the spine, forearm, and hip; the last incur the greatest morbidity and mortality and are the principal driver of osteoporosis-associated health care costs. The remaining lifetime probability of osteoporotic fractures in women at the age of 50 years exceeds 40% in developed countries. The USPSTF recommends that women aged  $\geq 65$  years be screened routinely for osteoporosis and that routine screening begins earlier for women at increased risk for osteoporotic fractures. In response to the fact that bone mineral density (BMD) testing is not available in resource-poor areas, the World Health Organization has developed the FRAX tool, a validated model predicting an individual’s 10-year risk of osteoporotic fracture based on nine accepted risk factors. The FRAX score may be computed with or without a BMD value and is appropriate to use in men age  $>41$  years and across several different ethnic groups.

and his physical examination is unremarkable. Which of the following screening tests is most appropriate for this patient based on the most evidence of benefit?

- A. Low-dose chest CT
  - B. PSA
  - C. Urinalysis
  - D. Abdominal ultrasound
  - E. Exercise treadmill test
3. A 20-year-old woman who is sexually active with men presents for routine screening. Which of the following tests is indicated?
    - A. HIV, gonorrhea, chlamydia, Pap smear cytology, and HPV screening
    - B. HIV, gonorrhea, chlamydia
    - C. HIV, gonorrhea, chlamydia, Pap smear cytology
    - D. HIV, gonorrhea, chlamydia, HPV screening

### Answers

1. B
2. D
3. B

## Board Practice

# 110

## Approach to the Internal Medicine Board Examination

KENNETH B. CHRISTOPHER

The purpose of this chapter is to focus on the American Board of Internal Medicine (ABIM) examination, its purpose, and its likely test scenarios. Because the Maintenance of Certification (MOC) process is undergoing substantive changes, the initial certification testing has been extensively validated and is unlikely to change much in its character. Essentially, the ABIM wants to determine if you have the core knowledge in all the disciplines to be an “effective and efficient” physician. Many candidates, in their increasing anxiety over the subject matter, lose sight of these major objectives. To pass the examination, it is not necessary to regurgitate in photographic detail one of the standard textbooks of medicine or the latest medical knowledge self-assessment program review. However, you should know the core body of knowledge in all the major medical specialties. For example, you should know, in depth, the diagnosis, rapid assessment, and appropriate management of an acute coronary syndrome. All internal medicine programs that have Residency Review Committee approval have their residents spend time in a coronary care unit and have exposure to cardiologists. So, too, you should expect to be able to manage an acute respiratory decompensation, determine its etiology, and know how to manage the acute presentation and the intermediate strategies. It is not expected that you be the expert pulmonary specialist, but it is expected that you know when to call the specialist for the help that only he or she can provide. And you are expected to have done more than the basics before calling for further help; you need to successfully and appropriately manage the patient. Furthermore, an economy of testing as well as cost considerations is important. The effective internist/clinician is economically sensitive and efficient in spending the patient’s time and money. Furthermore, they are aware of pretest probabilities, false-positive rates, and other such considerations that inform the considered uncertainty surrounding the best patient management.

These principles should be obvious from your training and not a cause for enhanced study. Where the examination causes more anxiety is material from specialties that require

fewer patient hospitalizations. You may have had less exposure to some of these specialties, but you are required to know the common diseases that appear to the generalist and how to get the basic diagnosis and treatment plan. A concrete example is the “classic” presentation of rheumatoid arthritis. This is an illness with a prevalence of about 1 in 200 and is mostly managed in the outpatient setting. By presenting it to you, it allows the board to test both your diagnostic acumen and your outpatient management skills. More outpatient exposure (be it general or subspecialty based) is now emphasized in training programs, and with this increased emphasis approximately 75% of questions are outpatient oriented.

The ABIM suggests certain examination preparation strategies that are worth noting. The ABIM recommends that you work within a small study group, ensure that you stake out time to prepare, and develop a schedule to study. The ABIM also recommends practicing with questions using the board format, such as single best answer. Certain “red flags” hinting at the answer, such as forested area in the northeast (Lyme disease) or cola-colored urine (rhabdomyolysis), should be kept in mind as “red herrings” and will not be tested. Pay particular attention to your areas of weakness on your residency in-service examinations.

The ABIM has a core fund of knowledge they want to be sure you have mastered (Table 110.1). These questions are easily identifiable and sometimes change in format but not core content. They appear over and over to identify that you have mastered the core content. The core, or what the ABIM refers to as the “Blueprint,” is published on the ABIM website ([www.abim.org](http://www.abim.org)). Remember, the Board wants to test your core knowledge and validate that it is sufficient for you to be certified. But another mission of the test is to provide a discriminatory measure of who demonstrates more knowledge in a standardized environment.

Importantly, the concept of managing a patient involves not just the physician but also the entire health

**TABLE 110.1 2017 ABIM Certification Examination “Blueprint”**

Medical Content Category	Relative Percentage
Cardiovascular disease	14%
Endocrinology, diabetes, and metabolism	9%
Gastroenterology	9%
Infectious disease	9%
Pulmonary disease	9%
Rheumatology/orthopedics	9%
Hematology	6%
Nephrology/urology	6%
Medical oncology	6%
Neurology	4%
Psychiatry	4%
Dermatology	3%
Geriatric syndromes	3%
Obstetrics/gynecology	3%
Allergy/immunology	2%
Miscellaneous	2%
Ophthalmology	1%
Cross-Content Category	Relative Percentages
Critical care medicine	10%
Geriatric medicine	10%
Prevention	6%
Women’s health	6%
Clinical epidemiology	3%
Ethics	3%
Nutrition	3%
Palliative/end-of-life care	3%
Adolescent medicine	2%
Occupational medicine	2%
Patient safety	2%
Substance abuse	2%

care system. It is a mistake to see a case and rapidly go to the answer or diagnosis that seems self-evident. Pause to consider the ethics of the situation, the cost of the testing or therapy you are considering, and the health care systems involved. You will be expected to be respectful of the patient in your answers, have appropriate concern for their families, understand their social situation and home environment, and have an appropriate respect for

the other members of the health care team. You will be expected to understand the cultural context of your patient’s lifestyle. You will need to be attuned to tell-tale signs of abuse or neglect that the patient might not share with you. These aspects of appropriate care are absorbed in the training environment by appropriate mentoring, role modeling, and constructive feedback. In addition, examination of the candidate’s knowledge of medical systems will be tested. Although this will manifest itself mostly in the option to readily use expensive or unnecessary tests and therapies, cultural competency, sensitivity to literacy, and patient financial situation may be tested.

The format for the examination is as follows. The examination is held over 1 day with four modules. Each of the modules is of 2 hours duration and comprises up to 60 questions. Up to 100 minutes of break time between modules is allowed over the course of the day. The questions reflect primary content areas (77%) being the traditional medicine subspecialties and “non-core specialties” (23%) comprising questions in allergy/immunology, dermatology, gynecology, neurology, ophthalmology, and psychiatry. In addition, the Board tests “cross-content areas” (critical care, geriatrics, prevention, women’s health, clinical epidemiology, ethics, nutrition, palliative/end-of-life care, adolescent medicine, occupational medicine, patient safety, and/or substance abuse).

Each question is formatted with a clinical “stem” (patient) followed by “lead-in” (last sentence), question, and then choices. The ABIM is looking to test analytic skills not simple memorization. There are no so-called “trick” questions. The material will not be controversial and will likely be dated at 2 years or older. Because the questions are generally written by practicing internists they will reflect current widely accepted practice.

Some strategies for answering questions are worth considering. The most important is to answer all questions. It is better to not get stuck on one question but rather to go back and tackle the difficult question if there is time later. You should aim to take approximately 2 minutes per question. Although there are many different ways to answer questions, one popular strategy is to try to answer before looking at the choices and not change the answer unless you remember new information.

The discussion so far has addressed applicants taking the examination for the first time. But many taking Board Review Courses are doing MOC testing preparation. Substantial changes to MOC standards have occurred, and more changes are expected in the coming years. The ABIM website is very helpful in describing the current MOC standards as well as an overview of the examination.

A representative case follows that illustrates these points with a discussion at the end of the “best choice” for each of the questions.

## CASE STUDY

An 84-year-old Caucasian male presents to your emergency department (ED) complaining of shortness of breath.

He has a long history of rate-controlled atrial fibrillation and a 10-year-old mitral valve repair. He has been on warfarin therapy for 15 years with no difficulty in maintaining an international normalized ratio (INR) of 2.5 to 3. He has never had any bleeding complications.

His wife of 56 years died 8 months ago. You had seen him about a month after her death, and he was independent, eating and well groomed. He has two supportive children who live in the community. At the time you saw him he was normotensive, heart rate was 68 beats per minute, and his weight was 154 pounds (he is 65 inches tall). His lungs were clear. He had a long-standing 1/6 apical midsystolic murmur that radiated slightly to the axilla and was unchanged for years. There was no organomegaly and no edema. Jugular venous pulse was <4 cm of water.

In the ED, he was dyspneic at rest at 45 degrees, with a respiratory rate of 22 breaths per minute. He was afebrile. There was dullness at the right base one-third of the way up the hemithorax. There were moist rales halfway up on both lungs. There was an S3 gallop, and his murmur was now 3/6 at the apex. Jugular venous pressure (JVP) was 7 cm at 45 degrees. The liver was not distended and not pulsatile, but there was a suggestion of a fluid wave in the abdomen. There was 3+ edema of the legs.

He was taking his medications, namely verapamil 240 extended release, Lanoxin 0.25 mg, warfarin 4 mg, and lisinopril 5 mg all daily.

An electrocardiogram showed atrial fibrillation and no acute ST-T changes and no interval *q* waves or loss of *r* waves. A standing chest posterior-anterior and lateral x-ray showed a large pleural effusion on the right and cardiomegaly. There was prominent vascular redistribution to the upper and middle lobes. There were no Kerley B lines noted.

Laboratory results showed a hemoglobin (Hb) of 13.9 g/dL, hematocrit (Hct) of 40%, a white blood cell count of 7500/mm<sup>3</sup> with a normal distribution, sodium 132 mEq/L, potassium 4.5 mEq/L, chloride 104 mEq/L, carbon dioxide (CO<sub>2</sub>) 25 mEq/L, blood urea nitrogen (BUN) 46 mg/dL, and creatinine 1.6 mg/dL. AST and ALT were each twice normal. INR was 3.3.

He was admitted to the hospital.

## Questions

- What is the most likely diagnosis?
  - Congestive heart failure (CHF)
  - Chronic renal emboli with renal failure
  - Noncompliance
  - Salt overload
  - Endocarditis

He was managed with bed rest and intravenous (IV) furosemide, and his other medications were continued. His weight on admission was 175 lb (up from 153 lb when last seen). He started to diurese about 1.5 kg/d; however, his murmur remained unchanged, and his liver tests remained moderately elevated as did his INR.

- Which test do you want now?
  - CT urogram
  - Transthoracic echocardiogram

- Agitated saline microbubble echocardiogram
- Transesophageal echocardiogram
- Gastrointestinal (GI) consult with evaluation for liver biopsy
- MRI of the abdomen and pelvis, with special attention to the prostate

The echocardiogram shows a flail mitral valve with nearly complete mitral regurgitation. The left atrium is only moderately enlarged. No clots or vegetations are seen.

- The next step in your management should be:
  - Transesophageal echocardiogram to rule out vegetations
  - Peritoneal dialysis to rapidly remove fluid
  - Cardiothoracic surgery consultation
  - Six blood cultures

The patient was seen by cardiology and cardiothoracic surgery. Because his congestive failure was very significant, and because he had previous mitral valve surgery, it was felt he should undergo semiurgent mitral valve repair. He was taken to the operating room (OR), and the mitral valve was repaired without untoward difficulty. He remained in atrial fibrillation. He was given intraoperative and postoperative second-generation cephalosporin coverage.

After the surgery he had trouble eating. Speech and swallow studies showed recurrent aspiration. Although his congestive failure improved daily, he failed to thrive, and a week after the surgery a percutaneous endogastric (PEG) tube was placed. He was transferred to a local rehabilitation facility 3 days after PEG tube placement. Discharge medications were digoxin 0.25 mg a day, verapamil 120 mg extended-release daily, warfarin 3 mg a day, furosemide 40 mg twice daily, and K<sup>+</sup> supplementation.

You had contact with him by phone in the rehabilitation facility. His spirits were good, but he still was on PEG feedings. Because of some diarrhea he was placed on "an antibiotic." Touching base with him a week later revealed that he had developed worsening diarrhea and was now on oral vancomycin. You called the covering physician at the rehabilitation facility and found out that the patient had a positive *Clostridium difficile* toxin assay. At the time of your call the patient was passing 10 to 12 stools a day. One week later he was sent into the ED with abdominal pain and distention.

His CT from the ED is shown in [Fig. 110.1](#).

His white count was 35,000/μL with 90% polymorphonuclear (PMN) cells. His Hb/Hct were 10.9 g/dL/33.2%; electrolytes were sodium 129 mEq/L, potassium (K<sup>+</sup>) 3.1 mEq/L, chloride 109 mEq/L, and CO<sub>2</sub> 16 mEq/L.

His blood pressure was 90/60 mm Hg, heart rate was 110 beats per minute and irregularly irregular, and his abdomen was distended. His murmur was 1/6,

• Fig. 110.1 Abdominal flat plate.

and as on discharge he had no S3. Bowel sounds were a rare high-pitched tinkle. There was no succussion splash. Neurologically he was intact. He was very fatigued and exhausted.

4. At this point what is the best approach to management?
  - A. Admit to the hospital and start oral vancomycin.
  - B. Obtain a surgical consultation for consideration of total colectomy.
  - C. Stat transthoracic echocardiogram.
  - D. Administer 120 mg of IV furosemide.

The patient was urgently taken to the OR and underwent a total colectomy. In the OR, the team had trouble maintaining his blood pressure, and the patient received pressors and IV fluid resuscitation. He survived the surgery, and after 3 days in the intensive care unit, he was able to transfer to the floors.

#### Answer Key and Discussion to the Case

1. The best answer is A (Congestive heart failure [CHF]). The patient has CHF by the chest x-ray, and he has an S3 and elevated JVP. This answer is correct. The other choices can be eliminated as less accurate or more speculative. Yes, the creatinine is elevated, but why invoke renal emboli when there is no supporting evidence? Yes, he could have been noncompliant, but he had been stable (and presumably compliant) for years. This same argument can be made for acute sodium overload (i.e., why now?). Endocarditis could cause his CHF and increasing murmur, but there are no physical stigmata to support this, and he is afebrile. Choosing this as the answer will cause problems because you may choose many of the wrong answers in the questions to follow, and so it

is important to not be too cagey in your answers. You know he has CHF, and you know little else to support any of the other answers.

2. The best answer is B (Transthoracic echocardiogram). He does not require a transesophageal echocardiogram (TEE) (answer D) because that is expensive and uncomfortable and at this moment unnecessary. You want to see his mitral valve, because the murmur is unchanged despite the treatment. If the murmur had been loud initially because of acute CHF and dilation of the valve ring, you would think his murmur would be diminished as his congestion improved. The fact that it is unchanged is suggestive that the valve itself has changed and caused his acute decompensation.

A Bubble echocardiogram study is useful for patent ductus arteriosus and that is not a consideration. A CT urogram would look for renal obstruction or collecting system/prostatic obstruction and is there to see if you will “bite” and select it as his BUN and creatinine were elevated in the ED. A GI consult is there because of his elevated liver function tests, but certainly you would at least want further values for them before getting a consult. Lastly the MRI of the abdomen/pelvis is there for the ascites/renal function and, again, not a good choice with this amount of information and a good working diagnosis of CHF as the unifying principle.

3. The best answer is C (Cardiothoracic surgery consultation). You suspect there is something wrong with the valve. It was replaced 10 years ago, and now he has a louder murmur and CHF. Although he could have endocarditis as the cause, there is no fever, no physical stigmata of subacute bacterial endocarditis, and no persistent and severe decompensation as would be seen with acute bacterial endocarditis. So, although answers A (TEE) and D (six blood cultures) are plausible, they are not the best answer. And indeed, if you were thinking endocarditis, how would you decide A versus D as the one best answer? Choice B, peritoneal dialysis, does not make sense because the diuresis is proceeding nicely at 3.3 lb a day.
4. The best answer is B (obtain a surgical consultation for consideration of total colectomy). This is a complex question, and it is not just about the answer, which may appear to be very aggressive.

The Board is trying to encourage your continuing care of the patient, although he might be under the direct care of someone else (the physician at the rehabilitation facility or an ED doctor). You know the patient, in his totality, best. You made his initial diagnosis and helped shepherd him to surgery. You are aware of his postoperative difficulties and subsequent PEG and aspiration problems.

Furthermore, the Board expects you to be able to read the CT and recognize that there is implied pan colitis from *C. difficile* with severe (and ominous) distension of the entire colon.

You are also, once again with this patient, expected to know when to get help from another discipline, namely GI surgery. It is a common failing of internal medicine trainees to call their surgical colleagues in late rather than recognizing that the patient's problem is best solved surgically.

Answer A, oral vancomycin is used in refractory or recurrent *C. difficile* infection, but this patient is too sick for simply this treatment.

Answer C, a transthoracic echocardiogram, would also be plausible to see if the valve were somehow now problematic or if there were constriction postsurgery

causing low blood pressure, but with the constellation of symptoms and the low CO<sub>2</sub> (which implies a metabolic acidosis) this is not a good early choice at this juncture. Lastly there is no reason to give this hypotensive patient more furosemide because there is no sign of decompensated heart failure or fluid overload.

## Board Practice 1

SONJA R. SOLOMON

## Questions

1. A 48-year-old male with alcoholic cirrhosis presents to reestablish primary care. He has no history of ascites, encephalopathy, or variceal bleeding and does not take any medications. A routine upper endoscopy reveals large varices.

Which of the following treatments are indicated to reduce this patient's risk of variceal hemorrhage?

- A. Transjugular intrahepatic portosystemic shunt (TIPS)
  - B. Propranolol
  - C. Spironolactone
  - D. Octreotide
  - E. No current therapy is effective for primary prophylaxis of variceal hemorrhage.
2. A 35-year-old painter presented to his primary care physician with fatigue, myalgias, and a rash (Fig. 111.1) after a weekend on Cape Cod. His physician prescribed a 14-day course of doxycycline (100 mg twice daily). He returns 10 days later with worsening myalgias, fever, nausea, and vomiting. Routine laboratory values reveal a hematocrit of 34%. He also has an elevated lactate dehydrogenase (LDH) and total bilirubin.

What is the most likely diagnosis?

- A. Inadequately treated Lyme disease
  - B. Babesiosis
  - C. Malaria
  - D. Rocky Mountain spotted fever
  - E. Drug reaction to doxycycline
3. A 31-year-old nanny recently diagnosed with acute myelogenous leukemia is admitted to the hospital 12 days after her first cycle of high-dose cytarabine consolidation chemotherapy with febrile neutropenia. She is appropriately treated with intravenous ceftazidime. Seven days into her hospitalization all blood cultures have been negative, and the white blood cell (WBC) count is beginning to recover. She now develops a new fever to 101°F, cough, and pleuritic chest discomfort. Her serum galactomannan and beta-glucan are both elevated. The patient's chest CT is shown in Fig. 111.2. What is the likely diagnosis?
- A. Pulmonary histoplasmosis
  - B. Disseminated *Candida albicans* infection
  - C. Invasive aspergillosis
  - D. Cryptococcal infection
  - E. Pulmonary embolism with lung infarction

4. A 66-year-old female had her thyroid-stimulating hormone (TSH) checked after presenting with mild fatigue and tachycardia. The thyroid examination was normal. Her bone mineral density was checked 1 year ago, at which time the lowest T-score was  $-2.3$  at the femoral neck.

TSH 0.011 mIU/L (normal 0.5–5 mIU/L)

Free thyroxine ( $T_4$ ) 1.5 ng/L (normal 0.8–1.8 ng/L)

What is the optimal approach to this patient?

- A. Reassurance
  - B. Treat with levothyroxine
  - C. Treat with methimazole
  - D. Obtain a thyroid ultrasound
5. A 36-year-old male in generally excellent health presents to the emergency department (ED) with “palpitations” for 3 to 4 days in duration. He denies chest pain or dyspnea. He also complains of right hip pain and generalized fatigue for several weeks and recalls

• **Fig. 111.1** Image of the skin rash from the patient described in Question 2.

a vague rash on his right leg 1 month ago. Examination is notable for heart rate of 45 beats per minute and mildly limited range of movement in right hip. An electrocardiogram (EKG) is obtained, and a telemetry strip is shown in Fig. 111.3.

What is the next appropriate treatment step?

- A. Placement of permanent pacemaker
  - B. Placement of permanent pacemaker and implantable cardioverter defibrillator
  - C. Temporary pacemaker and initiation of intravenous corticosteroids
  - D. Temporary pacemaker and initiation of intravenous ceftriaxone
  - E. Aspirin plus heparin bolus and drip
6. A 59-year-old man with a medical history that includes a prior deep vein thrombosis and chronic kidney disease requiring hemodialysis is admitted to the hospital for elective knee replacement. His warfarin had been stopped a few days prior, and he is started on intravenous unfractionated heparin on admission. On his sixth hospital day, his platelet count falls to 75,000/ $\mu\text{L}$  from 195,000/ $\mu\text{L}$  the day prior. In addition to discontinuing the intravenous heparin, you should do which of the following?
- A. Await the results of an antiplatelet factor-4 assay before restarting anticoagulation.
  - B. Transfuse platelets to prevent postoperative bleeding.
  - C. Start subcutaneous enoxaparin immediately.
  - D. Start subcutaneous fondaparinux immediately.
  - E. Start intravenous argatroban immediately.

• **Fig. 111.2** CT scan of the chest from the patient described in Question 3.

• **Fig. 111.3** Electrocardiograph strip from the patient described in Question 5.

7. A 78-year-old female with diabetes is admitted to the hospital with signs, symptoms, and urinalysis consistent with a urinary tract infection. On initial evaluation in the ED, her blood pressure is 70/30 mm Hg but improves briskly with intravenous fluids, and the patient is admitted to the medical floor. Her complete blood count (CBC) revealed a mild leukocytosis but is otherwise normal. Shortly after admission, she begins experiencing lower abdominal cramping and passes several stools with evidence of dark blood. Which of the following is the most likely explanation for her gastrointestinal bleeding?
- A. Hemolytic uremic syndrome
  - B. Acute mesenteric ischemia
  - C. Chronic mesenteric ischemia
  - D. Ischemic colitis
  - E. Bacterial colitis
8. A 34-year-old woman presents to establish primary care. Her past Pap smear was 3 years ago and showed normal cytology and negative testing for human papilloma virus (HPV). She had two abnormal Pap smears in the past, at age 21 and 22 (both with atypical squamous cells of undetermined significance). She has had regular Pap smears since that time with normal cytology. Which of the following would represent an acceptable approach to screening for cervical cancer in this patient?
- A. Repeat cytology now.
  - B. Repeat HPV testing now.
  - C. Repeat cytology and HPV cotesting now.
  - D. Repeat cytology and HPV cotesting in 2 years.
  - E. A or D
9. A 68-year-old man with a history of cardiovascular disease presents to his primary care physician asking about the need for antibiotics before he goes to the dentist to get his teeth cleaned. His medical history includes hypertension, mitral valve prolapse (MVP) with mild regurgitation, a pacemaker placed 8 months ago, a total hip replacement 18 months ago, and two coronary artery stents placed 4 months ago. Which of the following should his physician recommend?
- A. Antibiotic prophylaxis because of his MVP with regurgitation
  - B. Antibiotic prophylaxis because of his recent pacemaker implantation
  - C. Antibiotic prophylaxis because of his recent joint replacement
  - D. Prophylactic antibiotics are not required.

10. A healthy 25-year-old graduate student presents to the student health clinic complaining of a sore throat, cough, and fever for the past 3 days. On examination, her throat is erythematous and without exudates. She has no neck tenderness or palpable lymphadenopathy. Which of the following is the most appropriate plan for this patient?
- Reassurance; she is unlikely to have streptococcal pharyngitis.
  - Perform a rapid strep test and prescribe antibiotics if positive.
  - Prescribe a course of antibiotics to take if she is no better in 3 days.
  - Prescribe a course of antibiotics to begin taking now.
  - Obtain a throat culture, prescribe antibiotics, and have her stop antibiotics if it is negative.
11. Over the next 5 days, her throat pain worsens. She continues to have high fever with chills and now notes painful left-sided neck swelling. Representative images from studies of her neck and chest are shown in Figs. 111.4–111.6. Which of the following would not be an appropriate antibiotic choice in this case?
- Ceftriaxone plus metronidazole
  - Piperacillin/tazobactam
  - Imipenem
  - Vancomycin
12. A 28-year-old nonsmoking graduate student presents with 1 week of wheezing, cough, and yellow sputum. He has had several prior episodes of “bronchitis” in the last 2 years. Examination is notable for oxygen saturation 90% on room air and scattered wheezing and rhonchi. Laboratory values are notable for leukocytosis and eosinophilia: WBC  $14.4 \times 10^3/\mu\text{L}$  (53 neutrophils, 20 lymphocytes, 15 eosinophils). Prior pulmonary

• Fig. 111.4 Neck image from the patient described in Question 11.

function tests have shown a mild obstructive pattern. Small, scattered opacities are seen on chest x-ray (CXR), and the chest CT shown in Figs. 111.7 and 111.8 is obtained. What is the next appropriate step?

- Bronchoscopy
  - Skin prick test for reactivity to *Aspergillus fumigatus*
  - Strongyloides* serology
  - Induced sputum  $\times 3$  samples
  - Prednisone taper
13. A 30-year-old man presents to his primary care physician with a new rash on his back and trunk (Fig. 111.9). The lesions are red and raised. He says it is itchy but not painful. He has never had a rash like this before. He has used no new lotions, soaps, or medications. He does comment that he has a similar rash in one spot on his back a few weeks before the current eruption.

• Fig. 111.5 CT scan of the neck from the patient described in Question 11.

• Fig. 111.6 CT scan of the chest from the patient described in Question 11.

• **Fig. 111.7** CT scan of the chest from the patient described in Question 12.

• **Fig. 111.8** CT scan of the chest from the patient described in Question 12.

What is the most likely outcome for this rash?

- A. It will spontaneously resolve in 6 to 10 weeks.
  - B. It will resolve with steroids and recur with episodes of stress.
  - C. It will resolve with calcipotriene ointment.
  - D. It will resolve with benzoyl peroxide.
  - E. It will require treatment with psoralens plus ultraviolet A (PUVA) and possible chemotherapy.
14. A 57-year-old woman with no history of cardiac disease develops substernal chest pressure during her routine hemodialysis session. The episode lasts about 5 minutes and resolves spontaneously before she arrives in the ED. Her vital signs are normal, and her cardiac biomarkers are not elevated. Her EKG is shown in Fig. 111.10.

Which of the following treatment plans is most appropriate for this patient?

- A. Urgent cardiac catheterization
- B. Heparin, clopidogrel, aspirin, and cardiac catheterization if cardiac biomarkers become elevated

• **Fig. 111.9** Skin image from the patient described in Question 13.

- C. Imaging stress test before considering catheterization
  - D. Admission for observation and telemetry monitoring
  - E. Correction of electrolyte abnormalities and reassurance
15. A 46-year-old lawyer presents to the ED with bright red emesis. He had been drinking heavily for several days and started vomiting food and bile last night. He was retching all night and, in the morning, threw up frank blood. Examination reveals a heart rate of 110 beats per minute, rising to 135 beats per minute when standing up, blood pressure of 104/76 mm Hg, falling to 80/56 mm Hg with standing. He has clear lungs and a nontender abdomen.
- What is the first step in caring for this patient?
- A. Start an intravenous proton pump inhibitor (PPI).
  - B. Give fresh frozen plasma because he likely has liver disease.
  - C. Resuscitate the patient with intravenous fluids.
  - D. Perform esophagogastroduodenoscopy.
  - E. Perform gastric lavage with a nasogastric tube.
16. Given the previous patient's history, what is the most likely diagnosis?
- A. Dieulafoy lesion
  - B. Peptic ulcer disease
  - C. Erosive esophagitis
  - D. Mallory-Weiss tear
  - E. Variceal bleed
17. A 67-year-old woman presents with 2 weeks of progressive fatigue, dyspnea, and easy bruising. She now notes dyspnea at rest, a severe headache, and blurry vision. She is afebrile with a heart rate of 113 beats per minute, normal blood pressure, and an oxygen saturation of 89% on room air. On examination, she has scattered

• **Fig. 111.10** Electrocardiogram from the patient described in [Question 14](#).

ecchymoses, retinal hemorrhages, and bibasilar rales.

Blood studies ([Fig. 111.11](#)) show:

- WBC 113,800/ $\mu$ L
- Hematocrit 24.1%
- Platelets 27,000/ $\mu$ L

Which of the following treatments is it most important to start as soon as possible?

- A. Intravenous normal saline bolus
- B. Hydroxyurea
- C. Red blood cell transfusion
- D. Leukapheresis
- E. Rasburicase

18. A 46-year-old Asian-American male presents with diabetes mellitus. He reports sugars in the 300 mg/dL range, and his hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) returns at 6.8%. You explain that these laboratory values could be secondary to all of the following except:

- A. Glucometer malfunction
- B. Laboratory error
- C. Hemolytic anemia
- D. Polycythemia vera
- E.  $\beta$ -thalassemia

19. A 79-year-old male arrives at the ED complaining of right-sided facial droop and right arm weakness. His symptoms started about 3 to 4 hours ago during breakfast. Physical examination confirms findings consistent with a left-sided middle cerebral artery stroke. Head CT shows no evidence of intracranial bleed. Which of the following treatments is indicated for initial therapy of this event?

- A. Intravenous tissue-plasminogen activator (tPA)
- B. Intravenous heparin
- C. Enoxaparin (low-molecular-weight heparin)
- D. Aspirin
- E. None of the above

• **Fig. 111.11** Peripheral blood smear from the patient described in [Question 17](#).

20. A 22-year-old pharmacy student with a history of eczema and a nut allergy presents with a painful, burning rash on her right thigh. Her symptoms began the prior evening after a day at the beach. This morning, the rash and pain are much worse. She also notes some pain on her hands, neck, and distal thigh ([Fig. 111.12](#)).

Which activity most likely led to the development of her symptoms?

- A. Walking through brush in her swimsuit
- B. Swimming in the ocean
- C. Applying sunscreen containing zinc oxide
- D. Squeezing limes while making mojitos
- E. Taking tetracycline for facial acne

• **Fig. 111.12** Multiple images of the rash from the patient described in Question 20. Panels B–D are shown in false color to highlight the rash.

21. A 57-year-old editor is admitted with dyspnea and marked hypoxemia. He undergoes a CT scan of the chest, which is shown in Fig. 111.13. He subsequently undergoes bronchoscopy, which reveals progressively bloodier return with alveolar lavage. These findings are consistent with diffuse alveolar hemorrhage (DAH). Which one of the following laboratory tests would be least likely to help determine an etiology of this man's disease?
- Antineutrophil cytoplasmic antibody (ANCA)
  - Antiglomerular basement membrane antibody (anti-GBM)
  - Angiotensin-conversion enzyme (ACE)
  - Antinuclear antibodies (ANA)
  - Toxicology screen
22. A 35-year-old store manager presents with arthralgias and the rash seen in Fig. 111.14. Her primary care physician ordered a chest radiograph, which is shown in Fig. 111.15. This constellation of symptoms is called:
- Löfgren syndrome
  - Hamman-Rich syndrome
  - Lemierre syndrome
  - Scimitar syndrome
  - Castleman disease
23. A 50-year-old African-American woman presents to establish primary care. She feels well. She is found on routine blood work to have a hematocrit of 34% (mean corpuscular volume 68 fL). Iron studies reveal serum iron 40  $\mu\text{g}/\text{dL}$  (normal 37–158), total iron-binding capacity 390  $\mu\text{g}/\text{dL}$  (normal 220–460), and ferritin 34  $\mu\text{g}/\text{L}$  (normal 10–170). Hb electrophoresis is normal. Which of the following is the most likely diagnosis?
- Iron deficiency anemia
  - Anemia of chronic inflammation
  - Alpha-thalassemia minor
  - Beta-thalassemia major
  - Hb H disease
24. After cardiac catheterization, a 72-year-old man develops prolonged bleeding at the arterial puncture site. Intravenous heparin is discontinued. Twenty-four hours later, he has a large groin hematoma, and his puncture site continues to ooze despite compression. He has no history of abnormal bleeding. His basic metabolic panel is normal. Other laboratory results show:
- Hematocrit 27% (was 38% on admission)  
 Platelets 210,000/ $\mu\text{L}$   
 International normalized ratio (INR) 1.2, partial thromboplastin time (PTT) 85 seconds

• **Fig. 111.13** CT scan of the chest from the patient described in Question 21.

• **Fig. 111.14** Skin image from the patient described in Question 22.

Which of the following will help determine the cause of bleeding in this patient?

- A. A trial of vitamin K administration
  - B. Measurement of von Willebrand factor activity
  - C. Platelet function assay
  - D. A 1:1 mixing study
  - E. Test for a lupus anticoagulant
25. A 46-year-old business executive comes to your office worried about hemochromatosis. His wife's brother was recently diagnosed with cirrhosis caused by this disease, and he is worried because he heard it is very common. He is of Swedish origin, completely asymptomatic, and has no history of liver disease in his family. His physical examination

• **Fig. 111.15** Chest radiograph from the patient described in Question 22.

reveals no abnormalities. What is the most useful test to screen him?

- A. *HFE* genotyping
  - B. Serum transferrin saturation
  - C. Hb/hematocrit
  - D. Serum alanine and aspartate aminotransferases
  - E. Liver biopsy with quantitative iron index
26. A 21-year-old female, who is sexually active and has a history of an abnormal Pap test, presents for a physical before moving to college. She reports three male sexual partners in the last year. Past medical history is otherwise unremarkable. Her last immunizations were at age 10. She states that she had all routine childhood immunizations. She had chickenpox as a child.
- Which of the following immunizations would be appropriate?
- A. Meningococcal, tetanus, diphtheria and pertussis (Tdap), HPV
  - B. Meningococcal, hepatitis B (Hep B), Tdap, HPV
  - C. Hep B, Tdap, HPV
  - D. Meningococcal, Hep B, Tdap, HPV, Pneumovax
  - E. Meningococcal, Hep B, Tdap
27. A 20-year-old male with no past medical history presents with left subscapular pain after bumping into someone earlier that day. He has had a cold over the last 2 weeks with a nonproductive cough. He takes no medications. On physical examination, he is in no acute distress. Heart rate is 122 beats per minute, blood pressure is 110/76 mm Hg, respiratory rate is 22 breaths per minute, and oxygen saturation is 91% on room air. There are decreased breath sounds over the left hemithorax (CXR in Fig. 111.16).

• **Fig. 111.16** Chest radiograph from the patient described in Question 27.

What is the most appropriate next step?

- A. Nebulizer treatment with albuterol and ipratropium
  - B. Azithromycin orally for 5 days
  - C. Nasal oxygen and close observation overnight
  - D. Chest tube placement
  - E. Pulmonary function tests with single-breath diffusing capacity of the lung
28. A 54-year-old businesswoman presents with profound fatigue. CBC reveals hematocrit of 30% and platelets of 42,000/ $\mu$ L. Her creatinine is 2.6 mg/dL, and her LDH is 1080 U/L. Coagulation profile is normal. Her blood smear is shown in Fig. 111.17.
- What would be the most appropriate therapy for this patient?
- A. Plasmapheresis
  - B. Prednisone
  - C. Rituximab (rituxan)
  - D. Intravenous immunoglobulin
  - E. Cyclophosphamide
29. A 56-year-old farmer presents with right upper quadrant tenderness. He has no history of liver disease or gallstones and is originally from Greece. His physical examination reveals no fever or jaundice but mild right upper quadrant tenderness. A CT scan is obtained (Fig. 111.18).
- What is the most reasonable treatment approach?
- A. Watchful waiting
  - B. Endoscopic retrograde cholangiopancreatography
  - C. Empirical treatment with ciprofloxacin and metronidazole
  - D. Albendazole treatment followed by surgical resection
  - E. Immediate percutaneous drainage

• **Fig. 111.17** Peripheral blood smear from the patient described in Question 28.

• **Fig. 111.18** CT scan of the abdomen from the patient described in Question 29.

30. A healthy 58-year-old high school teacher presents to urgent care complaining of feeling “fuzzy” in class and having a hard time grading tests over the weekend. She has been constipated for several days. She takes only Tums (Tums is an antacid made of sucrose and calcium carbonate [ $\text{CaCO}_3$ ]) and an occasional aspirin.
- Laboratory values reveal a calcium level of 14.2 mg/dL, phosphorus 2.5 mg/dL, creatinine 2.6 mg/dL, and bicarbonate 34 mEq/L. Her parathyroid hormone (PTH) level is low, and she has an undetectable PTH-rP.
- Imaging studies show no abnormalities.
- All of the following would be appropriate therapy in the acute setting except:
- A. Hydration with normal saline
  - B. Intravenous zoledronic acid
  - C. Discontinuation of  $\text{CaCO}_3$
  - D. Use of a loop diuretic after volume repletion
  - E. Calcitonin, 4 U/kg intramuscularly every 12 hours

## Answers

1. B. Nonselective beta-blockers such as propranolol and nadolol are recommended for primary prophylaxis of variceal bleeding in patients with varices that are medium or large in size or have red wale markings on endoscopy. There is also evidence to support endoscopic ligation/banding of varices to prevent hemorrhage. TIPS is indicated for management of “active” variceal bleeding (when endoscopic and pharmacologic treatment has failed) but is not appropriate for primarily prophylaxis of bleeding. Octreotide or somatostatin is indicated for management of active variceal bleeding but not primary prophylaxis. Spironolactone is effective for management of ascites but plays no role in prophylaxis of variceal bleeding. (Garcia-Tsao G, Sanyal AJ, Grace ND, et al. Prevention and management of gastroesophageal varices and variceal hemorrhage in cirrhosis. *Hepatology*. 2007;46(3):922–938.)
2. B. The initial presentation was consistent with early localized Lyme disease. The rash is erythema migrans. Treatment with doxycycline, 100 mg twice daily, is the appropriate therapy. An acceptable alternative would be a 10-day to 14-day course of amoxicillin. This clinical picture is characteristic of infection with *Babesia microti*, whose vector is also the *Ixodes* tick, and therefore patients can be coinfecting with the same exposure. Patients typically present with nonspecific complaints of nausea/vomiting, malaise, and fever as well as evidence of hemolytic anemia. Immunosuppressed hosts are more likely to have symptomatic *Babesia* infection, particularly asplenic patients or those with HIV.
3. C. *Aspergillus* can cause a broad spectrum of disease. Invasive aspergillosis affects the lung and occurs in severely immunocompromised patients. Beta-glucan is a cell-wall component of most or all fungi. The beta-glucan assay detects the presence of invasive fungal infections. Galactomannan is a cell-wall component of *Aspergillus*. The assay detects the presence of invasive aspergillosis. A chest CT “halo sign” is highly suggestive of angioinvasive fungus (*Aspergillus*). Voriconazole is the treatment of choice for invasive aspergillosis. (Segal BH. Aspergillosis. *N Engl J Med*. 2009;360:1870–1884.)
4. C. This patient has subclinical hyperthyroidism, which itself carries a risk of cardiovascular complications including atrial fibrillation and decreased bone mineral density. Given her age and history of osteopenia, treatment is favored over monitoring. (Ross DS, Burch HB, Cooper DS, et al. 2016 American Thyroid Association Guidelines for Diagnosis and Management of Hyperthyroidism and Other Causes of Thyrotoxicosis. *Thyroid*. 2016;26:1343.)
5. D. This patient has Lyme carditis with third-degree atrioventricular (AV) block. The Infectious Diseases Society of America (IDSA) recommended therapy is intravenous ceftriaxone for 14 to 21 days. AV block is a classic manifestation of “early disseminated” Lyme disease (typically occurring weeks to months after initial infection). Among Lyme disease cases, 1% to 10% develop Lyme carditis (possibly higher in Europe). In most cases of Lyme carditis, AV block resolves “spontaneously,” and permanent ventricular pacing is unnecessary. IDSA recommendations for intravenous antibiotics are based on expert consensus and are the general treatment strategy for early disseminated Lyme disease.
6. E. This patient has a clinical scenario highly concerning for heparin-induced thrombocytopenia (HIT). There is a 50% reduction in platelet count while exposed to heparin; it appears 5 to 10 days after exposure to heparin, although it can be <24 hours if heparin was given within the past 100 days. HIT is associated with an approximately 50% risk of thrombosis. All patients with intermediate or high suspicion for HIT should receive alternative anticoagulation immediately. Although the risk is lower, Lovenox can cause HIT and should never be used in patients with suspected or known HIT. Argatroban and lepirudin are approved for treatment of HIT. Fondaparinux has been studied for use in HIT but is renally excreted and not recommended for dialysis patients. (Arepally GM, Ortel TL. Clinical practice. Heparin-induced thrombocytopenia. *N Engl J Med*. 2006;355:809–817; Warkentin TE, Roberts RS, Hirsh J, et al. Heparin-induced skin lesions and other unusual sequelae of the heparin-induced thrombocytopenia syndrome: a nested cohort study. *Chest*. 2005;127[2 suppl]:35S–45S.)
7. D. Ischemic colitis (IC) is the most common form of bowel ischemia. The pathophysiology of IC is typically a nonocclusive ischemia (low-flow state). The vast majority of IC cases occur in the elderly. Typical symptoms include abdominal cramping and rectal bleeding. Treatment is typically supportive. The two other categories of mesenteric ischemia are:
  - Acute mesenteric ischemia is most commonly an embolic event to the superior mesenteric artery, causing acute, severe abdominal pain. Treatment is primarily surgical.
  - Chronic mesenteric ischemia is caused by diffuse atherosclerotic disease in 95% of cases. Typical symptoms include postprandial abdominal pain and weight loss.
8. E. Acceptable cervical cancer screening strategies for women age 30 to 65 years include cytology every 3 years or cytology with HPV cotesting every 5 years. This patient had two prior abnormal Pap smears, but these resolved spontaneously with subsequently normal cytology on all Paps. Therefore she is now at average risk of cervical cancer and can be screened using either of the routine strategies described earlier. Screening by HPV testing alone has been shown to be an effective screening strategy in some studies but is not currently recommended in most clinical settings.

9. D. In 2007 the American Heart Association revised its recommendations for antibiotic prophylaxis to include only cardiac conditions associated with the highest risk of adverse outcomes from endocarditis. These include prosthetic cardiac valves, prior endocarditis, unrepaired cyanotic heart disease, and repaired heart disease with prosthetic material within 6 months or with residual graft defects. MVP with or without regurgitation is no longer an indication for prophylaxis. Neither are pacemakers, automatic implantable cardioverter defibrillators, or coronary stents. The American Academy of Orthopaedic Surgeons advises against the use of antibiotic prophylaxis for routine dental work in patients with prosthetic joints.
10. A. Based on her presentation, this patient is unlikely to have group A streptococcal pharyngitis. She has only one of the four Centor criteria. (Centor RM, Witherspoon JM, Dalton HP, et al. The diagnosis of strep throat in adults in the emergency department. *Med Decis Making*. 1981;1(3):239–246.)
- Fever
  - Absence of cough
  - Tonsillar exudates
  - Tender anterior cervical lymphadenopathy
- The American College of Physicians, the Centers for Disease Control and Prevention, and IDSA guidelines recommend against strep testing for patients who meet no or one criterion. For patients who meet three or four criteria, the guidelines disagree about whether to treat empirically, based on a rapid strep test result, or based on culture results. (Bisno AL. Diagnosing strep throat in the adult patient: do clinical criteria really suffice? *Ann Intern Med*. 2003;139:150–151; Linder JA, Chan JC, Bates DW. Evaluation and treatment of pharyngitis in primary care practice. *Arch Intern Med*. 2006;166:1374–1379)
11. D. This patient has Lemierre syndrome, septic thrombophlebitis of the internal jugular vein, most often caused by the anaerobic gram-negative rod *Fusobacterium necrophorum* causing bacteremia and septic thromboemboli to the lungs. Appropriate antibiotic therapy includes beta-lactamase-resistant beta-lactams, carbapenems, clindamycin, or a beta-lactam combined with metronidazole. Vancomycin lacks anaerobic coverage and would not be appropriate as monotherapy. Antibiotics should be continued for 3 to 6 weeks. (Kuppalli K, Livorsi D, Talati NJ, et al. Lemierre's syndrome due to *Fusobacterium necrophorum*. *Lancet Infect Dis*. 2012;12(10):808–815.)
12. B. Allergic bronchopulmonary aspergillosis should be suspected if any one of the following is present:
1. CXR/CT with central bronchiectasis or recurrent infiltrates
  2. Refractory asthma symptoms
  3. Positive skin prick for *Aspergillus*
  4. Positive sputum cultures for *Aspergillus*
  5. Prominent peripheral eosinophilia
- Appropriate testing includes skin prick reactivity to *Aspergillus*, IgE level, and specific antibodies (IgE and IgA) to *Aspergillus*. Typical treatment includes glucocorticoids and/or itraconazole.
13. A. This is a picture of pityriasis rosea. The patient describes it beginning with a herald patch, a single lesion that precedes the generalized eruption by 1 to 2 weeks. It is a self-limited disease that usually resolves in 6 weeks without treatment and does not recur. (Stulberg DL, Wolfrey J. Pityriasis rosea. *Am Fam Physician*. 2004;69:87–91.)
- Other rashes in the differential diagnosis of this rash include the following:
- Psoriasis, which can be treated with topical steroids or topical vitamin D analogues
  - Tinea corporis, which resolves with antifungals
  - Mycosis fungoides (cutaneous T-cell lymphoma), which can be treated with PUVA and chemotherapy if there is systemic involvement
14. A. These are the typical EKG changes of Wellens syndrome:
- New precordial T-wave inversions (V2–V5 or V6) (Fig. 111.19)
  - T-wave inversions are usually symmetric or biphasic
  - EKG changes often more evident when chest-pain free
  - Associated with critical proximal left descending coronary artery lesion
  - Cardiac biomarkers are often normal or mildly elevated
  - If treated medically, 75% will develop an anterior myocardial infarction
  - Early cardiac catheterization is recommended and is typically followed by percutaneous revascularization or coronary artery bypass surgery (Rhinehardt

• Fig. 111.19 Electrocardiograph strip with precordial T-wave inversions described in the answer to Question 14.

- J, Brady WJ, Perron AD, et al. Electrocardiographic manifestations of Wellens syndrome. *Am J Emerg Med.* 2002;20:638–643; de Zwaan C, Bär FW, Wellens HJ. Characteristic electrocardiographic pattern indicating a critical stenosis high in left anterior descending coronary artery in patients admitted because of impending myocardial infarction. *Am Heart J.* 1982;103:730–736.)
15. C. The patient is in hypovolemic shock and needs immediate resuscitation with intravenous fluids. PPI therapy has an important role in bleeding related to peptic ulcer disease but should not be prioritized over resuscitation. Nasogastric lavage will not change the decision for acute endoscopic evaluation. Urgent endoscopy should be performed once the patient has been initially stabilized. (Huang CS, Lichtenstein DR. Nonvariceal upper gastrointestinal bleeding. *Gastroenterol Clin North Am.* 2003;32:1053.)
  16. D. Mallory-Weiss tears are linear mucosal tears in the gastric mucosa near the gastroesophageal junction. They are the cause of upper gastrointestinal bleeding in 5% to 10% of patients. They were initially described in 1929 in alcoholic patients. Alcoholic gastritis is also easily compatible with the history and presentation.  
The other conditions are also common causes of upper gastrointestinal bleeding but lack the distinctive clinical history of “hematemesis after initial nonbloody emesis.” (Dallal HJ, Palmer KR. Upper gastrointestinal hemorrhage. *BMJ.* 2001;323:1115.)
  17. A. This patient has an acute leukemia with signs and symptoms of leukostasis. The most important early therapy is hydration.  
Leukostasis is caused by poorly deformable leukemic WBC impeding circulation through small blood vessels. It is typically seen in myeloid leukemias with WBC  $>50 \times 10^3/\mu\text{L}$ . Clinical manifestations depend on the target organs affected and include dyspnea, hypoxia, headaches, visual changes, seizures, renal failure, and bleeding. Early administration of red blood cells (RBCs) increases blood viscosity and can further compromise local blood flow. Definitive treatment is to reduce cell counts with hydroxyurea, leukapheresis, or early induction chemotherapy. (Majhail NS, Lichtin AE. Acute leukemia with a very high leukocyte count: confronting a medical emergency. *Cleve Clin J Med.* 2004;71:633–637.)
  18. D. HbA<sub>1c</sub> measures glycosylated sugar on RBCs. If RBC life span is short, then HbA<sub>1c</sub> can falsely decrease. Hemoglobinopathies and hemolytic anemia typically decrease RBC life span. Hemoglobin variants can have a different mobility and may not be picked up by an HbA<sub>1c</sub> laboratory machine. A high RBC count would falsely elevate HbA<sub>1c</sub>.  
A1C can now be used as screening test, with diabetes mellitus defined as HbA<sub>1c</sub>  $\geq 6.5\%$ . (Gillett MJ. International Expert Committee Report on the role of the A1C assay in the diagnosis of diabetes. *Diabetes Care.* 2009;32:1327.)
  19. A. tPA (alteplase) is the only therapy currently US Food and Drug Administration approved for acute ischemic stroke. The benefit of tPA for treatment “beyond” the traditional 3-hour time window was established by two large trials (including ECASS [European Cooperative Acute Stroke Study] 3), which showed that treatment in the 3- to 4.5-hour time window can also yield modest benefits. Aspirin therapy may be appropriate to prevent early recurrence of ischemic stroke, but thrombolysis with tPA is a contraindication to immediate initiation of aspirin. Heparin is not currently recommended for patients with acute ischemic stroke, although it may be considered in limited, specific circumstances (known intracardiac thrombus, carotid thrombus). (Hacke W, Kaste M, Bluhmki E, et al. Thrombolysis with alteplase 3 to 4.5 hours after acute ischemic stroke. *N Engl J Med.* 2008;359:1317–1329.)
  20. D. This is a phytophotodermatitis, a cutaneous phototoxic eruption that results from contact with light-sensitizing substances and exposure to UVA radiation, often in bizarre, well-demarcated patterns (e.g., handprints).  
Symptoms begin 24 hours after exposure and peak at 48 to 72 hours but may take weeks to fully resolve. Effects range from hyperpigmentation to bullous eruptions. The most frequent causes include 5-methoxypsoralen in lime-peel juice (mangos, celery), furocoumarins in brushes (roses) and grasses, and bergamot oils in perfumes with essential oils (<http://emedicine.medscape.com/article/1119566-overview>).
  21. C. DAH has been associated with many diseases including:
    - Granulomatosis with polyangiitis, formerly known as Wegener granulomatosis, and microscopic polyangiitis (ANCA)
    - Goodpasture syndrome (anti-GBM)
    - Systemic lupus erythematosus (ANA) as well as rheumatoid arthritis, scleroderma, and mixed connective tissue disease
    - Cocaine inhalation (toxicology screen)
 DAH has also been associated with medications such as propylthiouracil, phenytoin, and retinoic acid. ACE is a test sometimes ordered when considering sarcoid, but there are no data to support its use in the diagnosis. The test has neither a good sensitivity nor a good specificity. Sarcoid is not a disease commonly associated with DAH. (Specks U. Diffuse alveolar hemorrhage syndrome. *Curr Opin Rheum.* 2001;13:12–17.)
  22. A. The rash on the legs is erythema nodosum. It is classically a painful, erythematous nodular eruption on the anterior legs. The constellation of hilar

lymphadenopathy (seen on CXR), arthralgias, and erythema nodosum is Löfgren syndrome.

The other syndromes are:

- Hamman-Rich: rapidly progressive, bilateral interstitial pneumonitis without a clear etiology
- Lemierre: thrombophlebitis of the internal jugular resulting from bacteremia associated with a head or neck infection
- Scimitar: constellation of anomalous venous drainage of the right lung into the inferior vena cava, hypoplasia of right lung and right pulmonary artery, as well as dextroposition of the heart
- Castleman: large, bulky, nonmalignant lymphadenopathy (Barnard J, Newman LS. Sarcoidosis: immunology, rheumatic involvement, and therapeutics. *Curr Opin Rheumatol*. 2001;13:84.)

23. C. This patient has a microcytic anemia with normal iron studies and normal Hb electrophoresis. The most likely diagnosis is alpha-thalassemia minor. Normal individuals have four functional genes encoding the alpha globulin. Alpha-thalassemia minor results from loss of function of two of the four genes ( $\alpha\alpha/--$  or  $\alpha/-\alpha$ ) and leads to a microcytic anemia, frequently with target cells on peripheral blood smear, and normal Hb electrophoresis. It is usually asymptomatic. Beta-thalassemia major causes clinically apparent disease early in life, including transfusion-dependent anemia, as well as skeletal changes, hepatomegaly, splenomegaly, and other complications. Hb H disease results from the deletion of three genes encoding the alpha globulin ( $\alpha/--$ ). Hb H is seen on electrophoresis, and patients have a more pronounced anemia and splenomegaly. (Piel FB, Weatherall DJ. The  $\alpha$ -thalassemias. *N Engl J Med*. 2014;371:1908–1916.)

24. D. This patient has a coagulopathy that preferentially affects the activated partial thromboplastin time (aPTT). A 1:1 mixing study will indicate if this patient has a factor deficiency or a coagulation inhibitor responsible for his abnormal bleeding.

Vitamin K deficiency preferentially affects the prothrombin time/INR. This patient's INR is nearly normal. Treatment with vitamin K is unlikely to correct his bleeding tendency.

Von Willebrand disease (vWD) causes postprocedural bleeding and can be acquired. The most common forms of vWD are hereditary, result in primarily mucosal bleeding, and rarely prolong the aPTT significantly.

Postcardiac catheterization patients are often on multiple antiplatelet agents, making platelet studies abnormal. Despite profound platelet inhibition, these patients rarely have severe catheter site bleeding or a prolonged aPTT once heparin has been discontinued.

A lupus anticoagulant will prolong the aPTT but is not associated with a tendency to bleed.

25. B. Hereditary hemochromatosis is one of the most common autosomal recessive diseases. Serum transferrin saturation is the most sensitive marker for the body's iron stores; a value of >45% should be followed up with ferritin and *HFE* determination. Serum ferritin levels are more helpful when one is assessing the severity of potential liver damage caused by hemochromatosis. Patients with serum ferritin levels <1000 ng/mL are extremely unlikely to have cirrhosis.

*HFE*, the gene for hemochromatosis, was cloned in 1996, but population-wide testing has not been recommended. The patient's wife should be genotyped for *HFE* mutations. (Khoury MJ, McCabe LL, McCabe ERB. Population screening in the age of genomic medicine. *N Engl J Med*. 2003;348:50; Beutler E, Hoffbrand AV, Cook JD. Iron deficiency and overload. *Hematology Am Soc Hematol Educ Program*. 2003;40.)

26. B. Meningococcal vaccine is recommended if there is a lifestyle risk such as a college freshman living in dorm, army recruits, or travelers to Mecca during Hajj or to sub-Saharan Africa. Asplenic patients or those with persistent complement deficiency should get a booster meningococcal vaccine again 5 years later.

Tetanus vaccination is required every 10 years. Tdap should replace a single dose of Td for adults age 19 to 65 years.

HPV should be received by females at age 11 or 12 years, or from ages 13 to 26 years, if not given previously. Because the vaccine covers multiple strains of HPV, patients with a history of an abnormal Pap smear or HPV positivity should still be vaccinated. Of note, all men should receive HPV vaccination up to age 21 years (if not previously vaccinated). Immunocompromised men and men having sex with men (MSM) should be vaccinated between the ages of 22 to 26 years, if not previously vaccinated.

Hepatitis B vaccine should be given to children age  $\leq 18$  years and to those age >18 years if there are risk factors: health care professionals, nonmonogamous sexual activity, intravenous drug use, history of sexually transmitted diseases, MSM, hepatitis B+ household contact, or living in a correction facility.

It should also be given to patients with end-stage renal disease, HIV, and chronic liver disease.

Pneumovax is not recommended for those age <65 years unless there is a chronic medical condition. (<https://www.cdc.gov/vaccines/schedules/hcp/imz/adult.html>)

27. D. This patient has a spontaneous pneumothorax. Possible etiologies include spontaneous rupture of a bleb, chronic obstructive pulmonary disease, pneumonia, asthma, and infections associated with HIV, especially *Pneumocystis jiroveci* pneumonia and tuberculosis.

Spontaneous pneumothoraces occupying <15% of the hemithorax can be treated conservatively with supplemental oxygen and observation; however, this practice is controversial. Larger pneumothoraces, particularly in this symptomatic patient, require chest tube placement. (Tschopp JM, Bintcliffe O, Astoul P, et al. ERS task force statement: diagnosis and treatment of primary spontaneous pneumothorax. *Eur Respir J*. 2014;46:321.)

28. A. The patient's signs, symptoms, and laboratory findings are consistent with thrombotic thrombocytopenic purpura (TTP). Plasma exchange is the best treatment for TTP. The classic pentad of TTP includes microangiopathic hemolytic anemia (LDH, schistocytes, elevated indirect bilirubin), thrombocytopenia, renal dysfunction, neurologic changes, and fever. However, with just thrombocytopenia and microangiopathic anemia and no other etiology, treatment should be initiated. (Sadler JE, Moake JL, Miyata T, et al. Recent advances in thrombotic thrombocytopenic purpura. *Hematology Am Soc Hematol Educ Program*. 2004;407–423; Moake JL. Thrombotic microangiopathies. *N Engl J Med*. 2002;347:589.)
29. D. This multiloculated cyst affecting the right lobe of the liver with a thick rim and few calcifications is most likely caused by the tapeworm *Echinococcus granulosus*. This worm has multiple endemic areas around the world. It inhabits the dog/wolf gastrointestinal system. Eggs are then ingested by sheep/cattle and humans, which leads to larval cysts in liver and lung. Patients may have an elevated alkaline phosphatase and eosinophilia.

Traditionally, treatment consisted of albendazole followed by surgical resection, taking caution not to spill any of the content of the cysts, which can cause severe hypersensitivity reactions. (Smego RA Jr, Bhatti S, Khaliq AA, et al. Percutaneous aspiration-injection-reaspiration drainage plus albendazole or mebendazole for hepatic cystic echinococcosis: a meta-analysis. *Clin Infect Dis*. 2003;37:1073.)

30. B. This patient most likely has milk-alkali syndrome. The most common causes of hypercalcemia are primary hyperparathyroidism and malignancy; however, there appears to be an increasing incidence of milk-alkali syndrome in women taking  $\text{CaCO}_3$ . Most patients respond to volume replacement with saline and cessation of  $\text{CaCO}_3$  ingestion, although not all regain normal renal function. Once the patient is volume replete, loop diuretics can be added to increase calcium excretion if needed. Patients with milk alkali may develop rebound hypocalcemia, so bisphosphonates should be used with caution. (Beall DP, Scofield RH. Milk-alkali syndrome associated with calcium carbonate consumption. Report of 7 patients with parathyroid hormone levels and an estimate of prevalence among patients hospitalized with hypercalcemia. *Medicine*. 1995;74:89-96; Medarov BI. Milk-alkali syndrome. *Mayo Clin Proc*. 2009;84(3):261–267; Stoney B, Bagchi G. Antacid abuse: a rare cause of severe hypercalcaemia. *BMJ Case Rep*. 2017 May 3;2017.)

## Acknowledgment

The author and editors gratefully acknowledge the contributions of the previous authors of this chapter, Rafael Bejar, Tyler M. Berzin, Rebecca A. Berman, and Chiadi E. Ndumele.

## Questions

- A 55-year-old man is diagnosed with a right femoral vein deep vein thrombosis (DVT). No provoking factors can be elicited such as recent travel, immobilization, or surgery; he is up to date on cancer screening, and a thorough history and physical are unremarkable. He is started on enoxaparin. Which of the following statements is correct?

  - Clinical trial data support the use of long-term anticoagulation in this patient.
  - Full body CT scan should be performed to rule out occult malignancy.
  - This patient should continue to be treated with low-molecular-weight heparin as opposed to warfarin.
  - Testing for antithrombin III deficiency should be performed immediately.
  - Warfarin is always the preferred agent for long-term anticoagulation in patients with DVT.
- A 64-year-old male diabetic is on the renal transplant list. He has had type II diabetes for over 30 years, often with hemoglobin A<sub>1C</sub> levels >8 mg/dL. His serum creatinine is now 3.2 mg/dL. He reports severe evening pain and discomfort in both feet, the right foot more than left, which improves with movement of his legs. The severity is such that he often has to get out of bed and walk in the bedroom. This is different from the diabetic neuropathic pain that he usually experiences during the day. He was prescribed pramipexole 0.25 mg 2 to 3 hours before bedtime, but after initial benefit, the symptoms are back and now also involve his upper limbs. Other relevant laboratory values are a hemoglobin of 11.4 g/dL and a serum ferritin of 32 ng/mL. Which of the following is true about his condition?

  - Opiates are contraindicated for pain from restless legs syndrome.
  - Intravenous (IV) iron is a therapy option.
  - High-dose gabapentin is the treatment of choice for end-stage renal disease with restless legs.
  - Increasing the pramipexole dose is necessary to control symptoms.
  - Cognitive behavioral therapy has evidence-based support for insomnia caused by restless legs.
- A 72-year-old woman presents for evaluation of new onset headaches that began 2 weeks prior. She has no fever, chills, fatigue, nasal congestion or discharge, visual impairment, double vision, neck pain or stiffness, vomiting, weakness, or numbness. On examination, vital signs are normal. There is no tenderness over her scalp, but there is mild pain on palpation over both temples. Fundoscopic examination is normal, as is visual acuity. Musculoskeletal examination of neck and shoulders is normal, and muscle strength and reflexes are normal. Laboratory values show hematocrit (HCT) 34%, erythrocyte sedimentation rate (ESR) 17 mm/h, and creatinine kinase 184 U/L; basic metabolic panel is normal. What is your next diagnostic step?

  - Head CT/CT angiography
  - Head MRI
  - Temporal artery biopsy
  - Doppler ultrasound of the carotid
  - Lumbar puncture
- Which of the following drugs may be associated with the electrocardiogram (EKG) tracing in [Fig. 112.1](#)?

  - Cephalosporins
  - Citalopram
  - Lidocaine
  - Methadone
  - A, C
  - B, D
- A 45-year-old man presents with a 3-month history of progressive shortness of breath. Despite completion of three courses of antibiotics for presumed pneumonia, his chest x-ray (CXR) shows persistent pulmonary infiltrates, and his shortness of breath continued to worsen. He worked as an electrician at a mental health institution and has a 20-pack-year smoking history. He reports working in a naval shipyard with asbestos exposure in 1983. At home he has two cats, a parrot, and three dogs. Chest CT scan is significant for bilateral ground glass opacification and diffuse micronodules; there is no significant lymphadenopathy or pleural calcifications. Which of the following is the next best step?

- A. Positron emission tomography (PET) scan to evaluate for malignancy  
 B. Broad-spectrum IV antibiotics  
 C. Workup for mesothelioma  
 D. MRI of the thorax  
 E. Treatment with corticosteroids
6. A 38-year-old woman is found to be hypertensive (160/90 mm Hg) at her first prenatal visit. Which of the following antihypertensive medications would be absolutely contraindicated?  
 A. Metoprolol  
 B. Methyldopa  
 C. Lisinopril  
 D. Labetalol  
 E. Hydrochlorothiazide
7. A 28-year-old man presents with 3 weeks of easy bruising not associated with trauma, epistaxis, and gum bleeding. He is otherwise healthy and takes no medications. His white blood cell count is  $7 \times 10^3/\mu\text{L}$ , HCT 45%, and platelet count 14,000/ $\mu\text{L}$ . Blood smear is notable only for low platelets. Which of the following is the next best step?  
 A. Plasmapheresis  
 B. Bone marrow biopsy  
 C. Corticosteroids  
 D. No treatment, spontaneous remission is common  
 E. Proceed directly to splenectomy
8. An 82-year-old man from Cape Cod with a history of coronary artery disease presents with weakness and shortness of breath. Temperature is 103°F. He has a mild elevation of aspartate transaminase and alanine transaminase, and HCT is 21%. There is no evidence of active bleeding. Direct Coombs test is negative. Bilirubin and lactate dehydrogenase are elevated; haptoglobin is depressed. Smear is negative for schistocytes but reveals rare intraerythrocytic parasites (~1%). All of the following are appropriate next steps except:  
 A. Test for Lyme disease  
 B. Test for anaplasma (serologies)  
 C. Treatment with oral atovaquone  
 D. Treatment with oral azithromycin  
 E. Treatment with oral doxycycline
9. A 78-year-old man who has been hospitalized for 6 days with community-acquired pneumonia develops new left leg swelling. He is otherwise asymptomatic. Past medical history is notable only for hypertension. What is the most appropriate test?  
 A. Venogram  
 B. Venous duplex ultrasound  
 C. D-dimer  
 D. Ibuprofen and ice  
 E. No further evaluation
10. A 30-year-old woman presents with acute dysuria, urgency, and frequency. She has been diagnosed with five urinary tract infections (UTIs) in the past 2 years. She last received trimethoprim-sulfamethoxazole 5 weeks ago for similar symptoms. Appropriate next steps in management include:  
 A. A 10-day course of ciprofloxacin  
 B. Cystoscopy to assess for structural abnormalities  
 C. A 5-day course of nitrofurantoin and counseling regarding UTI prevention  
 D. CT scan to assess for pyelonephritis  
 E. Dipstick urinalysis to assess for white blood cells
11. A 42-year-old male with a history of hypertension presents with a 6-month history of early satiety and chronic diarrhea with a 35-lb unintentional weight loss. He has normal liver function tests, amylase, and lipase, but his ferritin is low. An abdominal CT scan reveals diffuse lymphadenopathy without any localized masses. Laboratory workup of his diarrhea reveals an elevated immunoglobulin (IgA) antiendomysial antibody. What is the appropriate next diagnostic step?  
 A. Lymph node biopsy  
 B. IgA tissue transglutaminase antibody  
 C. Small bowel biopsy  
 D. IgA antibodies
12. A 69-year-old retired counselor presents with complaints of hoarseness, tremor, temporal hair loss, weight gain, and new hyperglycemia. Her blood pressure is 195/70 mm Hg. Dark terminal hairs are noted on her chin and abdomen. On testing, her dehydroepiandrosterone-S (DHEA-S) level is over four times the upper limit of normal. Which of the following laboratory findings is consistent with the clinical scenario?  
 A. Serum cortisol level suppresses with high-dose dexamethasone.  
 B. Thyroid-stimulating hormone (TSH) level is high.  
 C. Testosterone level is normal.  
 D. Serum cortisol level does not suppress with low-dose dexamethasone.  
 E. Plasma metanephrines are high.
13. A 54-year-old man with no significant past medical history presents to his primary care doctor with 2 days of constant chest discomfort. He had been seen in urgent care 1 week ago for an upper respiratory infection. His chest pain is pleuritic in nature and nonexertional. It worsens when supine and improves when sitting up. He denies any dyspnea, diaphoresis, radiation of the discomfort, palpitations, or dizziness. The EKG in Fig. 112.2 was obtained. Which one of the following is not an appropriate first-line treatment if this patient has no known drug allergies?  
 A. Aspirin 800 mg every 6 hours  
 B. Ibuprofen 800 mg every 8 hours  
 C. Prednisone 60 mg daily  
 D. Ibuprofen 800 mg every 8 hours + colchicine, 0.5 mg twice daily
14. A 32-year-old woman with palpitations, lid lag, and an audible bruit over her thyroid gland has a serum TSH less than assay and a free thyroxine level of 4.5 ng/L. A diagnosis of Graves is confirmed by a radioiodine-uptake study. Which of the following is correct?

- A. Antithyroid medications should not be prescribed because recurrence rates with them are >90%.
- B. Treatments (medications, surgery, and radioiodine treatment) differ in initial response rates but have similar relapse rates.
- C. Surgical thyroidectomy is indicated in this patient because it has the lowest relapse rate.
- D. If the patient is pregnant, she cannot be treated with propylthiouracil (PTU).
- E. Radioiodine treatment is intended to induce hypothyroidism.
15. A 29-year-old woman presents to the emergency department complaining of palpitations and shortness of breath. An EKG is obtained (Fig. 112.3) and compared with a previously obtained baseline EKG (Fig. 112.4). Which of the following is an appropriate treatment in this setting?
- A. Adenosine
- B. Carotid sinus massage
- C. Procainamide
- D. Esmolol
- E. Verapamil
16. A 59-year-old woman presents with an ST-elevation myocardial infarction, managed with emergent catheterization and drug-eluting stent deployment. Six days later, she returns with recurrent ST elevations in the same distribution. Her husband reports that she has been compliant with her prescribed aspirin and clopidogrel. Admission laboratories are remarkable for a platelet count of 80,000/ $\mu\text{L}$  decreased from 290,000/ $\mu\text{L}$  at discharge. A platelet factor 4 antibody assay is sent. Which of the following medical interventions is appropriate?
- A. Initiation of warfarin
- B. Initiation of low-molecular-weight heparin
- C. Discontinuation of clopidogrel and aspirin
- D. Initiation of bivalirudin
- E. Addition of cilostazol
17. A 20-year-old man is evaluated for facial and lower-extremity edema of 1 week's duration. For the past month, he has been fatigued. He was previously healthy and takes no medications. On physical examination, blood pressure is 90/55 mm Hg. There is periorbital edema and 2+ lower extremity edema. Cardiac, pulmonary, and abdominal examinations are normal. Laboratory data reveal a normal creatinine, a total cholesterol of 300 mg/dL, albumin of 2.9 g/dL, normal complement levels, and 3+ protein with oval fat bodies on urinalysis but no red blood cell (RBC) casts or dysmorphic RBCs. Which of the following is the most likely diagnosis?
- A. Membranous nephropathy
- B. IgA nephropathy
- C. Minimal change disease
- D. Membranoproliferative glomerulonephritis
- E. Postinfectious glomerulonephritis
18. A 44-year-old man presents with acute abdominal pain. Abdominal CT demonstrates portal and splenic vein thromboses and splenomegaly. He is generally healthy. Complete blood count (CBC) is notable for a white blood cell count of  $12.0 \times 10^3/\mu\text{L}$ , hemoglobin 56%, and platelets 400,000/ $\mu\text{L}$ . His oxygen saturation is normal. Which would you recommend at your initial evaluation?
- A. IV heparin
- B. Aspirin
- C. Testing for the *JAK2* mutation
- D. Bone marrow biopsy
- E. A, B, and C
19. A 52-year-old man presents with acute onset of left foot pain, numbness, and partial loss of motor function. His popliteal and pedal pulses are absent, and his foot is cool and mottled. EKG demonstrates atrial fibrillation. The appropriate next step is:
- A. Perform duplex ultrasonographic imaging
- B. IV heparin, urgent lower-extremity angiography, and plan for revascularization
- C. Perform MR angiography
- D. Perform a transesophageal echocardiogram (TEE) to look for a source of arterial embolus
- E. IV heparin and emergent cardioversion to restore normal sinus rhythm
20. A 45-year-old man presents with a 2-day history of fever and abdominal pain. His history is notable for cirrhosis caused by chronic hepatitis C. His medications include furosemide, spironolactone, nadolol, and lactulose. He is afebrile, blood pressure is 100/50 mm Hg, and pulse rate is 84 beats per minute. Abdominal examination is nontender with the presence of moderate ascites. Laboratory studies show mild anemia, leukocyte count of 3300/ $\mu\text{L}$ , international normalized ratio 1.8, albumin 2.2 g/dL, total bilirubin 4 mg/dL, and creatinine 1.6 mg/dL. Diagnostic paracentesis discloses a cell count of 1500/ $\mu\text{L}$  with 25% neutrophils, a total protein level of 1 g/dL, and an albumin level of 0.8 g/dL. Which of the following is the most appropriate next step?
- A. Treatment with IV ceftriaxone
- B. Treatment with IV ceftriaxone and albumin
- C. Oral ciprofloxacin
- D. Increased dose of furosemide
- E. Large-volume paracentesis
21. A 55-year-old woman presents with a 6-month history of cough. The cough is nonproductive, she does not report any fever, chills, weight loss, dyspnea, or hemoptysis, and she is a nonsmoker. There is no history of asthma during childhood or seasonal allergies. She is an accountant with no significant occupational exposures and does not have any pets. There was no travel outside the northeastern United States in the last year and no known exposure to tuberculosis. On examination, she is afebrile with normal vital signs, and lung examination is normal. Which of the following is not the most appropriate next step?

- A. Trial of bronchodilators
  - B. Obtain a CT scan of the thorax
  - C. Order pulmonary function testing
  - D. Treatment with antihistamines
  - E. Trial of proton-pump inhibitors
22. A 54-year-old man presents with unstable angina; cardiac catheterization reveals a chronically occluded right coronary artery and an acute-appearing 90% lesion in his proximal left anterior descending artery, which is treated with a drug-eluting stent. Lipid panel is notable for low-density lipoprotein 110 and high-density lipoprotein 50. Which of the following is correct regarding appropriate lipid management in this patient?
- A. Atorvastatin 80 mg daily should be initiated.
  - B. Lifestyle modification with a low-fat diet and exercise should be the first step in management.
  - C. Pravastatin 40 mg daily should be initiated.
  - D. Rosuvastatin 5 mg daily should be initiated.
  - E. Simvastatin 80 mg daily should be initiated.
23. A 41-year-old woman has a family history as follows: a first-degree cousin with breast cancer, father with recurrent removals of nonmelanomatous skin cancer, and a paternal grandfather with lung cancer. She presents to her primary physician for a routine annual examination and asks her physician for guidance regarding screening mammography. Which of the following is true?
- A. She should begin having annual screening mammograms now given her family history.
  - B. She should be referred for an MRI given her family history.
  - C. She should start having screening annual mammograms at age 50 years.
  - D. She should be referred for genetic testing given a family history suggestive of a hereditary cancer syndrome.
  - E. Referring her for a screening mammogram now is reasonable based on patient's decision.
24. A 50-year-old man is referred for a screening colonoscopy by his primary care physician. He has a history of well-controlled hypertension and no known family history of colorectal cancer. His colonoscopy shows scattered diverticula, and a 1-cm sessile polyp was found in the descending colon, which was resected completely. Pathology showed an adenomatous polyp. Which of the following statements is true?
- A. He needs a screening colonoscopy in 10 years.
  - B. He needs a surveillance colonoscopy in 1 year.
  - C. He needs a surveillance colonoscopy in 3 years.
  - D. He needs a surveillance colonoscopy in 5 years.
25. A 58-year-old woman with long-standing hypertension, hyperlipidemia, and diabetes mellitus presents with 4 weeks of progressive right shoulder pain. There is no history of trauma, and she is not engaged in any sporting activities and works as a hairdresser at a salon. She is unable to raise her arm over her head or reach

behind her, pain is worse at night, and she is unable to sleep on her right side. On physical examination, there is no point tenderness over her cervical spine, clavicle, or glenohumeral joint. There is some ill-localized tenderness over the acromioclavicular area, no obvious deformity or wasting is noted, and the drop arm test was negative.

The most appropriate next management step is:

- A. Antiinflammatory therapy and referral to physical therapy
- B. Order a shoulder x-ray
- C. Refer for an MRI of the shoulder
- D. Refer to orthopedic surgery for possible surgical management
- E. Steroid injection into the shoulder

### Answers

1. A. This patient had venous thromboembolism (VTE) without an identifiable provoking factor such as recent surgery, active malignancy, pregnancy, or use of estrogen-containing oral contraceptives. These patients have a high rate of recurrence after discontinuation of anticoagulation. Several clinical trials have demonstrated a reduced risk of recurrent VTE with longer-term anticoagulation in similar patients. Of course, consideration of longer-term anticoagulation must balance patient risks, benefits, and preferences. In patients without associated malignancy, low-molecular-weight heparins are generally second-line agents for chronic therapy given their expense and route of delivery, with warfarin or novel oral anticoagulants being preferred. In patients with malignancy, however, recurrent thrombotic events are less common with low-molecular-weight heparin than with warfarin; novel anticoagulants have not yet been studied in this population. Although occult cancer is a potential cause of unprecipitated VTE, full-body CT is not generally recommended. A careful history and physical, up-to-date cancer screening, and standard laboratory testing are reasonable. (Ridker PM, Goldhaber SZ, Danielson E, et al; PREVENT Investigators. Long-term, low-intensity warfarin therapy for the prevention of recurrent venous thromboembolism. *N Engl J Med.* 2003;348:1425; Lee AY, Levine MN, Baker RI, et al; Randomized comparison of low-molecular-weight heparin versus oral anticoagulant therapy for the prevention of recurrent venous thromboembolism in patients with cancer (CLOT) Investigators. Low-molecular-weight heparin versus a coumarin for the prevention of recurrent venous thromboembolism in patients with cancer. *N Engl J Med.* 2003;349:146; Schulman S, Wähler K, Lundström T, et al; THRIVE III Investigators. Secondary prevention of venous thromboembolism with the oral direct thrombin inhibitor ximelagatran. *N Engl J Med.* 2003;349:1713; Kyrle PA, Minar E, Bialonczyk C, et al. The risk of recurrent venous thromboembolism in men and women.

*N Engl J Med.* 2004;350:2558; Goldhaber SZ, Piazza G. Optimal duration of anticoagulation after venous thromboembolism. *Circulation.* 2011;123:664.)

2. B. Four drug classes are of benefit in restless leg syndrome (RLS): dopamine receptor agonists, the alpha-2 delta ligands gabapentin and pregabalin, opiates with activity at the  $\mu$  receptor, and iron. The pathophysiology of RLS seems to revolve around iron metabolism involving a deficit in central nervous system iron; many patients are not anemic yet may respond to iron replacement. Oral iron replacement by oral iron is often ineffective, a 2-month to 3-month trial is reasonable, but IV iron is frequently needed. The target ferritin in RLS is at least 50 ng/mL, ideally higher, such as 75 to 100 ng/mL. Opiates are useful in severe RLS or in those who have failed first-line therapy. When pain is a major symptom, starting with gabapentin/pregabalin (both of which accumulate in renal failure) is reasonable; opiates work regardless of the presence of pain. A common error is to progressively increase the dopamine receptor agonists when the reason for loss of control is augmentation or starting at high dose and multiple doses a day. Augmentation can be hard to differentiate from disease worsening when mild, but severe augmentation should be readily recognized with earlier onset, spread to previously unaffected body parts, and requiring progressively increasing doses, which have only transient benefit. Cognitive-behavioral therapy is unlikely to benefit the associated insomnia without direct management of RLS. (Garcia-Borreguero D, Silber MH, Winkelman JW, et al. Guidelines for the first-line treatment of restless legs syndrome/Willis-Ekbom disease, prevention and treatment of dopaminergic augmentation: a combined task force of the IRLSSG, EURLSSG, and the RLS-foundation. *Sleep Med.* 2016;21:1; Trenkwalder C, Benes H, Grote L, et al; RELOXYN Study Group. Prolonged release oxycodone-naloxone for treatment of severe restless legs syndrome after failure of previous treatment: a double-blind, randomised, placebo-controlled trial with an open-label extension. *Lancet Neurol.* 2013;12:1141.)
3. C. Giant cell arteritis. Common symptoms include new headache, vision loss or change, polymyalgia rheumatica-related myalgias, carotidynia, scalp tenderness, scalp beading, and jaw claudication. In 10% to 24% of patients, ESR is low or normal. Early temporal artery biopsy is key. Giant cell arteritis typically affects people age >50 years. Corticosteroid treatment should be initiated at once if there are visual symptoms or if there is significant clinical suspicion for giant cell arteritis. Steroids can be given before a temporal artery biopsy without affecting biopsy results. Long-standing disease can be treated with methotrexate, azathioprine, or tumor necrosis factor (TNF- $\alpha$ ) inhibitors. Aspirin is recommended unless contraindicated. (Layh-Schmitt G, Colbert RA. The interleukin-23/interleukin-17 axis in spondyloarthritis. *Curr Opin Rheumatol.* 2008;20(1):17.)
4. F. Citalopram and methadone. The EKG demonstrates a prolonged QT interval and nonsustained bursts of polymorphic ventricular tachycardia, consistent with torsades des pointes. Drugs associated with QT prolongation and torsades des pointes include

• Fig. 112.1 Electrocardiogram for Question 4.

antibiotics such as fluoroquinolones and macrolides, antidepressants including tricyclic antidepressants, selective serotonin-reuptake inhibitors, typical and atypical antipsychotic agents, and methadone. Cephalosporins are not typically associated with prolonged QT interval. A number of antiarrhythmics (e.g., sotalol, dofetilide, amiodarone) are associated with QT prolongation (although of note, amiodarone is very rarely associated with torsades), but lidocaine does not prolong the QT. ([www.azcert.org](http://www.azcert.org); Nachimuthu S, Assar MD, Schussler JM. Drug-induced QT interval prolongation: mechanisms and clinical management. *Ther Adv Drug Saf.* 2012;3(5):241.)

5. E. This patient presents with a scenario typical of hypersensitivity pneumonitis. Persistent infiltrates in the form of ground glass opacities on chest CT scan are likely inflammatory in nature rather than infectious. The pets, particularly the parrot, represent potential exposures that can trigger hypersensitivity pneumonitis. Treatment of hypersensitivity pneumonitis involves removal of the offending antigen and corticosteroids. Antibiotics are neither indicated nor beneficial in this clinical scenario. Pleural plaques or calcifications are absent; their presence would be concerning for asbestos-induced parenchymal disease given his history of prior exposure to asbestos. A PET scan would aid in lung cancer diagnosis, which typically presents as a mass rather than ground glass opacities. MRI would not add any additional information. (Mohr LC. Hypersensitivity pneumonitis. *Curr Opin Pulm Med.* 2004;10:401; Spagnolo P, Rossi G, Cavazza A. Hypersensitivity pneumonitis: a comprehensive review. *J Investig Allergol Clin Immunol.* 2015;25(4):237.)
6. C. Most drugs cross the placenta and are secreted in breast milk; therefore, the risk/benefit ratio must always be considered when prescribing medications to a pregnant woman. Angiotensin-converting enzyme (ACE) inhibitors are absolutely contraindicated at any time during pregnancy because they are associated with fetal cardiovascular, central nervous system, and renal malformations and dysfunction. Methyldopa is the agent with the most data in pregnancy. Labetalol, metoprolol, and hydrochlorothiazide are also generally considered safe in pregnancy. Atenolol and carvedilol should be avoided. (Abalos E, Duley L, Steyn DW, Henderson-Smart DJ. Antihypertensive drug therapy for mild to moderate hypertension during pregnancy. *Cochrane Database Syst Rev.* 2007;(1):CD002252. Seely EW, Ecker J. Chronic hypertension in pregnancy. *N Engl J Med.* 2011;365:439.)
7. C. This patient presents with a clinical scenario consistent with idiopathic thrombocytopenic purpura: thrombocytopenia with an otherwise normal CBC and peripheral blood smear and no clinically apparent associated medical condition or agent/medication that can cause thrombocytopenia. The first-line treatment is with corticosteroids, sometimes in conjunction with IV immunoglobulin. Second-line treatments include measures such as rituximab, splenectomy, or thrombopoietin receptor agonists. Spontaneous remission is most common in children and rarely occurs in adults. (Clines DB, Blanchette VS. Immune thrombocytopenic purpura. *N Engl J Med.* 2002;346:995; Provan D, Stasi R, Newland AC, et al. International consensus report on the investigation and management of primary immune thrombocytopenia. *Blood.* 2010;115:168; Kistangari G, McCrae KR. Immune thrombocytopenia. *Hematol Oncol Clin North Am.* 2013;27(3):495.)
8. E. The patient has babesiosis, a parasitic infection transmitted by tick bite or blood transfusion. Because coinfection with anaplasma (*Ehrlichia*) and Lyme can occur with babesiosis, the patient should be tested for both anaplasma and Lyme. Severe babesiosis is characterized by  $\geq 10\%$  parasitemia, significant hemolysis, splenic infarct, or renal/hepatic/pulmonary compromise. The low level of parasitemia in this case is suggestive of chronic low-level infection. Oral antibiotics are reasonable in this setting. The front-line therapy for mild-to-moderate babesiosis is atovaquone plus azithromycin, whereas clindamycin plus quinine is used in severe illness. Doxycycline has been used as part of multidrug regimens in refractory cases of *Babesia*; however, it is not a front-line agent. Although doxycycline is the treatment of choice for patients with Lyme disease and anaplasma, empiric therapy for these infections is not advised in patients with babesiosis. Partial or complete red blood cell exchange transfusion is recommended for patients with parasitemia  $\geq 10\%$ , severe anemia, or pulmonary, liver, or renal impairment. (Wormser GP, Dattwyler RJ, Shapiro ED, et al. The clinical assessment, treatment, and prevention of Lyme disease, or human granulocytic anaplasmosis, and babesiosis: clinical practice guidelines by the Infectious Diseases Society of America. *Clin Infect Dis.* 2006;43:1089; Edouard G, Vannier, Maria A. Diuk-Wasser, Choukri Ben Mamoun, et al. Babesiosis. *Infect Dis Clin North Am.* 2015;29(2):357.)
9. B. In choosing the correct diagnostic evaluation for a patient with possible venous thrombosis, the primary consideration is the clinical likelihood of DVT and the sensitivity and specificity of the D-dimer test. This patient, who has been bedbound in the hospital with pneumonia, has a moderate-to-high risk of DVT. Given the relatively poor specificity of the D-dimer test and the multiple potential reasons for an elevated D-dimer in this patient, a positive D-dimer would not be sufficient to establish the diagnosis. In these patients, venous ultrasound should be pursued. In contrast, for outpatients in whom the clinical suspicion is low, D-dimer is the appropriate first step; if negative, no further testing is indicated, whereas a positive D-dimer in this setting should prompt venous duplex ultrasound to further assess for DVT. (Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of

deep-vein thrombosis in clinical management. *Lancet* 1997;350:1795; Bates SM, Jaeschke R, Stevens SM, et al. Diagnosis of DVT: antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. *Chest*. 2012;141:e351S.)

10. C. This clinical scenario is consistent with recurrent uncomplicated cystitis. Women with two or more infections in 6 months or three or more in 1 year meet the criteria for recurrent UTI. There are no signs or symptoms to suggest pyelonephritis. In a patient with a convincing clinical history, neither a urinalysis nor culture is needed to diagnose uncomplicated cystitis. Recurrent cystitis occurring >1 month after the prior episode is considered a new episode rather than a treatment failure; recurrence within 2 weeks of a prior episode is classified as a relapse. A prolonged course of antibiotics has not been shown to be beneficial; however, an alternative first-line antibiotic such as nitrofurantoin is recommended in this setting, because of the possibility of resistance. Patients should also receive counseling regarding behavioral factors that increase their risk of recurrent infections. Risk factors for recurrent UTI in premenopausal women include the use of spermicidal products and being sexually active. Voiding after intercourse and increased fluid consumption have not been shown to protect against recurrence. (Hooton TM. Uncomplicated urinary tract infection. *N Engl J Med*. 2012;366:1028.)
11. C. Celiac sprue is a disease of the small bowel characterized by villous atrophy and crypt hyperplasia. Exposure to gluten is the inciting event. Celiac disease can present with gastrointestinal symptoms such as diarrhea, steatorrhea, weight loss, bloating, flatulence, abdominal pain, or extra gastrointestinal abnormalities such as abnormal liver function tests, iron deficiency anemia, bone disease etc. Pancreatitis and mesenteric lymphadenopathy may be seen in patients with celiac sprue. Elevated endomysial antibody is suggestive of a diagnosis of sprue (sensitivity 85%–98%; specificity 97%–100%), as is elevated antitissue transglutaminase antibody level. Small bowel biopsy, which can be obtained during endoscopy, is the recommended confirmatory diagnostic procedure. IgA antibodies are useful if the serologic tests are thought to be falsely negative. (Green PH, Cellier C. Celiac disease. *N Engl J Med*. 2007;357:1731; Rubio-Tapia A, Hill ID, Kelly CP, Calderwood AH, and Murray JA. ACG Clinical Guidelines: Diagnosis and Management of Celiac Disease. *Am J Gastroenterol*. 2013;108(5):656.)
12. D. The patient has Cushing syndrome possibly secondary to an adrenocortical carcinoma, which is characterized by elevated levels of DHEA, testosterone, and cortisol. Both the ovaries and the adrenals produce testosterone, DHEA, and androstenedione; thus DHEA, testosterone, and androstenedione levels were elevated in this patient. The elevated levels of DHEA-S are virtually diagnostic of a primary adrenal source because DHEA-S is produced only in the adrenals. Neither low-dose nor high-dose dexamethasone would suppress cortisol production, which is adrenocorticotrophic hormone-independent in this patient. Hypothyroidism is not typically associated with virilization, this degree of hypertension, or new hyperglycemia. Elevated plasma metanephrines would be consistent with pheochromocytoma, which does not cause virilization. (Derksen J, Nagesser SK, Meinders SK, et al. Identification of virilizing adrenal tumors in hirsute women. *N Engl J Med*. 1994;331:968; Nieman LK. Cushing's syndrome: update on signs, symptoms and biochemical screening. *Eur J Endocrinol*. 2015;173(4):M33.)
13. C. The patient's symptoms and EKG findings (diffuse ST elevations in multiple coronary distributions that are convex in shape, as well as PR depressions) are consistent with acute pericarditis. For acute

• Fig. 112.2 Electrocardiogram for Question 13.

idiopathic pericarditis, first-line therapy is with a non-steroidal antiinflammatory drug (NSAID) regimen, such as aspirin and ibuprofen. The rate of recurrent pericarditis is decreased in patients given colchicine, as is the duration of symptoms. Use of prednisone as a primary therapy is associated with increased risk of recurrence. Prednisone should therefore be used only in patients with an NSAID allergy or for pericarditis that is refractory to NSAIDs. (Imazio M, Bobbio M, Cecchi E, et al. Colchicine in addition to conventional therapy for acute pericarditis: results of the Colchicine for Acute Pericarditis (COPE) trial. *Circulation*. 2005;112:2012; Imazio M, Gaita F, LeWinter M. Evaluation and treatment of pericarditis: a systematic review. *JAMA*. 2015;314(14):1498.)

14. E. The three treatments for Graves disease, antithyroid medications (PTU, methimazole), radioiodine treatment, and surgical thyroidectomy, have similar initial response rates but differ in their relapse rates. Around 40% of patients initially treated with antithyroid medications will have recurrent disease. Although recurrence rates are best for surgical thyroidectomy (~5%), this is the approach least commonly used as a first-line treatment. Methimazole cannot be used in pregnancy; in contrast, PTU can be used in pregnant patients. Radioiodine treatment is intended to induce hypothyroidism; this is achieved in approximately 80% of cases. (Brent GA. Graves' disease. *N Engl J Med*. 2008;358:2594.)
15. C. Procainamide. In patients with Wolff-Parkinson-White syndrome and atrial fibrillation, drugs (beta-blockers, calcium channel blockers, adenosine) and interventions (vagal maneuvers including carotid sinus

massage) that block the atrioventricular node should be avoided because they can paradoxically increase the ventricular rate caused by increased conduction down the bypass tract. Procainamide and ibutilide are the drugs of choice in this setting because they will slow conduction in the bypass tract. (Fuster V, Rydes LE, Cannon DS, et al. American College of Cardiology Foundation/American Heart Association Task Force. 2011 ACCF/AHA/HRS focused updates incorporated into the ACC/AHA/ESC 2006 guidelines for the management of patients with atrial fibrillation: a report of the American College of Cardiology Foundation/American Heart Association Task Force on practice guidelines. *Circulation*. 2011;123:e269.)

16. D. The patient's presentation is highly concerning for in-stent thrombosis secondary to heparin-induced thrombocytopenia (HIT). For patients suspected to have HIT, empiric anticoagulation is indicated. Heparinoid products, including low-molecular-weight and unfractionated heparin, should be carefully avoided. Warfarin should not be administered in the acute phase because it can increase the risk of clotting. Direct thrombin inhibitors (e.g., argatroban, bivalirudin) are the initial treatment of choice. Antiplatelet agents should be continued. The patient's likely stent thrombosis is unlikely to be caused by a failure of antiplatelet therapy; modification of the antiplatelet therapy is not advised. (Warkentin TE, Grenacher A. Heparin-induced thrombocytopenia: recognition, treatment, and prevention: the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. *Chest*. 2004;126:3115; McKenzie SE, Sachais BS. Advances in the pathophysiology and treatment

• Fig. 112.3 Presenting electrocardiogram in the emergency department for patient from Question 15.

of heparin-induced thrombocytopenia. *Curr Opin Hematol.* 2014;21(5):380.)

17. D. Nephrotic syndrome is characterized by proteinuria (>3 g/24-hour urine), edema, hypoalbuminemia, hyperlipidemia, and lipiduria. Minimal change disease is the most common cause of the nephrotic syndrome in children and young adults. Membranous nephropathy also causes nephrotic syndrome but typically presents in older individuals and is more insidious in onset. Membranoproliferative and postinfectious glomerulonephritis typically present with low complement levels, associated with active urine sediment-RBC casts or dysmorphic RBCs, and often do not have nephrotic range proteinuria. IgA nephropathy presents with hematuria and is less likely to cause overt nephrotic syndrome. (Hull RP. Nephrotic syndrome in adults. *BMJ.* 2008;336:1185; Hebert LA, Parikh S, Prosek J, et al. Differential diagnosis of glomerular disease: a systematic and inclusive approach. *Am J Nephrol.* 2013;38(3):253.)
18. E. This clinical scenario is consistent with polycythemia vera (P-vera). The diagnosis is suggested by an elevated red cell mass without a clear precipitant (e.g., hypoxemia). The *JAK2* mutation is present in virtually all P-vera patients, as well as some patients with other myeloproliferative neoplasms; demonstrating the presence of *JAK2* therefore supports the diagnosis of P-vera. Both venous and arterial thromboses are common in P-vera. When venous thrombosis is suspected in P-vera, immediate anticoagulation is essential to prevent clot progression. Aspirin is also recommended. Bone marrow biopsy findings can support the diagnosis but would not take precedence over treatment of the thrombosis. (Campbell PJ, Green AR. The myeloproliferative disorders. *N Engl J Med.* 2006;355:2452; Kumar S, Sarr MG, Kamath PS. Mesenteric venous thrombosis. *N Engl J Med.* 2001;345:1683; Kroll MH, Michaelis LC, Vertovsek S. Mechanisms of thrombogenesis in polycythemia vera. *Blood Rev.* 2015;29(4):215.)
19. B. This clinical scenario is consistent with acute limb ischemia that is likely caused by a cardioembolic event in the setting of atrial fibrillation. Given the presence of an immediately threatened limb, urgent anticoagulation and angiography with a plan for either endovascular or open surgical intervention are essential. In patients with viable or marginally threatened limbs, imaging may be considered to better understand the extent of the occlusion and plan intervention. TEE would delay appropriate therapy for acute limb ischemia and is not recommended in this setting. (Creager MA, Kaufman JA, Conte MS. Acute limb ischemia. *N Engl J Med.* 2012;366:2198.)
20. B. The most appropriate next step is treatment with ceftriaxone and albumin. The diagnosis of spontaneous bacterial peritonitis (SBP) has been confirmed with an absolute polymorphonuclear cell count of >250/ $\mu$ L and no evidence for secondary peritonitis. *Escherichia coli* is the most common pathogen causing SBP; other organisms include *Klebsiella pneumoniae* and pneumococci. Oral fluoroquinolones may be indicated in patients with stable hepatic and kidney function. The use of ceftriaxone plus IV albumin has been shown to decrease mortality and prevent worsening of renal function in patients with serum creatinine values of 1.5 mg/dL and/or advanced liver disease, as in this

• Fig. 112.4 Baseline electrocardiogram for patient in Question 15.

patient. Aggressive diuresis or large-volume paracentesis can trigger worsening kidney function. (Pedersen JS, Bendtsen F, Møller S. Management of chronic ascites. *Ther Adv Chronic Dis*. 2015;6(3):124; Khoulou-zidis A, Bhat S, Karagiannidis A, et al. Spontaneous bacterial peritonitis. *Postgrad Med J*. 2007;83:379.)

21. B. Chronic cough, defined as cough lasting longer than 3 months, accounts for 10% to 30% of primary care visits. Cough reflex hypersensitivity is a key feature of chronic refractory cough, which is persistent cough after empiric treatment for common causes of chronic cough. Patients present with an intermittent dry cough that may be triggered by nontussive (air conditioning and phonation) or low doses of tussive stimuli. The cough can persist for months or years. Differential diagnoses include asthma, gastroesophageal reflux disease (GERD), obstructive sleep apnea, ACE-I–induced cough, and so on. Red flags such as hemoptysis, smoking, and abnormalities on examination or CXR warrant further investigation. This patient has no red flags and no associated symptoms and is in good health overall. Thus therapeutic trials for GERD, reactive airways, and postnasal drip are all reasonable options. CT scan of the thorax is not indicated at this stage. (Gibson PG, Vertigan AE. Management of chronic refractory cough. *BMJ*. 2015;351:h5590.)
22. A. High-dose atorvastatin is recommended for patients presenting with acute coronary syndrome, based on the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) trial, which showed superiority of atorvastatin 80 mg/d over moderate-intensity treatment (pravastatin 40 mg). Rosuvastatin 5 mg/d represents moderate intensity statin therapy; although not directly compared with high-dose atorvastatin, the results of the PROVE-IT trial support the use of high-intensity statin therapy over moderate-intensity therapy in acute coronary syndrome patients. The US Food and Drug Administration has recommended that providers avoid using simvastatin at a dose of 80 mg/d given higher rates of myopathy at this dose observed in the SEARCH (Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine) trial. Lifestyle intervention alone is not considered adequate in patients requiring secondary prevention. (Cannon CP, Braunwald E, McCabe CH, et al; Pravastatin or atorvastatin evaluation and infection therapy–thrombolysis in myocardial infarction 22 investigators. Intensive versus moderate lipid lowering with statins after acute coronary syndromes. *N Engl J Med*. 2004;350:1495; Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH) Collaborative Group. Intensive lowering of LDL cholesterol with 80 mg versus 20 mg simvastatin daily in 12,064 survivors of myocardial infarction: a double-blind randomised trial. *Lancet*. 2010;376:1658; Stone NJ, Robinson JG, Lichtenstein AH, et al. American College of Cardiology/American Heart Association Task Force on Practice Guidelines. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;129(25 suppl 2):S1.)
23. E. Recommendations regarding screening mammogram depend on the relative risk of the patient. In patients with a concerning family history (which this patient does not have) suggestive of a hereditary predisposition to breast cancer such as a *BRCA* mutation, genetic testing is recommended to direct clinical management, which may include surgical intervention to reduce risk. For patients who have an average risk of breast cancer, as in this case, screening mammogram is now recommended every 2 years starting at age 50 years, although women may opt to have annual screening. Most expert groups recommend discussion and shared decision making for women in their 40s. If women decide to initiate screening in their 40s, most experts recommend screening every 2 years. The decision is at the discretion of the patient. Clinical breast examination is no longer recommended in patients at average risk of breast cancer. (Oeffinger KC, Fontham ET, Etzioni R, et al; American Cancer Society. Breast cancer screening for women at average risk: 2015 Guideline Update from the American Cancer Society. *JAMA*. 2015;314:1599. Nelson HD, Fu R, Cantor A, et al. Effectiveness of breast cancer screening: systematic review and meta-analysis to update the 2009 U.S. Preventive Services Task Force Recommendation. *Ann Intern Med*. 2016;164:244.)
24. D. Adenomas are recognized as precursors of colorectal cancer and in persons age <60 years, slightly >50% of adenomas are located in the distal colon. The factors that increase the risk of malignancy include large polyps >10 mm, older age, a history of smoking, a family history of cancer, and nonuse of NSAIDs. The recommended surveillance intervals are as follows: 10 years for no polyps or hyperplastic polyps <10 mm in the rectum or sigmoid colon; 3 years for 3 to 10 tubular adenomas, 1 tubular adenoma >10 mm, adenoma with high-grade dysplasia, villous adenoma; <3 years if >10 adenomas are seen. In the patient described, the presence of 1 tubular adenoma <10 mm in size requires that he be referred for surveillance colonoscopy in 5 years. (Strum WB. Colorectal adenoma. *N Engl J Med*. 2016;374:1065.)
25. A. The most common presentations of shoulder pain in primary care relate to rotator cuff disorders; other causes include glenohumeral disorders, acromioclavicular joint disease, and referred neck pain. In this patient, the subacute onset of pain, likely overuse of the shoulder in her occupation, nocturnal pain, and lack of muscle weakness point to rotator cuff injury/tendinitis. Rotator cuff disorders should be treated

initially with supportive measures including modified work routine and analgesics, followed by referral to physical therapy. Steroid injections may be considered if pain does not respond to conservative measures or too severe to participate in rehabilitation. Indications for referral to orthopedic surgery include pain and significant disability lasting more than 6 months despite treatment; shoulder instability; or red flags such as

history of cancer, signs of infection, trauma, obvious bony deformity, disabling pain, significant weakness, or neurologic deficit. Early referral to imaging is unlikely to improve recovery of simple rotator cuff injury or inflammation, and it is premature to refer this patient to orthopedic surgery. (Mitchell C, Adebajo A, Hay E, Carr A. Shoulder pain: diagnosis and management in primary care. *BMJ* 2005; 331:1124.)

## Board Practice 3

AJAY K. SINGH

### Questions

1. A 23-year-old actress with asthma presents to her primary care physician for routine follow-up. She reports that she has needed her albuterol inhaler two to three times a week for wheezing or shortness of breath. She also notes that she wakes up with cough three or four times a month. When this happens, she uses her inhaler with good relief. Her only current medication is her albuterol inhaler, used on an as-needed basis.

Which of the following would be the most appropriate management strategy?

- A. Having her use her albuterol inhaler on a standing basis
  - B. Starting a steroid inhaler
  - C. Changing to a combined bronchodilator inhaler
  - D. Treating her with theophylline
  - E. Starting a long-acting bronchodilator
2. A 23-year-old graduate student comes to see his primary care physician with 5 days of worsening bloody diarrhea and fever. He reports having eaten tacos at a local restaurant. He recently traveled to Vancouver. His evaluation reveals petechiae on his legs, a creatinine (Cr) of 3.0 mg/dL, hematocrit (Hct) 27%, with schistocytes on smear and platelets of 47,000/ $\mu$ L. His stool culture is most likely to show which organism?
- A. *Bacillus cereus*
  - B. *Salmonella* spp.
  - C. *Escherichia coli* O157:H7
  - D. *Staphylococcus aureus*
  - E. *Vibrio cholerae*
3. A 35-year-old painter initially presented with fatigue, myalgias, and a rash (Fig. 113.1) after a weekend on Cape Cod. His primary care physician prescribed a 14-day course of doxycycline (100 mg twice per day). He returns 10 days later with worsening myalgias, fever, nausea, and vomiting. Routine laboratory studies reveal an Hct of 34%. Which of these therapies would be the most appropriate?
- A. 14 additional days of doxycycline
  - B. 21 additional days of doxycycline
  - C. 14 days of intravenous ceftazidime
  - D. 10 days of clindamycin and quinine
  - E. 14 days of chloroquine
4. A 46-year-old salesman presents with recurrent nosebleeds and easy bruisability. He has no prior episodes of bleeding and takes a daily aspirin. He has oral mucosal hemorrhages, multiple bruises, guaiac-positive stool, and no petechiae. His laboratory evaluation reveals Hct 42%, his prothrombin time (PT) is 85 s (reference range 9.5–13.5 s), his partial thromboplastin time (PTT) is 150 s (reference range 60–70 s), and his platelet count is 339,000/ $\mu$ L. His parameters improve with three doses of vitamin K, 5 mg given subcutaneously, but after 1 week he is back to similar laboratory values. What is the most likely diagnosis?
- A. Lack of green vegetables in the diet
  - B. Congenital factor VII deficiency
  - C. Occult liver disease
  - D. Superwarfarin poisoning
  - E. Factor XI inhibitor
5. A 27-year-old woman is brought to the emergency department (ED) after being found unresponsive by her boyfriend who last spoke to her about 12 hours earlier. She was found with a suicide note and an empty bottle of Tylenol. On arrival to the ED, she is

• **Fig. 113.1** Rash on leg of patient in Question 3. (From Centers for Disease Control and Prevention. Lyme disease rashes and look-alikes. [https://www.cdc.gov/lyme/signs\\_symptoms/rashes.html](https://www.cdc.gov/lyme/signs_symptoms/rashes.html); 2015 Accessed 17.12.06.)

• **Fig. 113.2** Electrocardiogram of patient in Question 6.

unarousable with a heart rate of 120 beats per minute and a blood pressure of 100/50 mm Hg.

Which of the following is the most reasonable next step?

- A. Begin ipecac and gastric lavage immediately.
  - B. Administer activated charcoal, and then administer *N*-acetylcysteine (NAC).
  - C. Administer NAC immediately.
  - D. Send an acetaminophen level, and then begin NAC based on the level.
  - E. Send liver function tests, arterial blood gases, and coagulation studies before initiating any therapy.
6. A 26-year-old student presents to urgent care with an episode of palpitations accompanied by light-headedness. He reports that the episode lasted approximately 5 minutes. He has an examination tomorrow and is quite anxious. He has had two similar episodes over the last 2 years. He takes no illicit or prescribed drugs, does not drink alcohol, and has no family history of heart disease. His electrocardiogram (EKG) is shown in Fig. 113.2.
- What is the diagnosis?
- A. Right bundle branch block
  - B. Inferior myocardial infarction
  - C. Paroxysmal atrial fibrillation
  - D. Left ventricular hypertrophy
  - E. Wolff-Parkinson-White syndrome
7. A 32-year-old pharmacist is found to have a 3 × 3-cm nodule in the left lobe of her thyroid gland on routine examination. She has no symptoms. Her serum thyroid-stimulating hormone (TSH) concentration is normal. The next step in her evaluation should be:
- A. CT of the neck
  - B. Fine-needle aspiration (FNA)
  - C. Empiric thyroxine therapy
  - D. Surgical neck exploration
  - E. Nuclear medicine scan of her thyroid
8. A 31-year-old nanny presents with fever, bone pain, and anemia and is diagnosed with acute myelogenous leukemia. She undergoes induction chemotherapy with daunorubicin/cytarabine and achieves remission. Twelve days after her first cycle of high-dose cytarabine consolidation chemotherapy, she calls the office with a temperature of 102.5°F. She comes in and has no focal findings on examination, her catheter site is without erythema, and she has a clear chest x-ray (CXR). Her white blood cell (WBC) count is  $0.6 \times 10^3/\mu\text{L}$  with 12% polymorphonuclear cells. What do you do?
- A. Admit to hospital for observation
  - B. Admit to hospital for bone marrow transplant
  - C. Admit to hospital for intravenous cefepime
  - D. Administer granulocyte colony-stimulating factor
  - E. Prescribe oral amoxicillin/clavulanic acid and close outpatient follow-up
9. A 45-year-old female teacher presents complaining of severe left knee pain. She has a long history of rheumatoid arthritis, which has been well controlled for several years on a multidrug regimen of methotrexate, hydroxychloroquine, and nonsteroidal antiinflammatory drugs. Which of the following symptoms suggests secondary degenerative joint disease (rather than rheumatoid arthritis) as a cause of her knee pain?

- A. Prolonged morning stiffness  
 B. Pain that is exacerbated by activity  
 C. Increased fatigue  
 D. Multiple joint complaints  
 E. Weight loss
10. A 36-year-old photographer comes to your office with 1 week of malaise and fatigue and 2 days of scleral icterus. He has also lost his appetite, has persistent nausea, and noted his urine to be very dark. He has no other medical problems and takes no medications. He does not drink any alcohol and recently returned from a trip to Central America, where he was taking pictures for a magazine article. On physical examination, his sclerae are icteric, and his abdomen is soft with a liver span percussed to 13 cm. No spleen tip is palpable. He has no skin changes. His alanine aminotransferase is 3650 U/L, aspartate aminotransferase is 2893 U/L, alkaline phosphatase is 322 U/L, and total bilirubin is 6.3 mg/dL, with a direct fraction of 5.2 mg/dL. His PT is 12.2 s. What is the most likely diagnosis?
- A. Acute hepatitis A  
 B. Alcoholic hepatitis  
 C. Acute cholecystitis  
 D. Acute hepatitis C  
 E. Acetaminophen overdose
11. A 30-year-old lawyer presents to her primary care physician after her 65-year-old father died of a heart attack. She asks what can be done to reduce her risk of also having a heart attack. Her blood pressure is 118/62 mm Hg. Her fasting glucose is 72 mg/dL, her high-density lipoprotein is 52 mg/dL, and her low-density lipoprotein (LDL) is 134 mg/dL. She is a nonsmoker. You advise her to:
- A. Begin aspirin 325 mg daily  
 B. Begin aspirin 81 mg daily  
 C. Maintain a healthy diet and exercise four or five times a week  
 D. Begin simvastatin 10 mg daily  
 E. Begin beta-carotene supplements
12. A 29-year-old nurse comes to see his primary care physician because colleagues noted facial asymmetry. His facial symptoms began yesterday with a progressive left facial droop. He has some malaise and fatigue and achiness in the knees. However, he has no headaches, fever, or pain. On examination, he cannot furrow his left eyebrow and has dysgeusia. His sensation to light touch is normal, muscle strength in the extremities is 5/5, and deep tendon reflexes are intact. Skin examination reveals an erythematous rash that he first noticed a week ago. His head CT is normal. What is the most likely diagnosis?
- A. Bell palsy  
 B. Lyme disease facial palsy  
 C. Fibromyalgia  
 D. Herpes zoster infection  
 E. Zoster sine herpate

• Fig. 113.3 Chest CT scan of patient in Question 15.

13. A comatose 30-year-old male with type I diabetes mellitus is found down. He is afebrile and tachypneic, and his blood pressure decreases from 115/75 to 95/70 mm Hg with elevation of his head. Physical examination reveals a 154-lb acutely ill male with signs of extracellular volume contraction and nonfocal neurologic findings. Venous blood is drawn, and then 50% dextrose is given by intravenous push followed by 50 mL/h of 5% dextrose normal saline solution. The patient remains unconscious with progressive hypotension and tachycardia. The EKG shows a widened QRS, peaked T waves, absent P waves, and multiple premature ventricular contractions. Laboratory values show sodium is 130 mEq/L, potassium is 7.1 mEq/L, chloride is 95 mEq/L, bicarbonate is 10 mEq/L, blood urea nitrogen is 63 mg/dL, Cr is 2.3 mg/dL, and glucose is 450 mg/dL. His urinalysis has 3+ ketones. WBC = 17,000/mm<sup>3</sup>, and Hct is 44%. Which of the following should be the next step in treatment?
- A. Give 2 ampules of sodium bicarbonate.  
 B. Give calcium gluconate 10 mmol immediately via intravenous infusion.  
 C. Initiate hemodialysis.  
 D. Give 10 U intravenous insulin immediately.  
 E. Place a temporary wire.
14. A 38-year-old sanitation worker is bitten by a skunk. The skunk escapes capture. The patient is at high risk for what infection?
- A. Rabies virus  
 B. *Borrelia burgdorferi*  
 C. *Pasteurella*  
 D. *Aeromonas hydrophila*  
 E. *Capnocytophaga cynodegmi*
15. A 52-year-old carpenter is sent to his primary care doctor after a CXR performed in the ED revealed a pulmonary nodule. He is a never-smoker, has no family history of lung cancer, and has lived his entire life in New Hampshire. He has a follow-up CT scan, which is shown in Fig. 113.3. The pattern

of calcifications is described by the radiologist as “popcorn.”

The most likely diagnosis is:

- A. Carcinoid
- B. Small cell lung cancer
- C. Metastatic thyroid cancer
- D. Bronchial cyst
- E. Hamartoma

16. A 71-year-old man is found to have a prostate-specific antigen (PSA) of 23 ng/mL on routine screening. On digital rectal examination, he has an enlarged, hard, and asymmetric prostate with an apparent tumor extending beyond the prostate capsule. He has no other medical problems and feels well. Needle biopsy reveals poorly differentiated prostate cancer with a Gleason score of 8, and further imaging reveals no metastatic disease. Of the following options, which treatment option is most appropriate?
- A. External beam radiation
  - B. Radioactive seed implants
  - C. External beam radiation plus radioactive seed implants
  - D. External beam radiation with luteinizing hormone-releasing hormone analogue

### Answers

1. B. The National Asthma Education & Prevention Program recommends a stepwise approach to asthma care (National Institutes of Health publication). By their criteria, this patient has poorly controlled mild persistent asthma based on the following criteria:
  - Symptoms >2 times a week but <1 time a day
  - Nighttime symptoms >2 times a month
 In the stepwise approach to care, the next “step” would be initiation of a low-dose inhaled steroid. An alternative therapy would be a leukotriene modifier. Adding a long-acting bronchodilator before initiation of a steroid inhaler would be inappropriate because this has been associated with increased morbidity. The next step for poorly controlled moderate persistent asthma treated with a low-dose steroid inhaler would be the addition of a long-acting bronchodilator or increasing the dose of the steroid inhaler. ([www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf](http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf). Accessed February 11, 2011.)
2. C. This patient has hemolytic-uremic syndrome (HUS) as demonstrated by anemia, schistocytes, thrombocytopenia, and acute kidney injury. This food-borne illness is caused by *E. coli* serotypes (especially O157:H7) or *Shigella dysenteriae*. *E. coli* O157:H7 is the organism most commonly associated with HUS, causing 73,000 illnesses and 60 deaths in the United States annually. Cattle are a major reservoir of *E. coli* O157:H7. Endothelial damage occurs by binding of a bacterial toxin. *B. cereus* and *S. aureus* produce toxins that cause food poisoning, and *Salmonella* spp. can cause gastroenteritis with bloody diarrhea, but none of these organisms cause HUS. *V. cholerae* causes cholera with its typical voluminous rice water stools.
3. D. The initial presentation was consistent with early localized Lyme disease. The rash is erythema migrans. The treatment of doxycycline, 100 mg twice per day, is the appropriate therapy. An acceptable alternative would be a 10- to 14-day course of amoxicillin. The clinical picture is characteristic of coinfection with *Babesia microti*, whose vector is also the *Ixodes* tick. Immunosuppressed hosts are more likely to have symptomatic *Babesia* infection, particularly asplenic patients or those with HIV. Standard of care is treatment with clindamycin and quinine. A newer, perhaps better-tolerated regimen is atovaquone and azithromycin for 7 days. (Shapiro ED. Clinical practice. Lyme disease. *N Engl J Med*. 2014;370(18):1724–1731.)
4. D. This patient has superwarfarin (brodifacoum) poisoning; his warfarin level was undetectable, but the brodifacoum level was 270 ng/mL. Brodifacoum is the active ingredient of commercial rat poison. It is a cause of coagulopathy arising from accidental ingestion, suicide attempt, Münchausen syndrome, or poisoning. Clinical features include hematuria, intracerebral bleed, gastrointestinal bleeding, hemoptysis, and vaginal bleeding. Brodifacoum has a long plasma half-life (3–4 weeks), and repeated vitamin K dosing is necessary to maintain normal coagulation parameters (King N, Tran MH. Long-acting anticoagulant rodenticide (superwarfarin) poisoning: a review of its historical development, epidemiology, and clinical management. *Transfus Med Rev*. 2015;29(4):250–258.)
5. C. The mainstay of therapy for acetaminophen intoxication is NAC. Although there is evidence for efficacy of NAC even when given more than 24 hours after an ingestion, the efficacy progressively declines at 8 hours after the ingestion. Because of this, NAC administration should not be delayed in this case while awaiting activated charcoal administration, routine laboratory studies, or an acetaminophen level. There is a role for activated charcoal gastric decontamination, but it loses its efficacy more than 4 hours after the ingestion. There is no role for syrup of ipecac in acetaminophen intoxication. (Hammond RW, Schwartz AH, Campbell MJ, et al. American College of Clinical Pharmacy. Collaborative drug therapy management by pharmacist—2003. *Pharmacotherapy*. 2003;23:1052; Dargan PI, Jones AJ. Acetaminophen poisoning: an update for the intensivist. *Crit Care*. 2002;6:108.) In situations of massive acetaminophen intoxication extracorporeal therapy, emergency hemodialysis should be considered. Massive acetaminophen intoxication is suggested by a substantially elevated acetaminophen concentration and

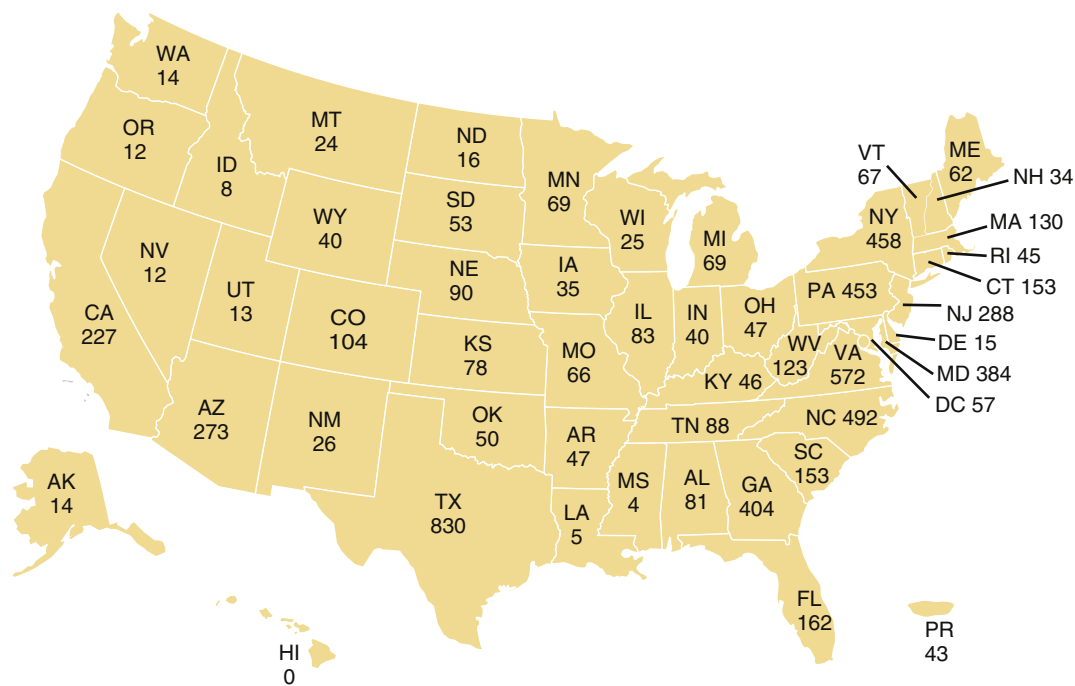

- signs of early mitochondrial failure, including coma, elevated lactate concentration, and metabolic acidosis present before the onset of hepatic dysfunction. Because NAC is also cleared by hemodialysis, its dose should be increased. (Serjeant L, Evans J, Sampaziotis F, Petchey WG. Haemodialysis in acute paracetamol poisoning. *BMJ Case Rep*. 2017 Jan 17;2017.)
6. E. This EKG shows typical features of Wolff-Parkinson-White syndrome—short PR interval and QRS prolongation with delta wave. The left axis deviation with right bundle branch block pattern and Q waves in III and aVF suggest left posteroseptal accessory pathway. (Benson DW, Cohen MI. Wolff-Parkinson-White syndrome: lessons learnt and lessons remaining. *Cardiol Young*. 2017;27(S1):S62–S67.)
  7. B. The single test that provides the most information is the FNA. All patients with solitary or multiple thyroid nodules should first have a TSH measured. If suppressed, this suggests excess thyroid hormone production, possibly from a hot nodule. A thyroid scan should be obtained. If TSH is normal, all thyroid nodules >1 cm should be considered for needle aspiration under ultrasound guidance to rule out thyroid cancer. Approximately 10% of thyroid nodules are malignant. Functional or “hot” nodules are nearly always benign. Although concern for malignancy is abated, such patients must be treated for their hyperthyroidism, usually with medication (methimazole) or radioactive iodine (<sup>131</sup>I). (Hegedüs L. Clinical practice. The thyroid nodule. *N Engl J Med*. 2004;351:1764; Castro MR, Gharib H. Continuing controversies in the management of thyroid nodules. *Ann Intern Med*. 2005;142:926; Miller MC. The patient with a thyroid nodule. *Med Clin North Am*. 2010;94(5):1003.)
  8. C. This patient has febrile neutropenia, a common complication of chemotherapy, especially in patients with hematologic malignancies. The standard treatment for these patients is hospitalization with broad-spectrum antibiotic coverage, often monotherapy with a third-generation cephalosporin. In patients with solid tumors who are generally considered at lower risk than patients with leukemia, an oral regimen (such as ciprofloxacin and amoxicillin/clavulanic acid) can be used. Out-patient antibiotic treatment is acceptable in low-risk patients after careful clinical assessment. (Martin F, Cullen FH. Management of febrile neutropenia, ESMO clinical recommendations. *Ann Oncol*. 2009;20(suppl 4):166–169; Pizzo PA. Fever in immunocompromised patients. *N Engl J Med*. 1999;341:893; Donowitz GR et al. *ASH Education Book*. Vol 2001, No 1. Washington, DC: American Society of Hematology; 2001:113–139.)
  9. B. Patients with rheumatoid arthritis are at increased risk for developing other musculoskeletal problems, including secondary degenerative joint disease, septic arthritis, osteoporotic fractures, and tendon rupture. However, differentiating between increased rheumatoid arthritis activity and degenerative joint disease is critical considering the toxicities of disease-modifying antirheumatic drugs. The features that suggest synovitis as a cause of pain include multiple joint inflammation with warmth and swelling, constitutional symptoms, and morning stiffness. Degenerative problems are more common in heavily used and weightbearing joints and are, therefore, more localized. Also, the pain is exacerbated by activity and worse at the end of the day. (Koutsky L. Epidemiology of genital human papillomavirus infection. *Am J Med*. 1997;102:3S; McInnes IB, O’Dell JR. State-of-the-art rheumatoid arthritis. *Ann Rheum Dis*. 2010;69:1898.)
  10. A. The patient’s hepatitis is characterized by malaise and jaundice, significant elevation of aminotransferases and bilirubin, and a normal PT. Given his recent travel, the patient most likely has acute hepatitis A. This infection is acquired via the fecal-oral route. Recent epidemic cases have been linked to contaminated food such as salad, scallions, and shellfish. Central and South America, Africa, India, and Southeast Asia are highly endemic regions where travelers are at increased risk of infection. The overall mortality from fulminant hepatic failure is rare (<0.5%) but more likely in older patients. However, vaccines are available that should lower the incidence of the disease in high-risk endemic populations. Acute hepatitis B virus infection can produce an identical clinical picture. Acute hepatitis C infection is typically subclinical in its presentation and often not recognized. (Koff RS. Hepatitis A. *Lancet*. 1998;351:1643; Mayer CA, Nielson AA. Hepatitis A—prevention in travellers. *Aust Fam Physician*. 2010;39:924.)
  11. C. This case focuses on primary prevention of coronary heart disease (CHD). There is evidence for the following goals in primary prevention. (American Heart Association, Pearson TA. AHA scientific statement—AHA guidelines for primary prevention of cardiovascular disease and stroke: 2002 update. *Circulation*. 2002;106:338; Sathiyakumar V, Blumenthal RS, Nasir K, et al. Addressing knowledge gaps in the 2013 ACC/AHA guideline on the assessment of cardiovascular risk: a review of recent coronary artery calcium literature. *Curr Atheroscler Rep*. 2017;19(2):7.)
    - Smoking cessation
    - Goal blood pressure <140/90 mm Hg
    - Healthy diet
    - Goal LDL <190 U/L if ≤1 cardiovascular disease risk factor
    - 30 minutes of exercise most days of the week
    - Body mass index 18.5–24.9
    - Fasting glucose <110 mg/dL
 Low-dose aspirin is only indicated in patients with ≥10% 10-year risk of CHD. Our patient has 1% risk based on the Framingham point score.

Beta-carotene is not indicated because it has no proven benefit and possible adverse effects (Pearson TA. AHA scientific statement – AHA guidelines for primary prevention of cardiovascular disease and stroke: 2002 update. *Circulation*. 2002;106:388; Evensen A, Elliott M, Hooper-Lane C. Clinical inquiries. Which patients benefit from lowering LDL to <100 mg/dL? *J Fam Pract*. 2010;59:706; Mishriki YY. Puzzles in practice. Case report. *Postgrad Med*. 2010;122:192.)

12. B. The history and examination are classic for Lyme disease facial palsy. Lyme disease is caused by infection with the spirochete *B. burgdorferi*. Manifestations also reflect the body's immunologic response to the infection. *B. burgdorferi* is transmitted from host to host by the *Ixodes* or deer tick. The manifestations of Lyme disease have been divided into three stages: localized, disseminated, and persistent. The first two stages are part of the early infection, whereas persistent disease is considered late infection. The primary symptoms of stage 1 are erythema migrans and some associated symptoms. The primary symptoms of stage 2 include intermittent arthritis, cranial nerve palsies and radicular symptoms, atrioventricular nodal block, and severe malaise and fatigue. The primary symptoms of stage 3 include prolonged arthritis; chronic encephalitis, myelitis, and paraparesis; and symptoms consistent with fibromyalgia. (Shadick NA, Phillips CB, Sangha O, et al. Musculoskeletal and neurologic outcomes in patients with previously treated Lyme disease. *Ann Intern Med*. 1999;131:919–926; Practice parameter: Steroids, acyclovir, and surgery for Bell's palsy (an evidence-based review): report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2001;56:830; Hazin R, Azizzadeh B, Bhatti MT. Medical and surgical management of facial nerve palsy. *Curr Opin Ophthalmol*. 2009;20:440; Lorch M, Teach SJ. Facial nerve palsy: etiology and approach to diagnosis and treatment. *Pediatr Emerg Care*. 2010;26:763.)
13. B. The EKG changes are typical of severe hyperkalemia (flat P waves, prolonged QRS progressing to sine wave, and peaked T waves). The serum potassium of 7.1 mEq/L supports this contention. The patient has underlying diabetic ketoacidosis. The immediate treatment should be the infusion of calcium gluconate to protect from cardiac toxicity (stabilize the myocardial membrane). Sodium bicarbonate infusion takes >4 hours to facilitate translocation of potassium back into cells. Hemodialysis could be dangerous in an unstable situation. Insulin should be administered, but the immediate focus ought to be in protecting the myocardium. The pacing issue is irrelevant presently. (Greenberg A. Hyperkalemia: treatment options. *Semin Nephrol*. 1998;18:46; Mattu A, Brady WJ, Robinson DA. Electrocardiographic manifestations of hyperkalemia. *Am J Emerg Med*.

2000;18:721; Elliot MJ, Ronksley PE, Clase CM, et al. Management of patients with acute hyperkalemia. *Can Med Assoc J*. 2010;182:1631; Rossignol P, Legrand M, Kosiborod M, et al. Emergency management of severe hyperkalemia: guideline for best practice and opportunities for the future. *Pharmacol Res*. 2016;113(Pt A):585–591.)

14. A. This patient has a bite from a skunk. There are two common skunks in the United States: the more common striped skunk (*Mephitis mephitis*) and the spotted skunk (*Spilogale gracilis*). Both are members of the weasel family and are equipped with a powerful and protective scent gland that can shoot a potent and pungent liquid as far as 6 to 10 ft. The secretion is acrid enough to cause nausea and can produce severe burning and temporary blindness if it strikes the eyes. When a patient receives a bite from a non-domestic animal such as a skunk, rabies infection must be considered; the incidence of rabies in raccoons, skunks, bats, and foxes has increased in recent years. Skunks that seem tame or listless and wander about during daylight hours should be treated with great caution because this behavior is symptomatic of rabies. Also if they exhibit no fear of people or pets and show some aggressive behavior, chances are quite high that they are rabid. In addition to careful cleansing of the wound (as in any animal bite), patients should receive both rabies immune globulin and begin the rabies vaccination series as soon as possible. If a patient has not had a tetanus booster in the past 6 months, he should receive one. If the animal is captured, it should be sacrificed and tested for rabies. (Warrell MJ, Warrell DA. Rabies and other lyssavirus diseases. *Lancet*. 2004;363:959; Hankins DG, Rosekrans JA. Overview, prevention and treatment of rabies. *Mayo Clin Proc*. 2004;79:671; Wunner WH, Briggs DJ. Rabies in the 21<sup>st</sup> century. *PLoS Negl Trop Dis*. 2010;4:e591; Dendle C, Looke D. Management of mammalian bites. *Aust Fam Physician*. 2009;38:868.)
- The distribution of rabid feral animals in the United States is illustrated in Fig. 113.4. These include the following species: raccoons (37.2%), skunks (30.7%), bats (17.2%), and foxes (5.9%).
- Pasteurella* infections as well as infection with *Capnocytophaga* are common after dog or cat bites but not undomesticated animals. *B. burgdorferi* is the spirochete that causes Lyme disease and is transmitted by tick bites. *Aeromonas hydrophila* causes diarrheal illness in people who are exposed to contaminated water.
15. E. The CT scan demonstrates classic findings of a hamartoma, which is a benign tumor of the lung. Hamartomas are collections of fat and cartilaginous tissue. Features of pulmonary hamartomas include peripheral location, smooth border with lobulations, calcifications (“popcorn pattern”), and fat present on CT.

• **Fig. 113.4** Reported cases of rabies in the United States 2009 (for [Question 14](#)). (From Blanton JD, Palmer D, Rupprecht CE, et al. Rabies surveillance in the United States during 2009. *J Am Vet Med Assoc.* 2010;237:646–657.)

Predictors of benign versus malignant solitary pulmonary nodules include age of patient (increased risk with older age); cigarette smoking; size of lesion (>3 cm much higher risk); spiculated versus smooth; and rate of growth (doubling time 20–400 days implies malignant). (Szeto CC, Chow KM. Pathogenesis and management of hydrothorax complicating peritoneal dialysis. *Curr Opin Pulm Med.* 2004;10:272.)

16. D. This patient has clinical stage T3a disease with adverse prognostic features of a PSA >10 ng/mL and a Gleason score of 8. He is at high risk of cancer spread

beyond the prostate and is unlikely to be cured. For locally advanced prostate cancer (T3 or greater), radiation therapy combined with androgen deprivation results in longer survival than radiation therapy alone. Hormonal treatment alone is the first-line of therapy for metastatic disease.

# Fast answers and trusted evidence

Drive better outcomes with a clinical search engine that makes it easier to find and apply relevant knowledge.

## Fast

Anticipates your query, recognizing concepts and offering shortcuts

## Complete

Draws relevant answers from a wide range of current, comprehensive content across 30+ medical and surgical specialties

## Convenient

Accessible at the patient's bedside or on the go, making it easy to discover, share, and apply content anywhere

## Trusted

Content from Elsevier, the name healthcare professionals worldwide rely on
